Sellin–Wolfgang Scale of Severity

Paul E. Tracy
University of Texas, Dallas, Richardson, Texas, USA

Glossary

complex criminal event A crime can involve multiple and separate violations, including bodily injury, property theft, property damage, and intimidation by verbal threat or a weapon.
crime severity Quantitative aspects of the seriousness of a criminal event as measured through kinds and amount of actual harm caused by the crime.
hierarchy rule Federal Bureau of Investigation method of counting crimes by using only the most serious offense regardless of how many other crimes were committed during the same crime event.
ratio scale A measurement scale that not only uses equidistant points along the scale but also has a meaningful zero point. Ratio scales are the most sophisticated scales because they incorporate all the characteristics of nominal, ordinal, and interval scales. As a result, a large number of statistical calculations are applicable.
Sellin–Wolfgang scale A ratio scale of the severity of a criminal event that uses a weighting scheme to score all the components of a crime.

This article discusses the measurement of the gravity, severity, or seriousness of crime through the use of the Sellin–Wolfman scale. The characteristics of this ratio scale of crime severity are described, examples of the scoring system are presented, and potential uses of the scale for research and policy are discussed.

Classification and Measurement of Crime

Social scientists and criminal justice officials have long recognized the need for precise and accurate indicators of the amount of criminal behavior existent in a given place and time. Without such measures of crime, it would be difficult, if not impossible, to determine with any degree of certainty the level of criminal activity and the effectiveness of efforts to address crime. General agreement exists among scholars and practitioners that adequate measures of crime are necessary not only for testing scholarly research hypotheses but also for the evaluation of criminal justice policies and procedures and the rational allocation of an increasingly scarce pool of criminal justice system resources. As a consequence of this general requirement for high-quality social indicators surrounding crime, the escalation in criminal justice-related statistical information has been dramatic in the past 10–20 years. In fact, the growth in the amount and complexity of criminological research in no small way has resulted from the burgeoning of the statistical data made available to researchers by federal agencies. Furthermore, the audience for this crime-related information has increasingly included the general public as well as academics, legislators, and criminal justice officials.

Although numerous crime-related data are available, the most common and widely used database is the Uniform Crime Report (UCR) compiled by the Federal Bureau of Investigation (FBI). The UCR uses a scheme called the Standard Classification of Offenses (SCO) for classifying criminal behavior. The SCO system classifies criminal events in two categories: (i) index or part I offenses and (ii) nonindex or part II offenses. The seven offenses in the index offense category comprise the well-known "crime index" and consist of nonnegligent criminal homicide, rape, robbery, aggravated assault, burglary, larceny, and vehicle theft. All other offenses, from simple assault to parking violations, are contained in the part II category. With very few modifications, this system has been the basis of the UCR reporting system since its inception in 1930.

The basic rationale for the adoption of the part I offenses as the basis of a crime index was the assumption that these so-called "serious" offenses would be reported to the police most often and thus constitute the closest measure of the total amount of crime that is committed. Thus, the sum of the seven index offenses is treated as the volume of serious crime that is known to the police. Although this system seems reasonably capable of producing an index of crime, an index that details both the volume and the seriousness of criminal behavior, the method used to classify and count offenses renders the system misleading, if not erroneous, in several respects.

First, the index classification system does not provide for multiple offenses (i.e., a complex criminal event that comprises several distinct crimes). That is, according to the hierarchy principle of the SCO, only the crime that has the highest rank order in the list of ordered categories shall be counted. Thus, for example, an incident composed of a rape, an aggravated assault, and a robbery would be recorded for UCR index purposes as only one crime—rape—because rape has the highest rank order of the three crimes committed.

Second, the classification of offenses according to the broad legal label attached to them ignores the fact that each legal category consists of a variety of offenses that should not be equated and contribute the same amount to the crime rate. A robbery, for instance, may be the armed holdup of one or more persons, the infliction of serious harm, and the theft of large sums of money. On the other hand, a robbery may also be the taking of a child's lunch money by a schoolmate. Many criminal acts that lie between these two extremes would all be classified as robberies, regardless of the degree of injury or the amount of property loss. The other index offenses are similarly affected by the broad continuum of behavior that is subsumed under each category.

Third, the SCO does not differentiate between criminal events that are successful and those that are merely attempted. Equating these two categories clearly masks the amount of actual harm or loss incurred by the community and gives a distorted view of crime severity.

Last, there is no weighting system in the compilation of the index crime rate. Thus, two auto thefts are allowed to contribute as much to the crime rate as do two homicides.

The method of classifying and counting criminal offenses for index purposes just described has two overriding deficiencies. First, by counting only one offense when at least two are conjoined, and by using an arbitrary set of ordered categories, the UCR reporting system provides only a partial enumeration of the specific offense actually known to the police. This clearly provides misleading data concerning the actual volume of criminal behavior. Second, by equating all offenses that carry the same generic legal label, and by confounding completed and attempted acts, considerable differences in the degree of seriousness of various offenses are concealed. In other words, the UCR method provides no solution to the problem of how to deal statistically with a complex of offenses or with simple offenses that vary appreciably in seriousness but that carry the same legal title.

Wolfgang was among the first to express this skepticism regarding the characteristics of the UCR classification system and raise doubts about the usefulness of the crime index system. Wolfgang and his colleague and mentor, Thorsten Sellin, at the Center for Studies in Criminology and Criminal Law at the University of Pennsylvania, determined that because the FBI's measurement approach misrepresents and even masks the actual volume and seriousness of criminal behavior, an alternative measurement scheme needed to be developed. Their goal was to capture both the quantitative and the qualitative dimensions of criminal behavior and, thus, offer greater substantive utility to research and policy making on crime.

The First Sellin–Wolfgang Scale: 1964

At the time when Sellin and Wolfgang sought to develop a scale of the severity, gravity, or seriousness of crime, efforts to scale various social phenomena were not new. The work of Likert, Guttman, and others had been widely employed in creating categorical and ordered scales. However, Sellin and Wolfgang determined that such scales were inadequate for weighting the amount of harm in a criminal event because they have neither a zero point to anchor the scale nor can distances along the scale be reliably determined. For example, although it is relatively easy to determine that a homicide is a more serious crime than a rape or a robbery, the usual scaling methods do not adequately capture the severity differentials or distance among these crimes. Furthermore, even within a particular offense type, such as robbery, available scales do not allow a researcher to measure the crime severity differentials among a robbery with injury and theft, a robbery with just injury, and a robbery with just theft. Sellin and Wolfgang thus sought to develop a ratio scale of perceived severity to overcome these shortcomings by generating a continuous measure of crime weighted for the severity of the event.

Sellin and Wolfgang turned to the literature on psychological scaling and found a variety of procedures for developing a ratio scale. They noted that Thurstone's 1927 method of paired comparisons had been widely adopted in psychological and social psychological measurement, but a Thurstone technique was not feasible owing to the fact that Sellin and Wolfgang anticipated that a very large number of offense comparisons were needed to capture

the various components of offense severity. Fortunately, Stevens and Galanter had recently made significant contributions in the field of psychophysics by developing a less complex ratio scaling method based on magnitude estimation procedures. The magnitude estimation method is a procedure in which a subject makes direct numerical estimates of a series of subjective impressions. Usually, the subject is presented with a base stimulus, known as the modulus, which may have an arbitrary score of 10. Subjects then receive another stimulus and judge its intensity compared to the modulus using any range of numbers they choose. If a subject believes that the new stimulus is twice as intense as the modulus, then a score of 20 would be reported for this item, whereas if the new item is deemed to be half as intense as the modulus then a score of 5 would be assigned.

Scaling the Gravity of Crime

Armed with this new technique for ratio scale construction, Sellin and Wolfgang began their effort to develop a quantitative measure of crime severity by extracting the components or aspects of criminal conduct from the Philadelphia Crime Code. Although Sellin and Wolfgang questioned the value of the particular crime index developed by the FBI, they were in full agreement that a crime index system must be based on certain components of offensive conduct. However, instead of selecting these crime components on the basis of the title given them by the criminal code, they believed that the nature of the harm inflicted in the criminal event should govern the selection of an index. Thus, they concluded that a scale of offense gravity should be constructed utilizing events that involve violations of the criminal law that inflict bodily harm on one or more victims and/or cause property loss by theft, damage, or destruction. Sellin and Wolfgang maintained that these harmful effects were more crucial to the establishment of an index of crime severity than the specific legal labels attached to the events. The Sellin–Wolfgang criterion of selecting events for a crime index differs in two major respects from the one reflected in the UCR system. First, it does not allow the inclusion of offenses that produce none of the components of harm just described. Thus, the offenses utilized in their scale all share one very important feature—some degree of measurable social harm to the community. Second, their system includes many offenses that are not counted among the index crimes category in the UCR. Simply stated, Sellin and Wolfgang chose the criterion of discernable consequences over that of an ordered set of legal categories that may or may not appropriately reflect the seriousness of criminal behavior.

Sellin and Wolfgang also determined that the class of violations to be utilized in the scoring system should be subdivided into three categories in order to indicate the major effect associated with the offense. The first category includes those events that produce bodily harm to a victim or to victims even though property theft or damage may also be involved. The second class of events consists of those offenses that do not involve injury but have a property theft component even when accompanied by damage. The last category consists of those offenses that involved only damage to property. In addition, because they believed that an event should not be evaluated solely in terms of the injuries and losses that occur, the system takes account of certain other factors in the event that aggravate the crime. For example, a crime is aggravated if the offender engages in intimidating behavior (either verbal/physical or by weapon). Furthermore, a property crime may be aggravated if the offender damages the premises by forcible entry. Thus, the crime severity scale takes account of both the components (injury, theft, and damage) and the aggravating factors (intimidation and premises forcibly entered).

Developing the 1964 Scale

Sellin and Wolfgang used these components of offense severity to develop 141 single-sentence offense descriptions or scenarios that were shown to a pilot group of 17 raters (university students). The raters were instructed to rate the criminal event on the basis of their perception of its severity or seriousness on a 7-point scale of severity. The small pilot study was deemed a success because it demonstrated that the offense descriptions were adequate and subjects could render comparative judgments.

The second stage of the research involved a determination by Sellin and Wolfgang as to the type of scaling technique to be used to develop the actual scale of crime severity. They followed the suggestion of Stevens and Galanter and employed both an 11-point category scale and a magnitude estimation ratio scale for comparative validation purposes. The second stage also involved the selection of the raters who would make the judgments concerning crime severity. They considered a variety of subject groups and selected a total of 569 respondents: 286 police officers, 245 university students, and 38 juvenile court judges. The ratings of the 141 offense scenarios by these respondents constitute the "primary index scale." Sellin and Wolfgang then compared the results of the 11-point category scale with the magnitude estimation ratio scale and found that for each of the rating groups, there was remarkable consistency when the category scores were plotted against the magnitude values. In light of this consistency, Sellin and Wolfgang could confidently adopt the magnitude estimation scores as the basis for constructing the scale, and thus derive a set of ratio scores by which the relative gravity of crimes could be documented.

Table I Offense Scores and Ratio Values, l964

Offense scenario	*Mean magnitude scale values*	*Ratio score*[a]
Larceny $1	16.93	1
Larceny $5	22.09	1
Larceny $20	27.77	2
Larceny $50	32.31	2
Larceny $1000	52.99	3
Larceny $5000	69.13	4
Burglary $5	40.62	2
Robbery $5 (no weapon)	52.25	3
Robbery $5 (weapon)	86.33	5
Assault (death)	449.20	26
Assault (hospitalized)	115.60	7
Assault (treated and discharged)	69.32	4
Assault (minor harm)	22.50	1
Rape (forcible)	186.30	11
Vehicle theft (no damage)	27.19	2
Forcible entry	18.53	1
Intimidation (verbal)	30.15	2
Intimidation (weapon)	64.24	4

[a] Ratio scores are derived by dividing the geometric mean of an offense scenario by the geometric mean of larceny of $1 (i.e.,16.93).

Among the set of 141 offense scenarios was a set of 18 core items that Sellin and Wolfgang used to vary systematically the various aspects of crime severity so as to derive the weights for the various components that must be scored to compute a severity score for a criminal event. The actual scale values were computed as follows and displayed in Table I. The appropriate measure of central tendency for ratio judgments is the geometric mean that in practice is calculated by taking the antilog of the arithmetic mean of the logarithms of the responses, or the antilog of

$$\frac{\sum_{I=1}^{N} \log X_I}{N}.$$

Replications

The work of Sellin and Wolfgang has been replicated on several occasions both in the United States and in other countries, which confirms the validity of the principle that the severity of crime can be scaled using subjective judgment procedures. These replications were first done internationally; in Canada by Normandeau, in Puerto Rico by Velez-Diaz and Megargee, and in Taiwan by Hsu. In the United States, Rossi *et al.*, Figlio, and Wellford and Wiatrowski conducted similar studies of crime severity judgments.

The Second Sellin–Wolfgang Scale: A National Survey of Crime Severity

In the early 1980s, Wolfgang and colleagues at the Criminology Center at the University of Pennsylvania decided to update the original scale because approximately 5 years had passed since the first scale had been developed and they hypothesized that changes in the public's perception of crime might have changed. The research that ensued employed the same scaling techniques as its predecessor, but the researchers decided to expand the number of offense scenarios and use a nationally representative sample. The major purposes of the new survey were (i) to determine at the national level the public's perception of the relative severity of various kinds of crime; (ii) to investigate the perceived severities of criminal offenses according to regions, states, size of place, and a range of sociodemographic characteristics of the population; and (iii) to determine if the data generated by the survey would produce a structure resembling a quantitative scale similar to that previously reported in the literature.

The National Survey of Crime Severity (NSCS) was administered as a supplement to the National Crime Victimization Survey (NCVS), an ongoing national survey sponsored by the Bureau of Justice Statistics. The purpose of the NSCS was to measure household and individual victimizations by the major crimes of assault, burglary, robbery, larceny, and vehicle theft. The NCVS has utilized a rotating sample design with approximately 60,000 households interviewed over a 6-month period. The NCSC estimates were based on data collected during the period July through December 1977. The NCSC sample was a 50% sample of the NCVS full sample and was spread over 376 sample areas with coverage in each of the 50 states and the District of Columbia. The national-level magnitude estimation scores and ratio values that comprise the severity scale weights are shown in Table II.

The Sellin–Wolfgang Severity Scoring System

Offense Components

In order to score criminal events, the following items, insofar as they are applicable to a given event, must be collected and recorded so that the component of harm can be scored.

Number of Victims Injured

Each victim who receives some degree of bodily injury during a criminal event must be accounted for. Physical injuries usually occur as a direct result of assaultive events,

Table II Offense Scores and Ratio Values, 1985

Offense scenario	*Mean magnitude scale values*	*Ratio score*[a]
Larceny $1	21.9	1.0
Larceny $10	37.8	1.7
Larceny $50	63.0	2.9
Larceny $100	78.5	3.6
Larceny $1,000	150.2	6.9
Larceny $10,000	239.3	10.9
Burglary and theft $10	70.6	3.2
Robbery $10 (verbal threat)	144.8	6.6
Robbery $10 (weapon)	180.0	7.3
Assault (death)	778.4	35.6
Assault (hospitalized)	261.4	12.0
Assault (treated and discharged)	186.0	8.5
Assault (minor harm)	32.2	1.5
Rape (forcible)	565.6	25.8
Vehicle theft (recovered)	97.7	4.5
Vehicle theft (not recovered)	176.7	8.1
Forcible entry	43.6	1.5

[a] Ratio scores are derived by dividing the geometric mean of an offense scenario by the geometric mean of larceny of $1 (i.e., 21.9).

but they may be a by-product of other events as well. The following are the four levels of bodily injury:

Minor harm: An injury that requires or receives no professional medical attention. The victim may, for instance, be pushed, shoved, kicked, knocked down, and receive a minor wound (cut, bruise, etc.).

Treated and discharged: The victim receives professional medical treatment but is not detained for further medical care.

Hospitalization: The victim requires inpatient care in a medical facility, regardless of its duration, or outpatient care for three or more clinical visits.

Killed: The victim dies as a result of the injuries, regardless of the circumstances in which they were afflicted.

Number of Victims of Acts of Forcible Sexual Intercourse

This event occurs when a person is intimidated and forced against his or her will to engage in a sexual act (e.g., rape, incest, and sodomy). Such an event may have more than one victim, and the score depends on the number of such victims. A continuous relationship such as may occur in forcible incest is to be counted as one event. A forcible sex act is always accomplished by intimidation. Thus, the event must also be scored for the type of intimidation involved. Intimidation is scored for all victims in a forcible sex act (such is not the case for other events). The victim of one or more forcible sex acts during an event is always assumed to have suffered at least minor harm. Even when medical examination may not reveal any injuries, the event must be scored for minor harm. This level of injury should also be scored (rather than treated and discharged) when the victim is examined by a physician only in order to ascertain if venereal infection has occurred or to collect evidence that the sex act was completed.

Physical or Verbal Intimidation or Intimidation by a Dangerous Weapon

This is an element in all events in which one or more victims are threatened with bodily harm (or some other serious consequences) for the purpose of forcing the victim(s) to obey the request of the offender(s) to give up something of value, to assist in a criminal event that leads to someone's bodily injury and/or property theft or damage. In addition to rape, robbery is a classic example. Ordinary assault and battery, aggravated assault and battery, or homicide are not to be scored for intimidation merely because someone was assaulted or injured. The event must have also included the threat of force for intimidation to have been present. With the exception of forcible sex acts, criminal events involving intimidation are scored only once regardless of the number of victims who are intimidated. The types of intimidation are:

Physical or verbal: Physical intimidation means the use of strong-arm tactics such as threats with fists and menacing gestures. Verbal intimidation means spoken threats only, not supported by the overt display of a weapon.

Intimidation by weapon: Display of a weapon, such as a firearm, cutting or stabbing instrument, or blunt instrument capable of inflicting serious bodily injury.

Number of Premises Forcibly Entered

As used here, forcible entry means unlawful entry, even when not by "breaking" into premises of a private character to which the public does not have free access or the breaking and entering into premises to which the public ordinarily has free access. Such an entry is, in itself, an event to be scored if it causes some degree of damage to property (e.g., a broken lock, window, or door) even though it is not followed necessarily by an injury to a person or by a theft of and damage to property inside the premises.

Usually only one distinct premise will be entered, such as a family dwelling, an apartment, or a suite of offices, but some events may embrace several such entries. The scoring depends on the number of premises forcibly entered during the event and occupied by or belonging to different owners, tenants, or lessees. Contrary to the "hotel rule" used in the UCR, each hotel, motel, or lodging house room broken into and occupied by different tenants should be scored. If a building was forcibly entered

Table III Crime Severity Scoring Sheet (1985 Weights)

Effects of event: I (injury) T (theft) D (damage) (Mark all that apply)			
Crime severity component	*No. of victims*	× *Scale weight*	= *Total*
1. Injury			
a. Minor harm	_____	1.47	_____
b. Treated and discharged	_____	8.53	_____
c. Hospitalized	_____	11.98	_____
d. Fatality	_____	35.67	_____
2. Forcible sex acts	_____	25.92	_____
3. Intimidation			
a. Verbal or physical	_____	4.90	_____
b. Weapon	_____	5.60	_____
4. Premises forcibly entered	_____	1.50	_____
5. Motor vehicles stolen			
a. Recovered	_____	4.46	_____
b. Not recovered	_____	8.07	_____
6. Property theft and damage[a]	_____		_____
	Total severity score		

[a] The severity score for any value of theft or damage is produced as follows: $\log_{10}{}^{Y} = 0.26776656 \times \log_{10}{}^{X}$; where Y is the crime severity weight, and X is the total dollar value of theft or damage.

and further entries were made inside, the total number of entries scored should include the forcible entry of the building even when the building belongs to someone who is victimized by a further entry inside.

Number of Motor Vehicles Stolen and Recovery Status

As used here, motor vehicle means any self-propelled vehicle—automobile, truck, motorcycle, tractor, or airplane. Disregard self-propelled lawn motors and similar domestic instruments in this section; the value of such items is accounted for in the theft/damage section. Because motor vehicles may be either stolen and recovered or stolen and never returned to the legal owner, the number of vehicles in each category must be accounted for separately and will receive a different score value.

Total Dollar Amount of Property Loss through Theft or Damage

Regardless of the kind of event scored and the number of victims, the total value of all property stolen or damaged must be determined, whether it is wholly or partially recovered and whether or not the loss is covered by insurance.

Motor vehicle thefts require special handling. The score of the event does not depend on the value of the vehicle stolen. Thus, the dollar value of the vehicle is ignored in this element. However, if the vehicle is recovered damaged and/or property has been taken from it, the loss is the sum of the cost of the damage and the value of the stolen articles.

The Crime Severity Scale Illustrated

The offense components discussed previously constitute the scale items in the Sellin–Wolfgang scale of the gravity of the crime. The scoring system used to evaluate the seriousness of crime can best be presented by first describing the elements of the system and then illustrating the scoring procedure with hypothetical offenses. Table III depicts the elements of the system. The first item that must be collected is the identification number. This is the number given to a particular criminal event. It may be a central complaint number, a district number, or some similar designation. If the same event is represented by more than one such number, all numbers should be recorded so that the event can be scored as a whole. In most cases, an event will be described in complaint or investigation reports carrying but one identifying number. In some cases, however, one event may become the subject of reports with different numbers (two or more such reports describing the same event). For instance, in a rape event with two victims, each victim may file his or her own complaint and thus it would be necessary to coordinate the separate reports before the event could be scored.

In order to classify the event, the presence of I (injury), T (theft), and D (damage) components must be determined. Because the construction of subindices is often necessary, as many of the components as apply should be circled. From this procedure, it is possible to derive six classifications of an event: I, T, D, IT, TD, and ITD. It is possible, therefore, to use this classification scheme as a solution to the problem of dealing with the complex criminal event in which more than one offense type is present simultaneously.

Following the determination of the class to which the event belongs, the event is scored for seriousness. Column 1 lists the various offense components and the particular levels of each. Column 2 refers to the number of victims who experience each level of the offense components. The exceptions to the rule of accounting for the number of times each component occurs involve criminal events other than rape in which intimidation is present and in which this component is scored only once regardless of the number of victims and the value of property loss that is summed across all victims. Column 3 gives the scale weight assigned to each element of the offense. Column 4 is reserved for the total score for a given component; this is obtained by multiplying the number in Column 2 (where applicable) by the weight listed in Column 3. By adding all the numbers in Column 4, the total score for the event is computed.

Illustrations of how the proposed scoring system works are given next. For the purpose of showing how it differs from that of the UCR system, the problems have been adapted from the "Uniform Crime Reporting Handbook" issued by the FBI. The problems as originally listed there generally do not contain all the necessary information. Therefore, hypothetical data have been supplied in parentheses.

Problem 1

A holdup man forces a husband and his wife to get out of their automobile. He shoots the husband, gun whips and rapes the wife (hospitalized) and leaves in the automobile (recovered later) after taking money ($100) from the husband. The husband dies as a result of the shooting.

Solution: Effects of event: ***Injury*** ***Theft*** Damage

Severity component	*No. of victims*	*Severity weight*	*Score*
Injury: hospitalized	1	11.98	11.98
Injury: death	1	35.67	35.67
Forcible sex act	1	25.92	25.92
Intimidation: weapon	1	5.60	5.60
Vehicle: recovered	1	4.46	4.46
Property loss: $100	n.a.	3.43	3.43
		Total score	87.06

In this event, the husband was killed (35.67), and the wife was raped (25.92), threatened with a gun (5.60), and did sustain injuries requiring hospitalization (11.98). The car was stolen and recovered (4.46). The total value of the property loss was $100 (3.43). In comparison to the UCR solution of one nonnegligent criminal homicide, the Sellin–Wolfgang scale finds an injury–theft event with a total score of 87.96.

Problem 2

Two thieves break into a warehouse (damage $20) and have loaded considerable merchandise (worth $3500) on a truck. The night watchman is knocked unconscious with some blunt instrument (treated and discharged). The thieves drive away in the stolen truck (not recovered).

Solution: Effects of event: ***Injury*** ***Theft*** ***Damage***

Severity component	*No. of victims*	*Severity weight*	*Score*
Injury: treatment	1	8.53	8.53
Premises entered	1	1.50	1.50
Vehicle: not recovered	1	4.46	4.46
Property loss: $3520	1	8.91	9.91
		Total score	23.40

This offense involves the forcible entry of a building (1.50), injury to the night watchman requiring treatment (8.53), theft of an unrecovered motor vehicle (4.46), and property loss of $3520 (8.91). The UCR would classify this event as a one robbery, whereas the Sellin–Wolfgang system reveals that it is a complex event that involves the combination of the three primary effects of crime (injury, theft, and damage) and has a total seriousness score of 23.40.

Problem 3

Three men break into a public garage (damage $20) after closing hours. They steal cash from the garage office ($50) and two automobiles from the lot. One vehicle was recovered undamaged; the other was not found.

Solution: Effects of event: Injury ***Theft*** ***Damage***

Severity component	*No. of victims*	*Severity weight*	*Score*
Premises entered	1	1.50	1.50
Vehicle: recovered	1	4.46	4.46
Vehicle: not recovered	1	8.07	8.07
Property loss: $70	1	3.12	3.12
		Total score	17.15

The UCR solution to this problem would be to record one burglary. The Sellin–Wolfgang system classifies the event as a theft–damage crime that involved forcible entry (1.5), two motor vehicles stolen with one recovered

(4.46) and the other not found (8.07), and property loss totaling $70 (3.12). The total score for the event is 17.15.

Problem 4

An automobile containing clothing and luggage valued at $375 is stolen. The car is recovered (undamaged), but the clothing and luggage are missing.

Solution: Effects of event: Injury ***Theft*** Damage

Severity component	*No. of victims*	*Severity weight*	*Score*
Vehicle: recovered	1	4.46	4.46
Property loss: $375	1	4.89	4.89
		Total score	9.35

In this example, the two scoring systems are similar because the UCR would record one auto theft, whereas the Sellin–Wolfgang classification would record a vehicle theft and property theft. However, the Sellin–Wolfgang scale further signifies that the vehicle was recovered (4.46) and that there was a loss of property in the amount of $375 (4.89), which results in a final score of 9.35.

Problem 5

Answering a broadcast of an armed robbery in progress, police become engaged in a gun battle with three armed robbers; one of the bandits is killed and the other two are captured. (Presumably no one was injured except the offender, who was killed.)

Solution: Effects of event: ***Injury*** Theft Damage

Severity Component	*No. of victims*	*Severity weight*	*Score*
Injury: death	1	35.67	35.67
		Total score	35.67

If no one was injured except the offenders, this would be a theft event if theft had actually occurred before the police arrived. If so, the event would be scored for intimidation by weapon (5.60) plus the score for the value of property taken—for instance, $100 (3.43)—which totals 9.03 for the event. If the robbers had not carried out the offense because the police came before any property was taken, the event would be rated as an attempted robbery and not scored at all within the index of crime severity. In the final analysis, this event would be scored for a felony murder (35.67) to account for the death of one of the robbers. The UCR would score this event as one robbery.

Problem 6

Answering a riot call, police find that seven persons were in a fight. A variety of weapons are strewn about. None of the participants is particularly cooperative. Each one claims innocence but is vague regarding who is responsible for the assault. Three of the seven are severely wounded (all were hospitalized) while the remaining four receive only minor cuts and bruises (no medical treatment).

Solution: Effects of event: ***Injury*** Theft Damage

Severity Component	*No. of victims*	*Severity weight*	*Score*
Injury: minor harm	4	1.47	5.88
Injury: hospitalized	3	11.98	35.94
		Total score	41.82

The UCR procedure for the enumeration of this event calls for the designation of three aggravated assaults. The Sellin–Wolfgang scoring process accounts for these same effects (35.94) as well as the four minor injuries (5.88). Taken together, these consequences produce a combined score of 41.82 for this injury event.

Problem 7

Ten persons are present in a nightclub when it and the 10 persons are held up by armed bandits. Two of the victims resist the robbery and are seriously injured (hospitalization). (The combined property loss is $1800.)

Solution: Effects of event: ***Injury*** ***Theft*** Damage

Severity component	*No. of victims*	*Severity weight*	*Score*
Injury: hospitalized	2	11.98	23.96
Intimidation	n.a.	5.60	5.60
Property loss: $1800	n.a.	7.44	7.44
		Total score	37.00

The UCR classification of the event as one robbery clearly hides several important ingredients. The Sellin–Wolfgang scale produces a combined injury–theft event that involved two hospitalized victims (23.96), intimidation by a dangerous weapon (5.60), and dollar loss of $1800 (7.44). The overall score of 37.00 indicates that the recording of one robbery could be very misleading.

Problem 8

Six rooms in a hotel are broken into (damage $60) by two sneak thieves on one occasion. (The total value of property stolen from the rooms, occupied by different tenants, amounted to $1200).

Solution: Effects of event: Injury ***Theft*** ***Damage***

Severity component	*No. of victims*	*Severity weight*	*Score*
Premises entered	6	1.50	9.00
Property loss: $1260	n.a.	6.76	6.76
		Total score	15.76

The UCR classification system would designate this event as one burglary and would not account for either the property damage or the theft losses. Alternatively, the Sellin–Wolfgang system provides for six victims of burglary and incorporates the significant dollar loss from damage and theft.

These examples of the Sellin–Wolfgang severity scale show that it yields a more accurate measure of the severity of a criminal event than other methods currently in use. Although other systems measure the quantity and quality of crime, they do not produce the same degree of precision available with the Sellin–Wolfgang scale. In particular, the UCR system of counting index crimes determines the degree of seriousness of a crime by selecting the single element in the offense that has the legal label that is highest in the rank order of offenses. Furthermore, it treats all aggravated assaults, robberies, and burglaries as equally serious and each offense contributes one unit to crime rate measures.

The method for dealing with the relative gravity of criminal offenses discussed and illustrated previously has the same ultimate aim as the UCR scheme but pursues it in a different manner. Instead of focusing on an ordered set of crimes, the Sellin–Wolfgang scoring system utilizes a scale that assigns different weights to certain designated elements of an index event. When these score values are added together, they provide a score for the total event—a score that can be placed on a severity continuum reflecting the quantity and quality of criminal behavior.

Applying the Crime Severity Scale

It should be stressed that the seriousness scoring system described previously has great potential for improving the measurement of crime. It seems that this benefit applies to researchers and criminal justice practitioners alike. However, there appears to be some question whether in practice the acknowledged value of the scale warrants the extra effort required by the scoring system, an effort not necessary with the simple enumeration system of the UCR, for instance. That is, there are critics of the Sellin–Wolfgang scale who have concluded that the UCR classification and counting methods may be more than adequate for representing the volume and seriousness of criminal behavior and the additional costs and difficulties surrounding the implementation of the gravity scale overshadow the potential benefits. It needs to be recognized that these critics are essentially referring to the process of applying the scale to aggregate-level data by merely weighting the frequency of index offenses recorded in the UCR by the mean Sellin–Wolfgang severity score of similar offenses.

This is a somewhat artificial critique because the Sellin–Wolfgang scale was not created to accommodate post hoc calculations. The Sellin–Wolfgang scale begins with individual criminal events. Through the scoring procedure outlined previously, the criminal event is evaluated for the presence of several important severity components and seriousness weights are assigned. Although the system can and should be used to construct aggregate rates of crime weighted for severity, criminal events must be scored at the individual level before any aggregate weighted rates are calculated. Simply, the process of merely multiplying the frequency of a crime by an average severity score compounds the measurement problems associated with the classification of the event in accord with UCR rules in the first place. Any such procedure ignores the wealth of data represented by the criminal event (especially because of the hierarchy principle) and thus vitiates the potential of the scale to capture the quantitative components of offense severity.

Research Applications

Crime Severity Rates

One of the most frequent research issues that confronts criminology is the construction and analysis of crime rates. Crime rates form the basis of analyses designed to investigate changes in crime over time or variation across certain levels of aggregation (e.g., national, regional, state, county, and city). Usually, researchers use the data available in the UCR for measuring total, violent, and property index offenses. It was noted previously that the UCR system gives equal weight to each of the offenses in the crime index to represent the total amount of serious crime and, when subdivided into violence and property, reflects the amount of category-specific crime. The essential problem with the rates of crime derived from the UCR is that the impact of the more serious and less frequent offenses (e.g., homicide, rape, and robbery) is attenuated by the more frequent and less serious offenses. For

Table IV Aggregate Crime Severity Measures

Measure	*Meaning*
1. $\frac{\sum \text{Seriousness score across crimes}}{\text{Total juvenile population}} \times 100{,}000$	Juvenile harm: Severity crime rate per 100,000 juveniles
2. $\frac{\sum \text{Seriousness score across crimes}}{\text{Total adult population}} \times 100{,}000$	Adult harm: Weighted crime rate per 100,000 adults
3. $\frac{\sum \text{Seriousness score across crimes}}{\text{Total population}} \times 100{,}000$	Community harm: Weighted rate per 100,000 adults
4. $\frac{\sum \text{Seriousness score across crimes}}{\text{Total crimes}}$	Average crime severity
5. $\frac{\sum \text{Seriousness score across events}}{\text{Total offenders}}$	Average offense severity per offender
6. $\frac{\sum \text{Seriousness score across offenders}}{\text{Total offenders}}$	Average offender severity

example, because homicide comprises only approximately 2% of the violent crime rate, more than a 50% increase in homicide would be needed to affect a 1% increase in the violent crime rate. Clearly, this aspect of the rate structure of UCR crimes seriously jeopardizes the value of such rates for research purposes, particularly with respect to measuring significant shifts in the severity of crime over time or differences across comparison areas.

Alternatively, crime rates could be calculated that reflect the relative severity of each individual crime; consequently, such rates would better capture changes in the actual quantity of social harm associated with criminal behavior. In their pioneering work, Sellin and Wolfgang suggested several possible indices or rates that could be based on crimes weighted for severity. These rates are shown in Table IV. Although these rates were designed primarily for application to juvenile delinquency, they have direct application to adult data as well. These weighted rates have been utilized in several studies.

Formula 1 provides the main comparative statistic for a weighted index of delinquency or "juvenile harm" as it was called by Sellin and Wolfgang. The index uses the familiar offense rate calculation: (i) The severity of all acts of delinquency are scored and then summed, (ii) the result is divided by the juvenile population at risk for delinquency (i.e., usually age 7 to 17 in most jurisdictions), and (iii) this result is then multiplied by a constant (usually 100,000) to allow comparisons across jurisdictions. The resulting statistic addresses the crucial issue of the amount of juvenile harm, or weighted crime severity, inflicted on the community by 100,000 juveniles.

Formula 2 is the complement to formula 1 because it provides a weighted index of adult harm. Formula 3 provides a weighted rate of overall community harm by indicating the amount of crime severity per 100,000 population of community members. These rates are analogous to the UCR index crime rates but they appear to be far more valuable because the elasticity of the most serious crime components (although relatively infrequent) are built into the weighting scheme. Furthermore, because age-specific rates are computed, it is possible to attribute the relative share of social harm that pertains to the important distinction between juvenile delinquents and adult criminals.

Formulas 4–6 are also useful measures because they represent statistics pertaining to average severity scores. Formula 4 calculates the average crime severity across all index crimes. Formula 5 provides the average crime severity across crimes and apportions it across the offenders involved regardless of how many such offenders there were, and formula 6 calculates the average crime severity attributable to offenders regardless of the number of events in which they were involved.

These six formulas are a sample of the weighted rates that can be computed using the Sellin–Wolfgang scale. Naturally, it is possible to use other denominators to encompass different gender, race/ethnicity, or social class groups and analyze comparative severity rates. It is also possible to compute rates for the three main categories of Sellin–Wolfgang index crimes—injury, theft, and damage. In this way, subindices can be constructed in order to compare severity scores both across and within offense types. Regardless of which rates are utilized, the use of severity scores to weight the various components of a criminal event produces an index system that can accurately as possible measure the real or actual extent of harm associated with illegal behavior in a given area across time periods or across areas within a single time period.

Wolfgang *et al.*, Tracy *et al.*, and Nevares *et al.* have shown that weighted rates of delinquency allow researchers to uncover important relationships between sociodemographic factors and crime that are generally not discernible using only frequency measures.

Criminal Careers

It should be clear that another very useful application of the scale concerns what might be called offense-specific analysis. It has been conclusively demonstrated that criminal offenses can be evaluated and scaled for severity components, thus providing a basis for comparing the relative severity between crimes. This can be accomplished in two ways. First, a numerical score can be computed and assigned to the event overall or for various subcomponents such as injury. Second, the event can be classified into one of three major categories depending on which major severity component (i.e., injury, theft, or damage) of crime severity characterizes the event. The value of these two approaches can be best illustrated with respect to research on criminal careers.

Ordinarily, an offender's criminal career is typified by the number of offenses he or she has committed. The offenses may be grouped into various classes of severity, such as crimes against persons or property. Furthermore, a "rap sheet" may indicate a long series of crimes that stretch over several years or even decades, including robberies, thefts, burglaries, and assaults as the legal code defines such illegal behavior. However, these labels do not in and of themselves give any indication of the severity of the illegal conduct in terms of either absolute severity or whether such severity fluctuates during an offender's career or escalates and becomes more serious as the career progresses.

Alternatively, if the offense career were scored for severity using the Sellin–Wolfgang system, this would provide a valuable enhancement to the study of criminal career progression. It would be possible, for instance, to study whether at an early stage of the career the offenses increased in severity as the career progresses regardless of the particular legal labels attached to the behavior and whether such increased severity was associated with a longer criminal career thereafter. The severity scaling of the offenses may also reveal differences, otherwise undetected, among offenders who produce particular harmful effects such as through injury or theft components and the extent to which these different offender types are likely to continue their illegal conduct or desist from crime. It may also be possible through severity scoring to find differences among offenders concerning such correlates as age, gender, race/ethnicity, and social class that do not readily appear when only the frequency of illegal conduct is studied.

This strategy for evaluating or analyzing a criminal career has clear benefits for research designed to go beyond the mere description of criminal careers by studying the explanatory factors underpinning longer and more serious careers from their less serious or shorter counterparts. Clearly, the severity scoring system provides a means for comparing the occasional offender with his or her more recidivistic counterpart, a basis that does not merely count offenses or use broad legal labels but rather quantitatively rates their degrees of actual social harm. This improves the attempt to delineate patterns of criminal conduct that may be hidden by the broad legal labels that are usually referenced when rap sheets as opposed to offense reports are used as the data collection source. As a result, our understanding of the phenomenon of crime may be enhanced. Furthermore, our ability to control, if not prevent, prolonged criminal careers may also be improved.

Wolfgang *et al.*, Tracy *et al.*, and Nevares *et al.* have shown that when delinquency offenses are scored for seriousness, the patterns of delinquency and offense escalation across the career become meaningful aspects of the analysis of juvenile delinquency careers. Furthermore, using crime severity scores, Tracy and Kempf-Leonard have show that offense escalation early in a delinquent's career portends a greater than average likelihood that the offender will make the transition to adult criminality.

Survey Data Weighted for Crime Severity

Increasingly, surveys of victims, such as the NCVS administered by the Bureau of Justice Statistics, U.S. Department of Justice, have come to occupy a central place in the measurement of crime. By interviewing respondents in a national probability sample of households, researchers can generate highly valuable estimates of the incidence of crime, information that does not depend on whether the victim reported the crime to the police or the manner in which the police responded to crimes that were reported. From these surveys, criminologists have learned that a considerable amount of crime actually occurs but is not reported to the police and cannot be included in crime rate calculations. Clearly, therefore, victimization surveys are an important adjunct to police statistics. Similarly, self-report surveys are used to illicit data on the hidden dimension of crime—the crimes that people commit for which there may not have been a report or there was no arrest. These data not only address the incidence of crime but also provide information about the prevalence of criminality across sociodemographic correlates of official statistics versus hidden crime.

It is not only feasible but also highly desirable to apply the Sellin–Wolfgang severity scaling procedures to these surveys. In so doing, research could address topics other than just the incidence of unreported victimization or the prevalence of hidden crime. For example, comparisons could be made between the severity of offenses that victims report to the police and those that victims choose to let go unreported. Are there strong severity differences

that explain the reporting phenomenon? Furthermore, research could investigate whether different segments of the population experience different degrees of harm. In terms of self-report data, the application of severity scoring procedures provides the opportunity to compare the severity of offenses that are known to the police with those for which the offender was never caught. In any event, victimization and self-report data weighted for severity components would enhance the important function that these measurement approaches serve in augmenting official crime statistics.

Evaluation Research

The Sellin–Wolfgang severity scale also appears to have potential application in program evaluation research. Generally, offender recidivism, or the lack thereof, is used as the basic success or outcome measure. Another important outcome measure that should be evaluated is the severity of crime. By scaling the offenses committed by program participants, evaluators could examine the possible effects of treatment, if not in preventing recidivism altogether, then at least in the extent to which such treatment affected a reduction in the severity of the post-treatment criminal behavior committed. For example, one might investigate the relative effectiveness of intensive, moderate, and minimal probation or parole supervision models or a violent offender program. By using crime severity data, such program evaluations could be rendered more substantial and perhaps lead to more definitive conclusions concerning the effectiveness of certain treatment methods.

Practitioner Applications

Law Enforcement

The use of the crime severity scale is not limited to research applications; it can be implemented in various spheres of the criminal justice system. For example, Heller and McEwen tested the utility of the 1964 version of the Sellin–Wolfgang scale for law enforcement functions. The results indicated that the scale may be useful in several ways. First, it can be employed as the basis for work assignments for detectives: cases with higher than average severity scores could be allocated first instead of arbitrarily choosing cases for investigation. In this regard, the scale was also suggested as providing a means to estimate a severity-of-offense clearance rate that would reflect more accurately the effectiveness of police operations. Second, the scale could also be used in the allocation of patrol personnel to shifts (watches) with the higher severity scores. Last, the scale could also be applied in the determination of patrol beats so that patrols would cover the higher severity areas more effectively rather than the places where the volume of crimes was highest (but might have lower severity scores).

Prosecution

The Sellin–Wolfgang scale has value in the prosecution area. The scale has been successfully implemented in the Prosecutor's Management Information System in Washington, DC, to estimate the urgency of a case prosecution. The scale can also be used to assist in the selection of cases for special prosecution procedures as in the career criminal programs that have been adopted in many jurisdictions. These programs are designed to provide more effective handling of the career criminal. The special procedures may involve more extensive investigations before trial and uniform case processing from indictment through sentencing. Naturally, these career criminals must first be identified so that they can be designated for special procedures. The usual procedure is to count rap sheet offenses until some threshold is reached. However, some career criminal prosecution programs also attempt to account for the severity of the criminal's career, but evaluation in this regard usually consists only of the determination of whether the offenses are crimes against the person versus property or felonies versus misdemeanors.

The identification and prosecution of career criminals could be greatly enhanced by using the crime severity scale. Prosecutors would have a quantitative measure with which to compare offenders and the overall severity of their offense record. Consequently, prosecutors could more easily identify the most suitable candidates for special handling by the career criminal unit, and the selection could be justified with reference to not only the volume of crimes but also the quality of the offense career by accounting for the extent of social harm inflicted by career criminal designees.

Sentencing

Another stage of the criminal justice system for which the Sellin–Wolfgang scale would seem to have particular relevance is the sentencing stage. With respect to determining the appropriate sentence for convicted criminals, the severity of the offense would likely be one of the most relevant aspects. As early as the 17th century, legal theorists of the classical school called for a punishment system that bases the nature and extent of criminal sanctions on the degree of harm inflicted on the victim and the wider community by the offender. It can be seen that punishments graduated for offense severity would serve the goals of both retribution and deterrence while at the same time possibly reduce the disparity and capriciousness that characterize other sentencing methods. Hence, offenders convicted of equally serious crimes would receive the same penalty and the sanction should be more harsh than that applied to less serious violators.

The classical school doctrine of "let the punishment fit the crime" dominated the criminal law until the late 19th century when perspectives about rehabilitating offenders became more persuasive. The rehabilitation approach, with its reliance on indeterminate sentencing models, became the primary thrust of criminal sanctions and the dominant philosophy in corrections until the late 1970s. At this time, owing to growing concerns that treatment approaches were not effective at reducing offender recidivism, an alternative approach known as the "just or commensurate deserts" became more prevalent. Essentially, the just deserts approach is a revival and extension of the classical perspective that punishment should be commensurate with the blameworthiness as reflected in the current offense as well as the offender's prior criminal record.

Clearly, the Sellin–Wolfgang severity scale has substantial value in sentencing under the just deserts approach. The scale could be used to rank the severity of both the current offense and the offenses in the prior criminal career along a quantitative continuum and thus ensure that punishments were appropriately matched to the degree of crime severity—a scientific measure of just deserts. Such gradients could be constructed in terms of both classes of events (i.e., injury, theft, or damage) and the severity rating scale. Either way, the scale could provide a meaningful operational definition of the just deserts principle and simultaneously ensure that disparity in sentences was minimized.

Conclusion

The Sellin–Wolfgang severity scale was first developed in the early 1960s and updated in 1977. This article described its development and reviewed the scoring procedure that should be used to capture the qualitative and quantitative dimensions of criminal conduct. It has been shown that the severity scaling system has been used to enhance criminological research, particularly in the area of criminal careers. It was also demonstrated that the scale has widespread applicability to a variety of research and practitioner applications.

The Sellin–Wolfgang scale of crime severity was innovative when it was first developed in 1964, and it was improved when it was updated in 1985, but it has been approximately 20 years since the scale was last updated. During this time, criminology has witnessed significant changes in the awareness of and attention focused on a broad range of offense types that heretofore were given only passing concern. For example, there is now a much higher priority to the study of crimes against women and children as society has come to appreciate the significance of domestic violence and the nature of child sexual abuse. Among the crime issues currently receiving significant attention, one of the most controversial concerns the problem of "child sex offenders," also known as "child molesters," "violent sexual predators," and so on. The debate has been fueled by a series of highly publicized homicides throughout the United States involving children who were kidnapped, sexually assaulted, and murdered. These cases have stimulated a host of "sexual predator laws" or sex offender notification statutes such as the federal Megan's Law and even state laws such as Ashley's Law in Texas.

The 1980s also ushered in a keener appreciation for the drastic economic consequences associated with white-collar crime, such as the savings and loan scandals and the junk bond fraud cases. Notably, the so-called Whitewater federal prosecutions in the 1990s that involved a host of notable Arkansas politicians, bankers, and their associates points to the heightened public policy significance attributed to such large-scale white-collar crime. Unfortunately, the past 20 years has also seen numerous incidents of terrorist crimes, such as the sabotaging of airliners with significant loss of human lives; the bombing of the World Trade Center in New York; the bombing of the federal building in Oklahoma City, which resulted in the deaths of 168 people and injuries to countless others; and the ultimate act of terrorism—the attack on September 11, 2001, which caused the loss of thousands of lives, countless injuries, and hundreds of millions of dollars in property losses in New York, Washington, DC, and Pennsylvania.

These crime-related developments during the past 20 years surely must have had an effect on the public's perception of crime and the effectiveness of efforts to control crime and punish offenders accordingly. Thus, it is necessary, if not crucial, to update the 1977 National Survey of Crime Severity by sampling a nationally representative group of respondents. These respondents could be administered a set of questionnaires with an updated set of offense descriptions or scenarios to capture the developments reviewed previously. This research would ensure that the Sellin–Wolfgang scale of offense severity would continue to be an important measurement approach with contemporary relevance and significance to researchers and policymakers.

Glossary

common causes The description given to variation in a stable process. This can also be described as natural variation in a system—in other words, nothing unusual is happening (e.g., no special causes). Common cause variation is also present in processes that are out of control and are constant over time and throughout the system.

control Here we see the relationship between prediction and control: "For our present purpose *a phenomenon will be said to be controlled when, through the use of past experience, we can predict, at least within limits, how the phenomenon may be expected to vary in the future. Here it is understood that prediction within limits means that we can state, at least approximately, the probability that the observed phenomenon will fall within limits*" (Shewhart; emphasis in original).

prediction The premise is that if a process is in statistical control, then the future behavior of that process is predictable for the foreseeable future. The notion of prediction comes from theory. The construction of a chart allows the evidence to be interpreted, using theory to predict what may happen next. Data on its own does not provide a prediction. "Rational prediction requires theory and builds knowledge through systematic revision and extension of theory based on comparison of prediction with observation" (from Deming).

Shewhart control chart A chart with two axes used to plot data taken from processes and products. The plotted data points on the chart illustrate "variation" in the "thing" being measured. The chart will also show the mean and upper and lower control limits. Charts are an operational definition of the distinction between common and special causes of variation. Charts can be used for (1) judgment of the past, (2) stability of the present, (3) prediction of the future by looking back on a set of results from a process, and as an *Operation* to attain and maintain an ongoing process.

special causes Causes outside natural variation in the process. In manufacturing, it could be some faulty material, an untrained employee making a mistake, or a worn machine tool, for example. They are often sporadic and may have a local impact on the process as a whole. Process instability is shown on the control chart as evidence of special causes that the operator or engineer will have to find, remove, or correct to get the process back into control.

subgroups Sets of measurements collected at specific times or points in a process to monitor the process. Each subgroup is treated as a sample and will display a pattern of behavior that may be treated as part of a population. If the patterns of behavior are consistent then the process may be assumed to be in control.

system "A system is a network of interdependent components that work together to try to accomplish the aim of the system" (from Deming).

variation In a system, variation is based on the premise that no matter how hard we try to do something there will always be some variation in the process and the outcome. Variation is a result of common and special causes.

Dr. W. A. Shewhart (1891–1967) was the founder of the modern quality movement with his application of modern statistical method to mass-production in the 1920s. Shewhart invented the control chart in 1924 and introduced the concept of assignable and common causes of variation. His contribution has never had the recognition it deserves in the West, while his work was developed by others in the post-World War II reconstruction in Japan. Deming, Juran, Ishikawa, and many others in their wake, took Shewhart's ideas and applied them to the improvement of quality, that grew throughout the 20th century. Significantly, the notion of continual improvement can be traced back to his publications in 1931 and 1939. Deming's PDSA wheel was always referred to as the Shewhart Cycle in his writing and teaching. Deming, more than any other, continued to praise the contribution made by this remarkable man, as he developed his own ideas until his death in 1993.

Introduction

Dr. W. A. Shewhart was employed as an industrial researcher at the Hawthorne Plant of Bell Telephones in the United States in the 1920s and 30s. Shewhart was asked to find a more economic way of controlling quality. The cost of relying on inspection was becoming prohibitive for a company employing thousands of workers producing telephones and telephone systems that consumed 110,000 different piece parts. Shewhart's task was twofold. The first was to reduce the number of defectives, and the second was to find economic and reliable methods of sampling products that could only be tested by destruction, e.g., the blowing of fuse. "The attempt to solve these two problems gave rise to the introduction of the operation of statistical control involving the use of the quality control chart in 1924, and may therefore be seen as the starting point of the application of statistical technique in the control of quality of a manufactured product" (Shewhart).

By 1931, Shewhart had published his treatise in which he systematically developed the principles of his statistical method. Indeed, much of this book is about statistical method being applied to mass production. However, with more careful reading we find that Shewhart read widely and in great detail. The appendices of this volume contain a lengthy section outlining the different books and the contribution they all made to his work. These include statistics and probability, economics, physics, mathematics, logic, philosophy of science, and psychology, plus an array of other peripheral works.

Shortly after this book was published, it appears that Shewhart came across the work of pragmatist philosopher Professor C. I. Lewis, who had published his theory of knowledge, *Mind and The World Order* in 1929. Shewhart was reputed to have read this book 14 times, and was apparently indebted to its influence on the development of his ideas over the next few years. Lewis' influence becomes apparent in Shewhart's 1939 book and can be seen in Deming's publications in 1986 and 1993.

While many have applied statistical methods over the past 80 years, Wilcox suggests that to fully understand what Shewhart was trying to achieve, we must understand the influence of Lewis and others from the philosophy of science (e.g., Whitehead and Eddington quoted in Shewhart; it should be noted that Shewhart first produced a control chart in 1924 to put these points into historical perspective).

Shewhart's work is based on an ontology of flux and the control chart is an epistemological device (or operational definition) to show how processes are in flux, or showing variation. Elements of Lewis' work can be traced back to Heracleites, and the notion that the world is in motion. Lewis argued that "mind" interacts with and interprets the here and now as the world passes by in motion. Control charts are a device for illustrating this phenomenon. If this point is not understood, then the chances are the application and use of control charts will not be fully realized.

Furthermore, Shewhart's aims were to help managers and engineers predict the future behavior of the processes in their organizations. This point is also often lost in the interpretation and application of the statistical method.

This article will therefore show Shewhart's work as a methodology for interpreting an organization as a system. The system is made up of interdependent processes. Getting the processes into a state of statistical control will then achieve maximum economic benefits. If all the processes are in a state of statistical control, then "Mass production viewed in this way constitutes a continuing and self corrective method for making the most efficient use of raw and fabricated materials" (Shewhart) Shewhart's work is probably the original theory for continual improvement and this article will show how he arrived at this concept.

The Problem with Inspection

Shewhart's task as a research worker at Bell Telephone's Hawthorne Plant was to find a more economic way of controlling quality. A basic telephone in the 1920s consisted of over 200 parts. A telephone system had over 110,000 parts. The annual production involved billions of parts, which were resourced from around the globe. Clearly, the cost of inspection, at source and during production, was becoming prohibitive. Furthermore, the marketing people had designed a slogan "as alike as two telephones," which was a potential embarrassment as the reliability of the equipment was not very good. Indeed, Shewhart also observed that the harder the managers tried to improve the quality, the worse things got. So, in short, inspection was costly and not providing reliable products.

Shewhart's solution was to try to gain control over the whole process of production. If control can be attained, then the future quality of the products is predictable. Shewhart used some interesting data from The Food Research Institute of Stanford University. The researchers had studied the returns of bread to bakeries as a loss to the system. Ten bakeries were studied over 36 weeks. Some had far more returns than others. From this, the deduction was made that the bakery with the least number of returns (1.99%) also showed better control over the 36 weeks. This was demonstrated by showing the data—not in tabular form, but on a control chart. The returns of the 10 bakeries were compared. The bakery with 1.99% returns also appeared to have the most stable system. Therefore, Shewhart argued: greater control, equals fewer defects.

Inspection, does not increase the degree of control over the system of production. This is only achieved by bringing the processes and the system as a whole into a state of statistical control.

Defining Quality

The word quality has been around for thousands of years and can be found in Plato's republic, for example. It has been particularly problematic for writers on quality, because of the subjective nature of the concept. For instance, what may be a quality product or service for you, may not meet my needs, and therefore does not satisfy my requirements. Shewhart gave the definition of quality some thoughtful attention. His chapter on defining quality in his 1931 book is worthy of attention by scholars struggling with this point. Space does not allow a full exposition of all of the points, but his distinction between the objective and subjective sides of quality are worth noting. Objective quality exists "independent of man," and comprises the physical attributes that can be measured, such as shape, size, and weight.

The subjective side of quality is related to the notion of value. This is broken down into four features: (1) Use, (2) Cost, (3) Esteem, and (4) Exchange. Shewhart recognizes the economic importance of the subjective features, but realizes they are notoriously difficult to measure and control. However, he suggests that the engineer must be aware of the customer's needs and have the ability to translate them into the physical (objective) characteristics of the product. "In taking this step intuition and judgment play an important role as well as the broad knowledge of the human element involved in the wants of individuals" (Shewhart).

We see here probably one of the first pieces of management writing, which advocates satisfying customer needs, long before the theories on marketing and the later work in the 1990s on customer satisfaction. We can also see the link to Deming's mantra about the customer being the most important person on the production line. These connections show the importance of Shewhart's work and why it may be seen as an epoch in the history of management.

A Solution and An Epoch

Shewhart's aim was to gain control over the processes of production. He did this by developing his statistical method for mass production. The statistical method was originally developed in the natural sciences, not in engineering or mass production. Shewhart's thesis could be interpreted as a polemic against what he called the "exact sciences." Statistical theories were based on the so-called "laws of nature" that exhibit variation and probabilities: "It follows, therefore, since we are thus willing to accept as axiomatic that we cannot do what we want to do and cannot hope to understand why we cannot, that we must also accept as axiomatic that a controlled quality will not be a constant quality. Instead, a controlled quality must be a variable quality. This is the first characteristic" (Shewhart). So instead of trying to make products that are exactly alike, we must accept that there will always be some variability. The variability is the result of a constant cause system, the roots of which we can never know. Three postulates were developed to underpin his theory of control:

1. *All chance systems are not alike in the sense that they enable us to predict the future in terms of the past*. So, for example, the economic laws that control inflation are very different from the laws governing the tossing of a coin. We can predict that the tossing of coin in 50 years time will provide similar results, because the cause systems are simple to understand. Conversely, we cannot predict the rate of inflation in 50 years time because there are far too many variables in an economic system.
2. *Constant systems of chance causes do exist in nature*. This is probably the most contentious of Shewhart's claims, a point he rightly acknowledges. "To say that such systems exist in nature, however, is one thing; to say that such systems of causes exist in a production process is another" (Shewhart). Shewhart backs up this claim from his own research which he suggests shows chance cause systems at work. What this suggests is that we can measure mass-production systems following the rules of statistical theory, and the data will show variation similar to that found in the natural world.
3. *Assignable causes of variation may be found and eliminated*. Assignable causes of variation are a cause of defects in the system and a greater source of defects. Shewhart's theory claims to be able to identify assignable causes of variation, which are outside the system of chance cause variation. Once identified using Shewhart's method, assignable causes may be eliminated. Shewhart appreciated making the distinction between chance and assignable causes, and in effect drew a line between those he could economically remove and those that should be left to chance. This is how he arrived at the 3 sigma limits: "We assumed, therefore, upon the basis of the this test, that it was not feasible for research to go much further in eliminating causes of variability." Thus, he established the 3 sigma limits for process control, not by statistical theory alone, but ultimately by judgment.

By such a procedure, processes can be brought into a state of statistical control. When systems are in control, they are predictable—all things being equal. If they are predictable, then the need for inspection is reduced. The result is a reduction in the cost of inspection and rejection, and a more uniform quality of output.

These three postulates form the basis of Shewhart's ideas. A controlled or constant system of chance causes is the ultimate aim—with the qualification that one is producing what the customer wants!

Measuring

Shewhart had to devise a reliable method for measuring the objective features of quality as the starting point in the construction of a control chart. He took into account the precise and accurate methods of measurement from Goodwin and the theory of errors, to account for variation in the measuring process. However, if there is variation (in everything), then the process of measurement becomes problematic.

Measurement(s) provide the data points that will eventually appear on the control charts. We can see how Shewhart perceived the engineer, reacting to and upon, an ever-changing environment.

"The operation of control is in this sense a *dynamic process* involving a chain of actions, whereas the criterion of control is simply a tool used in this process. The successful quality engineer, like the successful research worker, is *not a pure reason machine* but instead is a *biological unit* reacting to and acting upon an ever changing environment" (Shewhart; emphasis added).

According to Lewis, all knowledge of objects comes from our conceptual interpretation of the given. There is no knowledge without interpretation—and the first step in interpreting data stems from the observer, who takes the measurement. No measurement—and therefore no knowledge of the quality levels—can take place without the presence and perception of the observer. The act of measurement is a process, and the values are sequences of numbers plotted on a control chart.

The control chart was a unique invention by Shewhart in 1924. The chart represents the variation in the observations over time, including the measurement variation. The individual measures, capture a moment in time, which when seen collectively, manifest variation. The central line is the mean or median. The two outer lines are the upper and lower control limits calculated from the individual measures to represent 3 sigma limits. The control chart becomes the voice of process (Burr quoted in Deming)—in effect it tells a story. Collectively, the control charts have the ability to become the voice of the organization.

Prediction

Shewhart was trying to construct a theory of control and prediction premised on the notion that everything is in flux: "A phenomenon will be said to be in control when, through the use of past experience we can predict at least within limits how a phenomenon may be expected to vary in the future. Here it is understood that the prediction within limits means that we can state, at least approximately, the probability that the observed phenomenon will fall within given limits."

The data points on a control chart represent the evidence and the first step in the process of prediction. Prediction depends upon the relationships among (1) the data provided as evidence, (2) the prediction made on the basis of this evidence, and (3) the degree of belief in the prediction which is related to data described in (1). Therefore, the validity of the prediction depends upon the integrity of the (data) evidence collected and the stability of the process.Similarly, Shewhart refers to:

> *Nonstatic character of knowledge . . . we are forced to consider knowledge as something that changes as new evidence is approved by more data, or as soon as new predictions are made from the same data by new theories. Knowledge in this sense is somewhat of a continuing process, or method, and differs fundamentally in this respect from what it would be if it were possible to attain certainty in the making of predictions.*

This indicates how Shewhart thought that everything was in flux, or movement, showing the connection of past, present, and future. He was clearly influenced by a quotation from Lewis (1934)" . . . knowing begins and ends in experience; but it does not end in the experience in which it begins" (Quoted in Shewhart).

Shewhart linked the past, present, and future together to illustrate the notion of flux or flow. Then he took the three concepts of specification, production, and inspection from the exact methods of mass production and turned them into a circular spiral, into what became the origins of continual improvement.

"*The three steps constitute a dynamic scientific process of acquiring knowledge*" (Shewhart; emphasis in original). To show how this works, Shewhart explains how scientists and statisticians join forces. Scientists decide on the specification (step 1), and join forces with the statisticians (step 2) to eliminate assignable causes of variation to a point where predictions can be made. Statisticians need the scientists to eliminate the causes, because of their knowledge of the process (physical laws). When the state of statistical control has been attained the statistician can continue without the scientist, (step 3) and "*set up rules that lead to the most efficient prediction*" (Shewhart).

Shewhart described how this would work in practice:

> *In fact an economic standard of quality is not a written finality, but is a dynamic process. It is not merely the imprisonment of the past in the form of specification (step I), but rather the unfolding of the future as revealed in the process of production (step II) and inspection*

(step III), and made available in the running quality report (Shewhart; emphasis in original).

Thus we see the roots of continual improvement, and the basis of what Deming developed into the Shewhart cycle or PDSA Deming Wheel. Shewhart's discourse encapsulates the notion of flux in the passage above, and made the distinction between scientific and emotive language. He was well aware of the problems of communicating his theories to a somewhat skeptical engineering audience who were steeped in the language of the "exact" sciences. It was a long time before his work received the attention it deserved, and even in the 1980s Deming was predicting it would be another 50 years before the full impact of Shewhart's work would be realized.

Small Area Estimation

Ferry Butar Butar
Sam Houston State University, Huntsville, Texas, USA

Glossary

composite estimator The weighted average of a direct and a synthetic estimator.
direct estimator The estimator obtained from values of the variable of interest only from units in the area or domain of interest.
empirical Bayes estimation A Bayes estimate of the unknown parameter of interest that is obtained by using a prior distribution. The unknown parameters of the prior distribution in the estimator are then estimated by some classical methods.
empirical best linear unbiased prediction (EBLUP) A mixed linear model is used to produce the best linear unbiased predictor (BLUP). The variance components involved in the BLUP are estimated by a standard method (i.e., ANOVA). When the variance components of a BLUP are replaced by their estimates then it is called an EBLUP.
hierarchical Bayes estimation This method models prior parameters in stages. The parameter of interest is estimated by its posterior mean, and its posterior variance is a measure of precision.
indirect estimator The estimator obtained from values of the variable of interest not only from units in the area or domain of interest but also from other areas or domains of interest.
small area Small area (domain) generally refers to a subgroup of a population from which samples are drawn. The subgroup may refer to a small geographical region (e.g., state, county, and municipality) or a particular group obtained by a cross-classification of various demographic factors such as age, gender, and race.
synthetic estimator The estimator from the larger area that is used to estimate the smaller area with the assumption that the characteristics of the larger area are similar to those of the smaller areas.

Small area statistics are needed in regional planning and fund allocations. The direct survey method is an unreliable estimate for a subnational region due to small samples available from the region. Demographers have long used a variety of indirect methods for estimating small area populations in postcensal years. In estimating small areas, it is often necessary to borrow strength by using values from related areas to increase the effective sample size. The model-based approach to small area estimation, empirical best linear unbiased prediction, empirical Bayes, and hierarchical Bayes methods are based on explicit small area models. The model-based approach is very effective and offers several advantages.

Introduction

The history of small area statistics can be traced back to the 11th century in England. Records of births, baptisms, marriages, deaths, etc. were used to produce various small area statistics. At that time, sources of small area statistics were limited to various administrative records available from local governments.

The sampling design and the sample size of most large-scale national surveys are usually determined so as to produce reliable estimates of various characteristics of interest at the national level. Often, there is a need to produce similar estimates at the subnational levels (e.g., states and counties). The direct survey method is an unreliable estimate for a subnational region due to small samples available from the region. A similar situation occurs when estimates are needed for domains obtained by classifying the population according to various demographic characteristics (e.g., age, race, and sex). For example, Fay and Herriot considered the estimation of per capita incomes of small places (population less than 1000). In order to obtain their estimates, they combined information from two sources. The direct information came from the Current Population Survey, and the

second source of data derived from tax returns for the year 1969 and housing information from the 1970 census. They provided the empirical Bayes [which is the same as best linear unbiased prediction (BLUP)] estimator of per capita income, which is a weighted average of the Current Population Survey estimator of the per capita income and a regression estimator that utilizes tax return data and the data on housing. Another example is the drug prevalence estimation given by Meza *et al*. Since drug use is a relatively rare event, many counties in Nebraska have few or zero cases; therefore, the estimate based on individual counties is unreliable due to the small sample size. Such problems in survey sampling literature are known as small area estimation problems. Small area (domain) generally refers to a subgroup of a population from which samples are drawn. The subgroup may refer to a small geographical region (e.g., state, county, and municipality) or a particular group obtained by a cross-classification of various demographic factors, such as age, gender, and race. Other terms used to describe small area estimation include local area, small domain, subdomain, small group, subprovincial, indirect, and model dependent.

Reliable small area statistics are needed in regional planning and in allocations of government resources. Due to budgetary constraints, it is not possible to collect adequate sample sizes from the small areas. When information on one or more relevant covariates is available from various administrative records, synthetic estimators (i.e., regression estimators) have been proposed in the small area literature. Although the synthetic estimators have small variances compared to the direct survey estimators, they tend to be biased because they do not use the information on the characteristic of interest directly obtainable from the sample surveys. A compromise between the direct survey and the synthetic estimation is the method of the composite estimation.

Morrison described small area estimation methods used prior to 1970. Purcell and Kish reviewed demographic methods as well as statistical methods of estimation for small domains. In 1980, the National Research Council gave detailed information as well as an evaluation of the Census Bureau's procedure for making postcensal estimates of the population and per capita income for local areas. Schaible provided estimates on small area used in U.S. federal programs.

Demographic Methods of Small Area Estimation

Demographers use a variety of methods for estimating small area population in postcensal years. These methods, called symptomatic accounting techniques (SATs), utilize current "symptomatic" (e.g., number of births and deaths) data from administrative registers as well as related data from the latest census. The SAT methods consist of the vital rates, Census Component Methods II, the administrative records method, the housing unit method, and regression symptomatic method. Except for the regression symptomatic method, these methods do not use sampling.

The components method uses birth, death, and migration to estimate population. The net migration is the sum of the immigration and net interarea migration minus emigration, or $m_{0t} = i_{0t} + n_{0t} - e_{0t}$, where i_{0t} is the immigration during the time period between 0 and t, n_{0t} is interarea migration, and e_{0t} is the emigration for the period between time 0 and t. Then the population for small area is estimated by

$$P_t = P_0 + b_{0t} - d_{0t} + m_{0t}, \tag{1}$$

where P_0 is the population of the small area in the census year 0, and b_{0t} is the number of births and d_{0t} is the number of deaths in the small area during period 0 and t. Unlike net migration, registration of births and deaths is usually complete in the United States and Canada. In practice, net migration is often difficult to estimate. In the United States, military migration is obtained from administrative records, whereas civilian migration is obtained from school enrollment records (Component Method II) and from income tax returns (administrative records).

Direct and Synthetic Estimation

Direct Estimation

Direct survey estimation is the most understood and widely used technique. These estimators are motivated from the randomization principle of survey sampling and typically use information only from the small area and the time period of interest. The direct estimators are unbiased estimators. A simple example of direct estimation is the sample mean, which is an unbiased estimator. The slope estimated from regression using only data from small area is also unbiased. The direct estimate is an unstable estimate for small area due to the small sample size from the region; therefore, the variance is very large. Certain considerations at the design stage (e.g., less clustering and more stratification, and sample allocation that provides more samples for the small areas) and estimation stage (e.g., calibration) can improve direct estimation.

Synthetic Estimation

Suppose the characteristics of the small areas are the same as those of a large area in which the small area is located. For the large area, an unbiased direct estimator is

obtained from a sample survey. When this unbiased direct estimate is used to derive an indirect estimator for the small area, then this estimate is called a synthetic estimate.

Suppose the auxiliary variables are not available. Let $\bar{Y}_i = N_i^{-1} \sum_{j=1}^{N_i} y_{ij}$, where $i = 1, \ldots, m$, small area means are the parameter of interest, and the sizes, N_i, of small areas are known ($i = 1, \ldots, m$). The usual survey estimate of $\bar{Y}_i$ is $\bar{y}_{is} = n_i^{-1} \sum_{j=1}^{n_i} y_{ij}$, $i = 1, \ldots, m$. The variance of $\bar{y}_{is}$ for given n_i is of order n_i^{-1}; hence, the estimator, $\bar{y}_{is}$, is likely to yield large standard errors unless n_i is large. A simple synthetic estimator of $\bar{Y}_i$ is the weighted mean direct estimates,

$$\bar{y}_s = \frac{\sum_{i=1}^{m} n_i \bar{y}_{is}}{n}, \tag{2}$$

where $n = \sum_{i=1}^{m} n_i$. The mean square error of $\bar{y}_s$ is of order n^{-1}. If the mean of small area is approximately equal to the overall mean (i.e., $\bar{Y}_i = \bar{Y}$), then the mean square error (MSE) will be small and the estimator will be very efficient. If this assumption is violated, then the synthetic error has a greater concern for small areas rather than large. The estimation could be an underestimation in some areas and an overestimation in others. As a result, there is not a qualified improvement in smallest areas. The synthetic estimation is a bias estimator due to applying the same correction to areas with different coverage.

Now suppose the auxiliary information X, with known population mean $\bar{X}_i$ is available. The synthetic ratio estimator of $\bar{Y}_i$ is

$$\bar{y}_{is}^{r} = \frac{\bar{y}_s}{\bar{x}_s} \bar{X}_i. \tag{3}$$

In the usual direct estimate, one uses the ratio $\bar{y}_{is}/\bar{x}_{is}$ instead of $\bar{y}_s/\bar{x}_s$. Again, the assumption that $\bar{y}_s/\bar{x}_s = \bar{y}_{is}/\bar{x}_{is}$ is very strong and will usually not be true in practice. The rationale for the synthetic estimator is that the distribution of a characteristic of interest is highly related to the demographic composition of population. If the assumption is not valid, the synthetic estimators for some of the small areas can be highly design biased.

The variance of a synthetic estimator will be small compared to the variance of a direct estimator because it depends only on the precision of the direct estimator in a large area. To find the $\operatorname{mse}(\bar{Y}_{is})$, first find the $\operatorname{mse}(\hat{Y}_{is})$, since $\bar{Y}_{is} = \hat{Y}_{is}/N_i$, then $\operatorname{mse}(\bar{Y}_{is}) = \operatorname{mse}(\hat{Y}_{is})/N_i^2$. An approximate design unbiased estimator of MSE of $\hat{y}_{is}$ will be obtained using the unbiased direct estimator of $\hat{Y}_i$. The mean square error is

$$\operatorname{MSE}(\hat{Y}_{is}) = E(\hat{Y}_{is} - \hat{Y}_i)^2 - E(\hat{Y}_i - Y_i)^2 + 2\operatorname{Cov}(\hat{Y}_{is}, \hat{Y}_i). \tag{4}$$

If $\operatorname{Cov}(\hat{Y}_{is}, \hat{Y}_i)$ is approximately zero, where $\hat{Y}_i$ is a direct unbiased estimator of Y_i, then an approximate unbiased estimator of MSE of $\hat{Y}_{is}$ is given by

$$\operatorname{mse}(\hat{Y}_{is}) = (\hat{Y}_{is} - \hat{Y}_i)^2 - v(\hat{Y}_i), \tag{5}$$

where $v(\hat{Y}_i)$ is a design unbiased estimator of the variance of $\hat{Y}_i$. In practice, the assumption of $\operatorname{Cov}(\hat{Y}_{is}, \hat{Y}_i) \approx 0$ is realistic because $\hat{Y}_{is}$ is less variable than $\hat{Y}_i$.

The synthetic estimate also can be found by regression. Suppose X_i is a vector of covariates which are related to $\bar{Y}_i (i = 1, \ldots, m)$. Then $X_i' \hat{\beta}$, where $\hat{\beta}$ is an estimator of the vector of regression coefficients obtained by fitting $\bar{Y}_i'$s on the X_i's is called a synthetic estimator of $\tilde{\bar{Y}}_i (i = 1, \ldots, m)$. In case $X_i = 1$ (i.e., when there is no relevant covariate available), the synthetic estimator of $\tilde{\bar{Y}}_i$ reduces to $\bar{Y}$, the overall mean.

Composite Estimation

Composite estimates are indirect estimates that borrow strengths from other areas of interest. Although the synthetic estimators have small variances compared to the direct survey estimators, they tend to be biased because they do not use the information on the characteristic of interest directly obtainable from the sample surveys. A compromise between the instability of a direct estimator, $\hat{Y}_{i1} = \hat{Y}_i$, and the potential bias of a synthetic estimation, $\hat{Y}_{i2} = \hat{Y}_{is}$, is the method of the composite estimation. Broadly defined, a composite estimator is the weighted average of a direct survey estimator and a synthetic estimator. The synthetic and the composite estimators are usually obtained by implicit or explicit models that borrow strengths from related sources. The general form of a composite estimator of θ_i is

$$\hat{Y}_{iC} = W_i \hat{Y}_{i1} + (1 - W_i) \hat{Y}_{i2}, \tag{6}$$

where $0 \le W_i \le 1$ is determined from the data by some optimal method. Composite estimators generally perform better than both the survey estimators and the synthetic estimators in the average MSE sense. The weight W_i is determined by minimizing the classical MSE of $\hat{Y}_{iC}$ with respect to W_i. The design MSE of the composite estimator is

$$\begin{aligned} \operatorname{MSE}(\hat{Y}_{iC}) = {} & W_i^2 \operatorname{MSE}(\hat{Y}_i) + (1 - W_i)^2 \operatorname{MSE}(\hat{Y}_{is}) \\ & + 2Wi(1 - W_i) E(\hat{Y}_i - Y_i)(\hat{Y}_{is} - Y_i). \end{aligned} \tag{7}$$

By minimizing Eq. (7) with respect to W_i, the optimal weight W_i is

$$W_i(\text{opt}) \approx \frac{\operatorname{MSE}(\hat{Y}_{is})}{\operatorname{MSE}(\hat{Y}_i) + \operatorname{MSE}(\hat{Y}_{is})}, \tag{8}$$

assuming that the covariance term $\operatorname{Cov}(\hat{Y}_i, \hat{Y}_{is}) \approx 0$. These weights can be very unstable. Purcell and Kish

use common weight W and then minimize the average MSE with respect to W, and the weight is given by

$$W(\text{opt}) = 1 - \frac{\sum_{i=1}^{m} v(\hat{Y}_i)}{\sum_{i=1}^{m} (\hat{Y}_{is} - \hat{Y}_i)^2}. \quad (9)$$

If the variances of the $\hat{Y}_i$ are equal, then Eq. (9) becomes

$$W(\text{opt}) = 1 - \frac{m\bar{v}}{\sum_{i=1}^{m} (\hat{Y}_{is} - \hat{Y}_i)^2}, \quad (10)$$

where $\bar{v} = m^{-1} \sum_{i=1}^{m} v(\hat{Y}_i)$.

Empirical Best Prediction

Small area models can be classified into two types. The focus here is on model-based indirect estimators that combine data from administrative and census data with the sample survey data. The first type, area specific auxiliary information, x_i, is available for areas $i = 1, \ldots, m$. The population area mean is assumed to be related to x_i through a linear model

$$\theta_i = x_i' \beta + v_i, \quad i = 1, \ldots, m, \quad (11)$$

where β is a vector of the regression parameters, and v_i's are the random small area effects to be independent identically distributed (i.i.d) normal with a mean of 0 and variance of τ^2. Assume that the direct survey estimator Y_i of θ_i is known as

$$Y_i = \theta_i + e_i, \quad i = 1, \ldots, m, \quad (12)$$

where e_i's are the sampling errors with i.i.d normal with mean of 0 and known variance σ_i^2. Thus, combining Eqs. (11) and (12), the basic area level model is

$$Y_i = x_i' \beta + v_i + e_i, \quad i = 1, \ldots, m, \quad (13)$$

which is a special case of the generalized mixed linear model. This model involves design-based random variables, e_i, and model-based random variables, v_i. Assume that v_i and e_i are uncorrelated. In practice, the sampling variance of σ_i^2 may not be known, but it can be smoothed by some methods to stabilize the estimator $\hat{\sigma}_i^2$.

The second type of model, unit value y values, y_{ij}, are assumed to be related to auxiliary information $x_{ij} = (x_{ij1}, \ldots, x_{ijp})'$. A nested error linear regression model is

$$y_{ij} = x_{ij}' \beta + v_i + e_{ij}, \quad i = 1, \ldots, m; \; j = 1, \ldots, N_i, \quad (14)$$

where v_i's are i.i.d. normal random variables with mean 0 and variance of τ^2 and are independent of element errors $e_{ij} \overset{iid}{\sim} N(0, \sigma_i^2)$, and N_i is the number of population elements in the ith area.

For example, consider the Fay and Herriot model [i.e., Model (13)]. Model (13) is a special case of a generalized linear mixed model. We are interested in finding the best prediction (BP) [which is the same as empirical Bayes (EB) or BLUP in this case] estimator that minimizes the MSE in the class of linear unbiased estimator of $\hat{\theta}_i$. The BP estimator is a linear combination of fixed and random effects and is given as

$$\begin{aligned} \tilde{\theta}_i(\tau^2) &= x_i' \tilde{\beta}(\tau^2) + (1 - B_i)(y_i - x_i' \tilde{\beta}(\tau^2)) \\ &= (1 - B_i) y_i + B_i x_i' \tilde{\beta}(\tau^2), \end{aligned} \quad (15)$$

where $B_i = \sigma_i^2 / (\sigma_i^2 + \tau^2) (i = 1, \ldots, m)$ $(i = 1, \ldots, m)$ and $\tilde{\beta}(\tau^2)$ is the weighted least squares estimator of β with weight $(\sigma_i^2 + \tau^2)^{-1}$. The BP estimator in Eq. (15) is the weighted average of the direct estimator y_i and the regression synthetic estimator $x_i' \beta$. If the survey is reliable (i.e., σ_i^2 is small), then B_i is close to zero and the direct survey estimate is the BP estimate. If σ_i^2 is large relative to τ^2, then B_i is close to 1, and the BP estimate is close to synthetic estimator $x_i' \beta$. When both τ^2 and β are unknown, they can be estimated by the classical methods, such as the standard analysis of variance estimator, maximum likelihood estimator, and restricted maximum likelihood estimator. Inserting $\tilde{\beta}(\tau^2)$ for β and $(\hat{\tau}^2)$ for τ^2 in $\tilde{\theta}_i(\tau^2)$, the following empirical best prediction (EBP) (which is EBLUP in this case) estimator of θ_i is given by

$$\hat{\theta}_i(y_i; \hat{\beta}(\hat{\tau}^2, \hat{\tau}^2)) = (1 - \hat{B}_i) y_i + \hat{B}_i x_i' \hat{\beta}(\hat{\tau}^2). \quad (16)$$

In estimating the variance component τ^2 by MLE, there is a possibility that the value of τ^2 could be negative, especially for a small or moderate m, the number of small area. If τ^2 is negative, one simply assigns a value of zero. In the Bayesian method, the value of τ^2 is always positive; the problem is how one chooses a prior distribution of τ^2.

A measure of variability of $\hat{\theta}_i$ is given by $\text{MSE}(\hat{\theta}_i) = E(\hat{\theta}_i - \theta_i)^2$, where the expectation is taken over the mixed model. The estimator of MSE can be obtained by estimating the MSE of BP. This naive estimator is an underestimate of the true measure of uncertainty since it does not take into account the variability of the variance components. Several attempts that have been made to estimate the MSE of EBP include the delta method, bootstrap, and jackknife resampling. Extensive research on the measure of uncertainty of EBP has been conducted by Butar, Chen, Datta, Lahiri, Ghosh, Fuller, Jiang, Pfeffermann, Prasad, Rao, and other researchers during the past two decades.

Extension of the basic area level model (Eq. 13) and unit level model (Eq. 14) includes multivariate models, models with correlated sampling errors, time series and cross-sectional models, spatial models, random error variance linear models, logistic linear mixed models, models for mortality and disease rates, exponential family models, semi- and nonparametric models.

Hierarchical Bayes Estimation

Hierarchical Bayes (HB) estimation is also used in small area estimation. The primary objective of this approach is to account for small area variation that is generally ignored by other small area approaches. The model is built in stages, hence the name hierarchical. Consider the Fay–Herriot model example discussed previously: (i) Conditional on θ_i, y_i's are independent with $y_i \mid \theta_i \overset{ind}{\sim} N(\theta_i, \sigma_i^2)$; and (ii) prior distribution of $\theta_i \overset{ind}{\sim} N(x_i'\beta, \tau^2)$, $i = 1, \ldots, m$, where y_i is the income per capita from survey estimator for the ith area, σ_i^2 is the sampling variance of y_i, $x_i = (x_{i1}, x_{i2}, \ldots, x_{ik})'$ is a known vector from tax return data for the year 1969 and the data on housing from the 1970 census, and θ_i is the true income per capita. Here, the goal is to find the posterior distribution or the posterior mean (which is the same as the Bayes estimator under squared error loss function). The hyperparameters of the Bayesian model are estimated from the marginal distribution of y_i, and the estimators are substituted into the Bayes estimator to yield the EB estimator. The EB estimator here is the same as the EBP or the EBLUP.

In HB estimation, prior distributions on the hyperparameters are specified, the parameters of interest are estimated by the posterior mean, and their variability is measured by the posterior variance. For example, consider the unit level model mentioned in Eq. (14) and rewrite it as the HB model: (i) $y_{ij} \mid \theta_i \overset{ind}{\sim} \text{Ber}(e^{\theta_i}/(1 + e^{\theta_i}))$, (ii) $\theta_i = x_i'\delta + e_i$, (iii) $e_i \overset{ind}{\sim} N(0, r^{-1})$, (iv) $\delta \sim$ Uni Uniform (R^p) independent of $r \sim \text{Gamma}(a/2, b/2)$, where a and b are known; $i = 1, \ldots, m; j = 1, \ldots, N_i$, y_{ij} is alcohol abuse for the individual j and county i, $\pi_i = e^{\theta_i}/(1 + e^{\theta_i})$ is the true proportion of alcohol abuse in county i, and $x_i' = (x_{i1}, \ldots, x_{ip}) \in R^p$ are the covariates from the 1995 survey, such as adult liquor law arrest rate, adult drug arrest rate fraction, and any drug or alcohol diagnosis rate.

The posterior means or proportions and the variances are not closed forms; therefore, numerical integrations may be used. An alternative to the numerical integrations is Gibbs sampling. Gibbs sampling is a Markov chain Monte Carlo (MCMC) sampling method that requires the knowledge of the full conditional distribution. The problem here is to choose the priors so that the posterior is proper and the samples can be generated. Arbitrary starting values will be assumed. The first few iterations of the simulated Markov chain will be discarded in order to reduce the effect of the starting values. The posterior mean generated vector and covariance matrix of θ_i can be approximated using a large number of θ_i values generated using the Monte Carlo method. Convergence of the method will be investigated. A computer program called Bayesian inference using Gibbs sampling (WinBUGS) is widely used to implement MCMC and to calculate posterior quantities from the MCMC output. WinBUGS runs are monitored using a menu-driven set of S-Plus functions, called Convergence Diagnostic and Output Analysis. The WinBUGS software package is freely available. The Gibbs sampling method is a popular method of Bayesian data analysis.

Design Consistency and Data Consistency

The concepts of design consistency and data consistency have received considerable importance in the small area estimation literature. Design consistency is a large sample property that ensures the convergence (with respect to the sampling design) of an estimator to the parameter of interest. This is certainly a desirable property since we frequently encounter a few areas with relatively large samples. Data consistency is another desirable property that provides direct estimates of larger areas simply by an appropriate aggregation of small area estimates.

Snowball Sampling

Richard Wright
University of Missouri, St. Louis, St. Louis, Missouri, USA

Michael Stein
Lindenwood University, St. Charles, Missouri, USA

Glossary

ethnographic An approach to social research that focuses on the definitions, values, and meanings that actors bring to the situation(s) being studied. Ethnographic research invariably seeks to explain behavior in terms of native nomenclature and categories and involves at least some direct fieldwork.
fieldwork The gathering of social data *in situ*, that is, in the setting in which it is naturally embedded.
representative sample A sample that proportionally reflects relevant characteristics of the total population from which it is drawn.

Snowball sampling is a chain referral method whereby a sample is constructed from a base of initial contacts, who are asked to provide introductions to their associates, who, in turn, are asked to refer others. This process continues until a sample has been built. Snowball sampling is designed for the explicit purpose of obtaining systematic information in situations in which convenience sampling is inappropriate and probability sampling is unrealistic.

Appropriate Uses of Snowball Sampling

Snowball sampling is useful primarily in the study of hidden populations such as intravenous drug users or active street criminals outside of clinical or institutional settings. These populations have strong incentives to conceal their identities and/or activities from outsiders. As a result, they are difficult to reach through conventional channels and instead require introductions provided by trusted insiders. As Glassner and Carpenter (1985) pointed out, the parameters of these "wild" populations typically are unknown and often unknowable, making random sampling impossible.

Although snowball samples may be criticized as unrepresentative, it is important to keep in mind that, in certain circumstances, they likely are far more representative than those drawn from a clinical or institutional setting. For example, no one would seriously claim that individuals attending a drug treatment program are representative of drug users or that prisoners are representative of criminals. In addition, people are animals and, like other animals, they do not behave naturally when they are institutionalized. Imagine going to a zoo to study the hunting strategies of lions. If the goal is to study real-world behavior rather than adaptation to institutional life, a snowball sample may yield better data.

Procedural Considerations

Getting Started

Perhaps the most challenging phase of the snowball sampling enterprise involves making initial contact with a member of the hidden population of interest to the researcher. By definition, such individuals keep a low profile and are unlikely to step forward of their own volition. Various ways of making this initial contact have been suggested. McCall (1978), for instance, recommended using a chain of referrals (essentially snowball sampling

within snowball sampling) to locate someone who can introduce the researcher to a member of the proposed study population.

> *If a researcher wants to make contact with, say, a bootlegger, he thinks of the person he knows who is closest in the social structure to bootlegging. Perhaps this person will be a police officer, a judge, a liquor store owner, a crime reporter, or a recently arrived Southern migrant. If he does not personally know a judge or a crime reporter, he surely knows someone (his own lawyer or a circulation clerk) who does and who would be willing to introduce him. By means of a very short chain of such referrals, the researcher can obtain an introduction to virtually any type of criminal.* (p. 31).

This strategy can be effective and efficient, but it has pitfalls. From a practical standpoint, relying on referrals provided by outsiders—especially members of agencies charged with punishing, treating, or otherwise controlling the population of interest to the researcher—may backfire, by raising suspicion that the study is part of an effort to identify deviants so they can be dealt with by authorities. Hidden populations are skittish and susceptible to such rumors at the best of times; they are likely to interpret the researcher's link to officialdom, no matter how benign, as a signal to stay away. Another pitfall associated with using a chain of referrals initiated through official channels is that the resulting sample may be highly unrepresentative. It is likely that such a sample will include a disproportionate number of individuals who are known to care and/or control authorities. By the same token, such a sample almost certainly will exclude the most secretive and sophisticated individuals who avoid associating with colleagues known to these authorities.

A commonly suggested alternative to using a chain of referrals to make initial contact with members of the proposed study population is to frequent locales favored by these individuals, and thereby establish rapport with them. This is a standard ethnographic technique that has the advantage of mimicking the normal interactional processes through which most relationships of trust are established. But this strategy, too, has several potential drawbacks. First, members of the group the researcher wishes to study may not congregate in particular locales. Second, even if group members do favor certain locales, the researcher may not know about them, especially beforehand when such information could be most helpful. Third, this strategy requires an extraordinary investment of time because the researcher must devote many hours to establishing a reputation for trustworthiness before attempting to initiate the snowball sampling process.

Another popular way to establish initial contact with members of the proposed study population is to enlist the services of a field-based recruiter, an insider who already has the trust and respect of that population. For example, a number of criminologists have used offenders who have retired from crime or who remain only peripherally involved in lawbreaking to gain introductions to active criminals such as residential burglars, drug dealers, and armed robbers. One advantage in using a trusted and respected insider to initiate the snowball sampling procedure is that the individual's reputation for integrity increases the likelihood that the people contacted will cooperate in the research. Another advantage is that an insider, almost by definition, knows things about the proposed study population that remain hidden from outsiders, and thus can help with everything from verifying the eligibility of potential participants to brokering the disputes and breakdowns in communication that often arise during encounters between researchers and the researched.

Despite these advantages, using an insider to make initial contacts can present difficulties of its own because the better that individual is connected to the proposed study population, the more likely it is that he or she will fail to appreciate the esoteric aims and methods of the researchers. This is perhaps best illustrated by the experiences of Wright and Decker (1994), who employed a well-connected ex-offender as a field recruiter to introduce them to active residential burglars.

> *Not all of the difficulties we experienced . . . were created by the offenders; the project fieldworker—who, after all, bridged legitimate society and the criminal underworld—sometimes failed to follow stipulated procedures and had to be reminded of the importance of adhering to legal and ethical standards. On one occasion, for instance, we were riding in the back seat of the fieldworker's car when we heard him mention to the offender sitting in front that he did not have any auto insurance. We immediately terminated our research for the day, gave the fieldworker some money, and told him to get insurance. He assured us that he would do so right away, adding, "but first I have to get a driver's license"* (pp. 29–30).

The strategies outlined in this section do not exhaust the list of those used by researchers to make initial contacts for a snowball referral chain, but they are by far the most common approaches to doing so. Depending on the population wanted to reach, other possibilities include advertising in local newspapers or answering ads in personal columns. Both have been used with some success by researchers in the past, though the latter strategy has been challenged on ethical grounds because people who place ads in the personals are not seeking individuals to study their behavior. None of these techniques is foolproof, and it often is advisable to try to initiate snowball referral chains through several sources at once, both as a way of enhancing the chances of success and as a way of reducing the risk of tapping into just one network of like-minded members who are atypical of the population as a whole.

Maintaining Momentum

Once the researcher has located an initial contact, the next challenge is to maintain momentum by persuading this and subsequent contacts to provide introductions to similarly situated others. This can be difficult because, by their nature, hidden and/or deviant populations are permeated with mistrust. Virtually any researcher who has used snowball sampling can testify to the fact that initially promising contacts sometimes end up being unproductive and have to be dropped. Even productive contact chains are vulnerable to disruption and have a tendency to break down over time. There is no foolproof way to prevent such things from happening, but researchers can take simple steps to promote the snowball referral process.

Perhaps the best way to encourage contacts to provide introductions to others in their social circle is to offer them a "finder's fee" for each successful referral. Such payments, however small, are absolutely critical to securing the cooperation of individuals enmeshed in certain sorts of deviant or criminal subcultures. For example, it is a cardinal rule among street criminals that you must never do anything for nothing. Moreover, compensating individuals for the time and effort it takes to arrange introductions on the researcher's behalf provides tangible recognition that they are performing a valued and valuable service.

On its own, the offer of a finder's fee may not be sufficient to convince contacts to provide introductions to their associates, especially if the amount of money involved is modest. But not all rewards are monetary in nature, and there are other things that researchers can do to facilitate the snowball referral process. For starters, they can inform contacts that the research likely will be published and that their efforts are critical to its success. It would be difficult to overstate the potential effectiveness of this simple strategy, which encourages contacts to refer others by making them feel that they are participating in something important enough to be published. Beyond this, researchers can help to maintain the momentum of the snowball referral process by doing all they can to fit in with their contacts. This does not mean trying to be one of them, but rather learning enough of the study population's argot and/or other distinctive mannerisms so as to be able to interact comfortably with them.

Another big part of fitting in with contacts requires researchers to adhere strictly to their promises of confidentiality, which is easier said than done in the case of snowball sampling. The chain referral nature of snowball sampling means that some contacts inevitably know one another, often quite well. It is not uncommon for a contact to ask what the person who referred them (or, alternatively, the person they referred) said to the researchers about an incident they both witnessed and/or participated in. In most cases, such inquiries probably reflect nothing more than the contact's curiosity, though even then it is likely that word of any betrayal of confidence, however inadvertent, will quickly work its way up and down the referral chain, alienating previous contacts and deterring potential future recruits from participation.

Deciding When to Stop

Because snowball sampling is typically employed to reach populations whose parameters are unknown and often unknowable, it can be difficult to determine the optimal point at which to terminate the recruitment process. When can researchers be confident that additional referrals will not yield important new insights into the hidden world they are studying? The standard answer to this question is that researchers should continue to recruit participants until "sample saturation" is reached, which means that no new information is being provided by additional referrals. Although this is a good rule of thumb for researchers to follow, it is a far from perfect strategy that almost invariably leaves a nagging sense that, had the recruitment process been extended further, new information might well have surfaced somewhere down the line. Indeed, Heckathorn (2002) suggested that researchers should aim for more than sample saturation, demonstrating that, under certain strict conditions, it may be possible to obtain valid population estimates using snowball sampling. While this may be true, once the data provided by new recruits become highly repetitive, the value of any additional information likely will be overridden by the financial and other costs associated with generating it.

Be that as it may, researchers often have little say in the decision about when to terminate the recruitment process. It is in the nature of snowball sampling that, for a variety of reasons, referral chains frequently stall of their own accord. Sometimes researchers are able to overcome this problem by initiating a new referral chain, but success in doing so is far from guaranteed, especially when the breakdown results from a heightened perception on the part of members of the study population that the risks of participation have begun to outweigh any potential benefits. For example, a number of researchers have had their referral chains stall when the chance arrest of a study participant, or some other untoward event, became linked in the minds of would-be recruits with their project.

Snowball Sampling in Action

A study of armed robbers in St. Louis, Missouri by Wright and Decker (1997) provides a textbook example of the promises and pitfalls of snowball sampling in action. Concerned that the prison environment might distort the responses of incarcerated armed robbers, Wright

and Decker decided to try to locate and interview individuals actively involved in committing such offenses. To do this, they employed a snowball sampling technique similar to one they had used to recruit 105 active residential burglars for an earlier study of housebreaking. In their burglary study, Wright and Decker had initiated snowball referral chains by using a field-based recruiter who was well known and respected by several groups of street criminals operating in and around St. Louis. This fieldworker, an ex-offender who had retired from crime after being shot and paralyzed in a gangland-style execution attempt, had previously supported himself for many years as a highly skilled thief. He had been arrested just a few times and was never convicted. As a thief, he had acquired a solid reputation among his fellow criminals for toughness and integrity.

Wright and Decker turned to this individual once again for help in making contact with active armed robbers. He began by approaching some of his former criminal associates. All were still active offenders, and he found three who currently were doing armed robberies. He explained the research to them, stressing that it was confidential and that the police were not involved. He also informed them that those who agreed to be interviewed would be paid $50. He then asked the contacts to put him in touch with offenders actively involved in committing armed robberies, saying that they would receive $10 for each successful referral.

In adopting this strategy, Wright and Decker hoped to set in motion a self-perpetuating chain of referrals that would smoothly lead from one active armed robber to the next by word of mouth. Figure 1 outlines the networks through which the offenders were located. It also illustrates the uneven pace at which these networks were expanded.

Perhaps the best way to clarify the recruitment process is to select one of Wright and Decker's respondents, say, no. 56, who is situated about halfway down the figure just to the right of center, and identify the chain of referrals that led them to this individual. In this case, the fieldworker contacted a female acquaintance who made her living exclusively through non-violent street crimes. She introduced him to three active armed robbers—nos. 15, 16, and 21—but, more importantly, she also put him in touch with one of her male friends, another petty criminal, who helped the fieldworker find more than two dozen active armed robbers. Among these armed robbers was no. 24; he referred three additional offenders, including no. 36. Armed robber no. 36, in turn, provided the fieldworker with two additional contacts, one of whom, no. 50, introduced him to five further armed robbers; the last of these robbers was no. 56. As can be seen, the majority of the armed robbers were not referred directly by the original fieldworker, but rather through the efforts of various actors in the street scene, such as heroin addicts, gang members, and petty criminals. Wright and Decker almost certainly would not have been able to locate many of these armed robbers on their own, much less gain their cooperation.

Buried within Fig. 1 are various indicators of the difficulties that Wright and Decker encountered in generating their sample. Note, for instance, that armed robber no. 04, the first person that the fieldworker contacted, referred three other robbers before agreeing to be interviewed himself. When initially approached about the project, he denied any personal involvement in robbery, but added that, as a junkie and small-time heroin dealer, he came across a lot of people who did commit such crimes. Only after being named as an accomplice by one of his referrals did he admit to having taken part in the occasional stick-up. He had not admitted his involvement earlier because he was worried about the possibility of being set up for an arrest.

Armed robber no. 04 went on to provide Wright and Decker with many additional referrals. In fact, he acted as a backup fieldworker for them when, early in their research, the original fieldworker decided to slack off and went for over a month without recruiting a single armed robber. Desperate to keep the snowball growing, Wright and Decker turned to armed robber no. 04, agreeing to pay him $50 for each armed robber he located for them. This worked well in expanding the sample in the short term, but it led to considerable resentment on the part of the original fieldworker, who quickly regained his enthusiasm for the recruitment process. From then on, the two fieldworkers had to be kept apart; interviews had to be staggered accordingly and this further complicated Wright and Decker's efforts to construct a suitable sample.

Given the tensions between the two fieldworkers, Wright and Decker had to be careful to avoid the appearance of playing favorites. Each fieldworker brought his own unique mix of street connections to their project, and they did not want to alienate either one for fear of closing off their only viable conduit to potentially important subgroups of active robbers. As a close reading of Fig. 1 demonstrates, the armed robber samples generated by the two fieldworkers had different demographic characteristics. Almost all of the individuals recruited by armed robber no. 04 were older, African American males, whereas the original fieldworker was able to locate a more diverse range of armed robbers, including a sizable number of juveniles, over a dozen females, and several whites.

In an instructive aside, Wright and Decker note that none of the individuals referred by armed robber no. 04 seemed willing to put them in touch with fellow armed robbers directly. Instead, they insisted on using armed robber no. 04 as an intermediary. This suggests that he used his influence to maintain a firm grasp on the referral

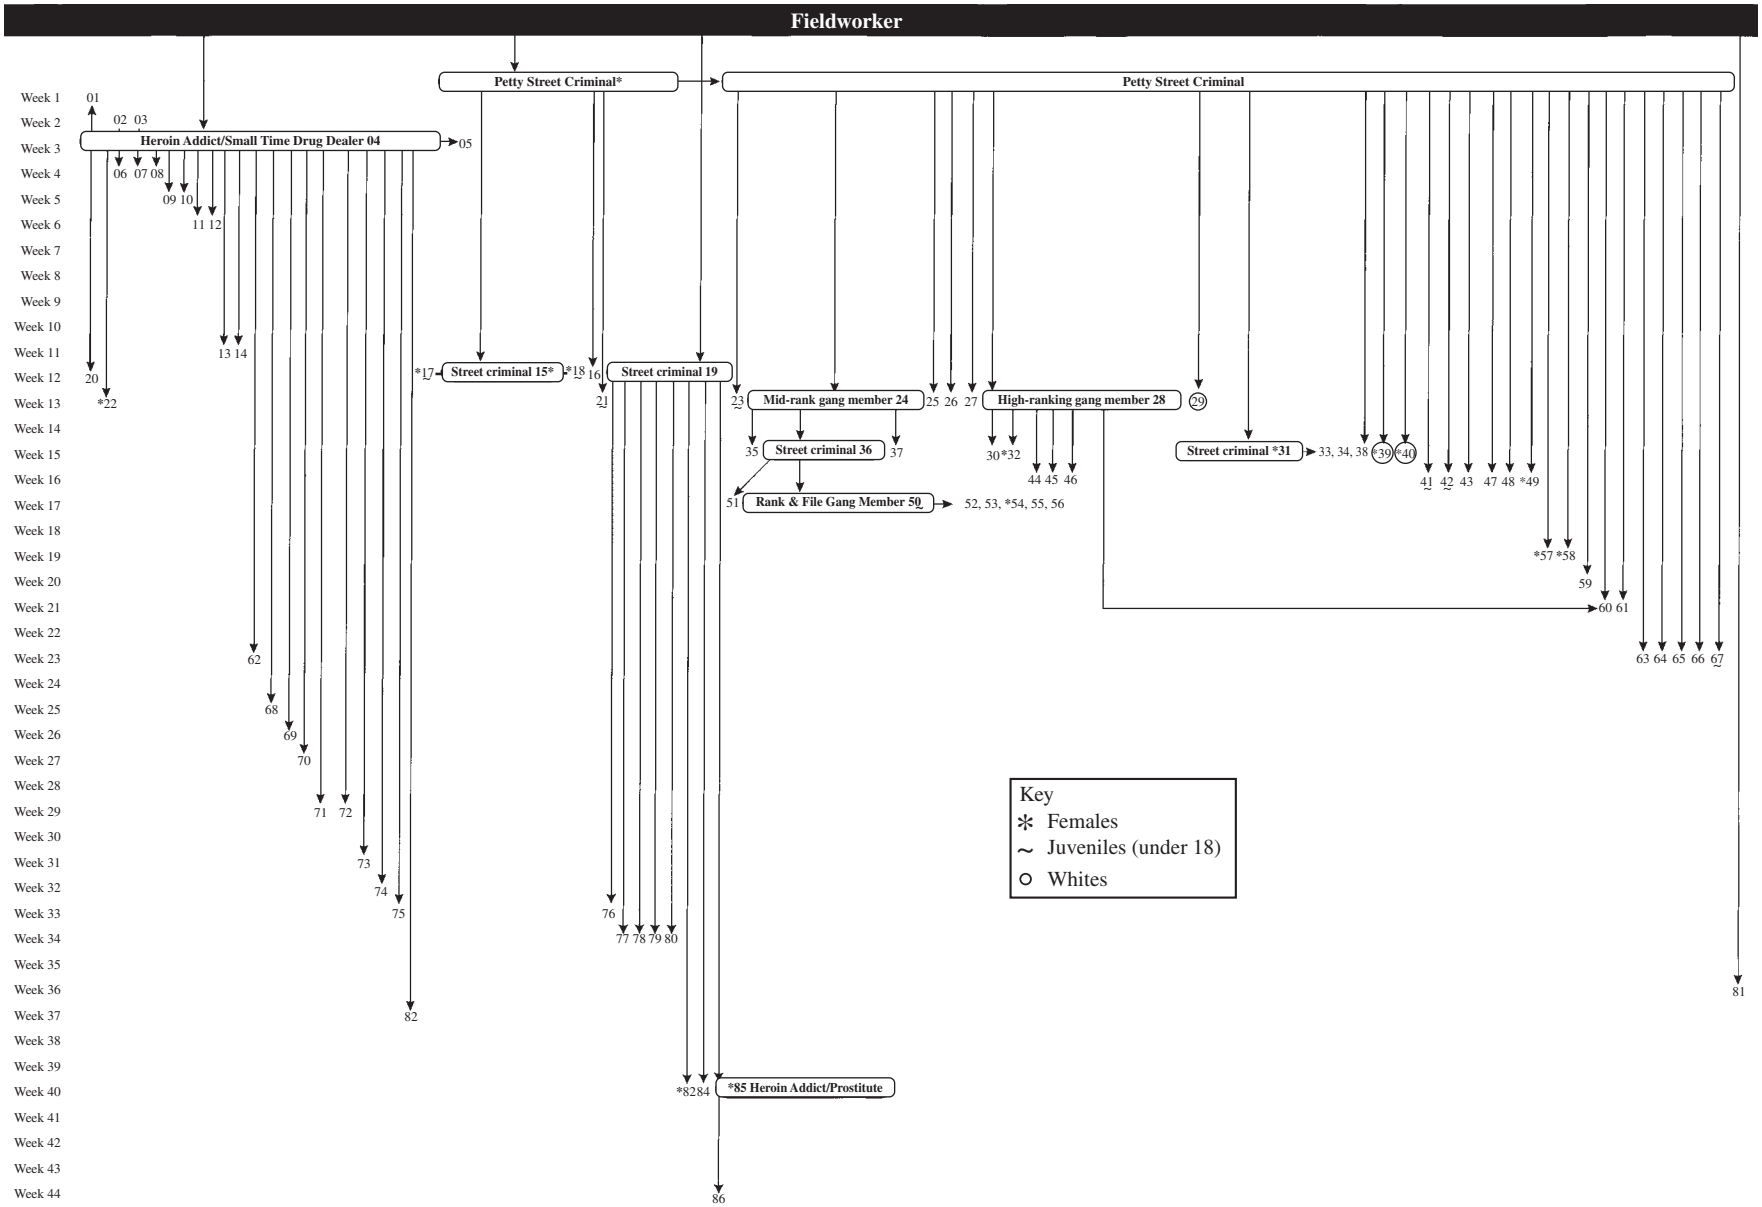

Figure 1 A snowball sample of active armed robbers in St. Louis, Missouri. (Reproduced with permission of the Northeastern University Press.)

process, presumably because he wanted the $50 finder's fee. Also instructive is the fact that, as Fig. 1 reveals, armed robber no. 04 had no success whatsoever in penetrating networks beyond the one in which he himself was a member. Wright and Decker speculated that this likely was because he inspired little trust outside his own circle of criminal acquaintances and had strong reasons to limit his recruiting efforts to his own neighborhood:

> *We know, for example, that armed robber No. 04 has a history of robbing illicit crap games and street corner crack dealers; in doing so, he has made deadly enemies and needs to "watch his back" wherever he goes, especially when traveling outside the boundaries of his own neighborhood.* (p. 22)

The most serious recruitment problem that Wright and Decker faced concerned armed robber no. 81, who is located on the extreme right-hand side of Fig. 1. He agreed to talk to them only after being repeatedly assured by the project fieldworker that they were not working for the police. During his interview, Wright and Decker discovered that he was a very well-connected armed robber and could serve as a valuable source of referrals. When they asked him if he might be willing to introduce them to his associates, he was initially reluctant but, after considerable reassurance that it was safe to do so, finally consented. As Fig. 1 indicates, however, this never happened; he was arrested and charged with armed robbery only hours after speaking to Wright and Decker. While the researchers had no hand in his arrest, the coincidence did not go unnoticed by other armed robbers in the area and, as a result, it became increasingly difficult for them to generate additional referrals. With the help of their fieldworkers, Wright and Decker did manage to induce a few more armed robbers to participate in their study, but the going got harder and harder and they terminated their research shortly thereafter.

The Enduring Relevance of Snowball Sampling

Snowball sampling is a powerful means of accessing hidden and/or deviant populations by using members of such populations as a source of recruitment for additional participants. Despite this fact, snowball sampling almost never proceeds in a straightforward manner for the simple reason that the sorts of populations it is used to access are often suspicious, unreliable, and unaccustomed to the arcane demands of systematic social research. In this sense, the term "snowball sampling" is a misnomer. Snowballs, after all, grow steadily bigger as they roll down an incline, whereas snowball samples grow in fits and starts, if they grow at all, and have to be restarted at irregular intervals owing to circumstances over which researchers often have little or no control.

The bottom line is that, for all its difficulties, snowball sampling frequently is the most effective strategy realistically available to researchers for contacting and studying hidden and/or deviant populations beyond the bounds of clinical or institutional control. For example, it has been used with substantial success in studies of populations at risk for AIDS (especially intravenous drug users and men who have sex with men), the homeless, and various sorts of active street criminals (including not only active armed robbers, but also active residential burglars, active drug dealers, and active car thieves). How else could such populations be accessed? As long as social scientists remain interested in the study of these and other hidden populations, snowball sampling will continue to be an important tool for gaining access to the real world of deviants and deviance.

Social Economics

Christine Rider
St. John's University, Queens, New York, USA

Glossary

institutionalism Accepting that institutions (organized patterns of behavior) influence individual economic activity.
normative economics Adding value judgments to economic analysis.
personalism Humans are a fusion of individuality and sociality, of body and spirit, of reason and emotion.
positive economics Economics as an objective, value-free, quantifiable social science.
rational economic man The autonomous economic agent who rationally calculates.
subsidiarity Any policy action should be taken by the private organization closest to the problem, and should be replaced by a government agency only when the private organization cannot function effectively even with government assistance.
utility Satisfaction realized from consuming a good or service.

Social economics is economics practiced as a social science involving human beings, who, in acting as economic agents, are often called on to address moral issues. Economics is the study of the material world, the study of the production, distribution, exchange, investment, and consumption of goods and services that are necessary for human survival (at the minimum) and which today make human life pleasant and comfortable for many. These activities take place in societies, human organizations that develop in order to organize and regulate human behavior. Social economics is the branch of economic analysis that explicitly recognizes the social dimension of economic activity. It recognizes that in economic affairs, humans act not only as individual beings as assumed in mainstream economics, but also as social beings, and, more importantly, recognizes that economics is a *moral* science. That is, it investigates the formation and impact of the values that influence what people and institutions in a society do; it adds an element of accountability to human behavior that is lacking in an "objective" approach, which is why many believe it is more relevant to modern reality. There are several strands of social economics, but all share a concern for understanding the philosophical roots of the discipline, a preference for identifying and solving social problems, and a holistic approach to analysis.

To summarize, social economists take account of the philosophical foundations of the discipline; attempt as accurate a description of an economy as possible; and use these insights to inform economic policy, in order to better provision human needs and wants.

Origins

Catholic Thought

Although it is possible to identify many earlier "social" economists who were outside and critical of the mainstream orthodox economics, social economics as a diverse and heterogenous strand of economic thinking began to coalesce in the period beginning 1941. At this time, the Catholic Economic Association, influenced by Thomas F. Divine and Bernard W. Dempsey, set out to replace the logical positivism of mainstream economics with a more specific, policy-oriented approach, which would necessarily involve incorporating ethical issues explicitly. Such a concern with normative values definitely contrasts with the distinction made by orthodox economics between normative and positive thinking, with the understanding that the former has no place in an objective science.

The emphasis on personalism is the main contribution to social economics made by Catholic social teaching,

according to Edward J. O'Boyle. What this means is that human beings are unique in the universe in that they alone are created in the image of God, and therefore cannot be reduced to the status of objects or commodities. While recognizing that humans obviously have physical/material needs, this view also recognizes the many other needs that make people human beings: for example, the need for work, for self-expression, for social relationships with others. Also, if basic economic needs are not met by the private sector, then, following the principle of subsidiarity, the state has a responsibility to help fill that need, legitimatizing the role of the state in the economy, a role that is often downplayed by mainstream economists.

Humanism

The humanist perspective, which can be traced back to Simonde de Sismondi, centers on the human person and human welfare. In economic affairs, the human person acts freely and independently, but, unlike the Rational Economic Man (REM) of standard economics, this perspective holds that the individual is not solely motivated by self-interest: interdependence encourages activity that enhances the common good. While the focus of REM might be appropriate if each economic agent had only one end to pursue at any one time, when there are plural goals, the standard approach fails. Choosing between different ends cannot be modeled mathematically—how to maximize utility given constraints—and instead requires other influences on choice making, especially when the choices are qualitatively different. It is the process of making these choices that involves individual freedom of judgment, not mechanical computation, and which is influenced by social relationships. This social setting calls for defining the economic agent more broadly than the autonomous, self-centered, utility-maximizing individual of conventional economics.

Ultimately, the end result is an economics that encompasses not only the needs of humans that are specifically individual and which, when met through individual action is called the good of the individual, but also the needs that derive from humans living together as one community, which when met through community action is called the good of the community, or simply the common good. These policy prescriptions designed to serve the common good clearly overlap with those derived from other influences on social economics: the right to material necessities, the right of economic democracy, and the right of future generations to economic sufficiency. Although the humanist strand derives from a nonreligious perspective, it essentially ends up in the same position as a religious one: that economic agents are neither objects nor instruments, but human beings with the ability to reason morally and act in accordance.

Institutionalism

Institutionalism is a uniquely American school of economic thinking in which seven key ideas can be identified. First, the economy should be studied as one unified system, in contrast to the orthodox focus on the many individual components that are then aggregated. Second, institutions—such as organized patterns of behavior, customs, beliefs, and laws—have an importance in influencing economic life. Third, society and the economy are seen in evolutionary terms as constantly changing into something new and unpredictable. Fourth, this in turn implies that the mainstream view that whenever shocked from an original equilibrium position, society and the economy always and predictably return in cyclic fashion to the same equilibrium state, is misplaced. Fifth, institutionalists believe that economic and social analysis is best understood in terms of conflict of interests between different groups in society, rather than as being ultimately harmonious. Sixth, a concern with social justice also colors this approach, with a more activist approach to social reform, the ameliorative aspect of social economics. Finally, institutionalists downplay the utility maximization goal of orthodox economic analysis, looking instead for a more nuanced and realistic approach to economic behavior. As can be seen, these concerns overlap with many of the other strands of economic thought making up social economics.

The founder of this school is considered to be Thorstein Veblen (1857–1929), who was writing at the time when American big business was flourishing, following post-Civil War industrialization. This experience seemed to leave many behind in the race to prosperity, and most likely influenced the emphasis on the "careful study of the economy as it really is," which is a hallmark of social economics. This emphasis was aided by the founding, in 1920, of the National Bureau of Economic Research (NBER) by several of Veblen's students, including Wesley Clair Mitchell. The NBER was established to collect and analyze economic data, especially for the study of business cycles, the periodic fluctuations in the level of economic activity.

Institutionalists, like other social economists, are critical of orthodox economic analysis, feeling that it is too protective of the status quo, even when reform is needed. While the Association for Evolutionary Economics is the main association for institutionalists, the overlap with social economics is clear. After 1970, when the Catholic Economics Association changed its name to the Association for Social Economics, many institutionalists joined forces, further blurring the distinction.

To summarize, all these different strands share a belief that economics should be practiced as a moral science where values do matter because they influence economic affairs through human behavior.

Similarities and Differences

Mainstream Economics

Most standard introductory economics textbooks will define economics as the study of the allocation of scarce resources among unlimited competing ends. The aim of economic activity is to maximize utility, the pleasure or satisfaction that comes from meeting material needs, given the constraint of limited resources. Certain key issues are as follows. First is the issue of resource *scarcity*; resources include both naturally occurring ones such as human labor power, agricultural and mineral resources, and those produced resources such as buildings, tools, and equipment. Second, it is assumed that there is potentially no limit to the uses to which these resources can be put, whether to meet basic human needs for food, clothing, and shelter, or to meet a variety of "wants"—for entertainment, enlightenment, luxury, dissipation, etc. In the more advanced industrial and postindustrial societies, these "nonbasic" wants have definitely multiplied, and entire industries, such as advertising and vacation travel, have developed to support and encourage the development of these new "needs."

Given scarcity and unlimited wants, economics can alternatively be described as the science of choice. For economists in the mainstream tradition, the task is to construct models that illustrate how resources are allocated to different uses, and, the parallel concern, to illustrate how income is distributed. (In a market capitalist economy, the main frame of reference, these two ends are two sides of the same coin: ownership of resources permits income to be earned which is then spent on the output that resource use gives rise to.)

Central to this tradition is the construct of the Rational Economic Man, the economic agent at the center of the model. Because economics aims to be as positivist a discipline as any of the natural sciences, but because of the impossibility of running laboratory experiments to test its hypotheses, REM is a convenient, objective simplification. REM has all the complete information necessary to make decisions, is not swayed by any noneconomic (say emotional, religious or altruistic) influences, and knows how to accomplish his goals. That goal is to maximize something, given the constraint of limitations. So if REM is a consumer, the task is to maximize the utility (pleasure or satisfaction) derived from the different choices of consumer goods and services that can be bought with a given income. If REM is a producer, the task is to maximize output produceable from the resources available. If REM is a profit-maximizing entrepreneur, the point is to maximize profit (net revenue) from the production process.

The ultimate goal for society is to expand the output of goods and services as much as possible. Also, the more efficient markets are, the better, because efficient market operations minimize waste and therefore make achieving this goal easier. With no market imperfections (defined as being anything which cannot be captured in the price, such as the cost of pollution, or as any noneconomic influence on prices, any of which would make this idealized state more difficult to achieve) the economy tends to a general equilibrium where goods and services are being produced in exactly the right amounts that will maximize society's utility. No policy intervention to redistribute income is necessary, because in this general equilibrium, no one person can be made better off without someone else being made worse off.

This position is called Pareto optimum, and describes an equilibrium, a point of rest, to which an economy will tend if it is composed of Rational Economic Agents operating in perfectly free markets which are not subject to any outside interference. The policy implication of the mainstream tradition is then clear. If prices in these markets do contain all the information necessary to achieve socially and individually desirable results, then it is important to keep them working this way. This legitimatizes state intervention only to remove imperfections; intervention is reactive, piecemeal, and justified only when needed. The survival of the (economically) fittest is the outcome of the operation of a competitive market system peopled by agents motivated by self-interest, and which will automatically produce a harmonious outcome.

Differences

In order to understand how and why social economics differs from orthodox mainstream (or neoclassical) economics, it is useful to start with the work of Adam Smith, the 18th century moral philosopher generally regarded as the founder of modern economics. Most strands of economic analysis can be traced back to Smith. Smith wrote two major books. In *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776), he tried to understand how a market economy held together. In this, his 18th century enlightenment views—in which an order based on natural law replaced a belief in the divine origin of things—are clear. As in the natural world which obeyed certain natural, and therefore rationally explicable, laws, so too could economic activity be understood once the laws which governed it were revealed. Central to this was his concept of the "invisible hand": the seemingly chaotic activities of markets where individuals pursued their own self-interest without any thought for others actually resulted in the common good *as though directed by an invisible hand*. That is, the free movement of prices and the price system effectively regulated activity. This strand is central to the subsequent development of orthodox economic thought.

His other book, *The Theory of Moral Sentiments,* was published in 1759, 17 years earlier than *The Wealth of Nations,* and is the work that shows how individual actions can produce social harmony rather than the anarchy that might be thought to result from the pursuit of self interest. Harmony results in societies because there are moral forces that restrain individual selfishness, such as, for example, sympathy, generosity, compassion, esteem, and mutual feelings for others. This strand of thinking can be seen as the origin of the social dimension of human economic behavior that is underscored in social economics.

Ethics

While much of social economics and the work of social economists themselves is critical of the mainstream, neoclassical tradition, there are certain identifiable themes that also make it a cohesive intellectual tradition in its own right. It is critical because of the observations that, in real life, market outcomes are not necessarily harmonious, do not result in an equitable income distribution, and leave many important human needs, both economic and noneconomic, unserved or underserved.

The first theme is the explicit recognition of the importance of the discipline's philosophical foundations: the ideas and values that influence the construction of the economic systems which coordinate economic behavior, and which also influence the approach of the economic analyst. How values are formed in a society and transmitted to society's members and groups is a valuable acknowledgement that no science in which human behavior is the subject can be value free. Social economics is concerned with "normative, moral—philosophical, and even theological perspectives" (from Nitsch) because it is concerned with the creation and perpetuation of a just economy and society. Orthodox economics sees as its ultimate goal the maximum expansion of material things, and while social economics recognizes the importance of efficiency and abundance, it also prefers that the resulting wealth be distributed equitably, and that minimal human needs are addressed adequately.

If the focus is simply on analyzing and promoting the operations of free markets in an objective way, this reduces people (labor), land (natural resources), and even money to commodities, or things, that can be produced for sale, or discarded if there is no demand for them. To social economists, this commoditization harms the creation of a just, humane society. Human beings are not things, hence the historical reality of the development of a protective safety net, in the form of the welfare state and government intervention, is not an imperfection, but rather a necessary element in the development of a just society. Similarly, social economists would not view money as neutral, as a commodity, but rather see it as a socially created mechanism that assists the integration and functioning of economic activity. The former view simply observes that a self-regulating market system automatically restores stability when beset by financial crises. The latter view sees these crises as harmful to human lives and the way production is organized, hence making it imperative that action be taken to remedy the problems. This difference highlights one way in which economics is seen and practiced as a moral science.

To be more specific, there are four ways in which values matter. First, they matter because social economists are value-directed: their values help inform the questions or issues to study, and the possible remedies to suggest. Second, because the values people hold influence how they act, it is important to see how these values are formed if we are to understand human action. Third, values make social economics problem-oriented, in that the search for the causes of problems becomes a holistic one, ready to move outside the strict boundaries of economics whenever the causes are noneconomic. Finally, values matter because social economics is ameliorative, especially when it comes to trying to make economic processes work better for those left behind.

Social

As noted, orthodox economic analysis centers on the construct of the Rational Economic Man, who springs, *ab ovo,* with a complete set of tastes, preferences, abilities, information, and so on. The actions of this atomistic individual are independent of the institutional context in which choices are made; little concern is given to where these attributes come from. In contrast, social economics focuses on the interdependency of human actions that take place in an institutional structure that both creates and is created by human actions, values, and history. Rather than focus on individual maximization of utility, a social economist will also be concerned with the social groupings that influence behavior, and on the achievement of the common good. Institutionalists in particular analyze this impact, but social economists deriving from the Catholic social thought tradition also analyze the impact on the wider community.

A good example of this is the periodic analysis of papal encyclicals, which provide guidance on the incorporation of ethical values into everyday life. This dovetails with social economics' concern to encourage the development of a just society, which is also economically effective by encouraging standards of conduct that do more than just serve one individual's interests. For example, the 1991 papal encyclical, *Centesimus Annus,* does not criticize private property and free markets, but does denounce consumerism as a moral vice. The policy implication here is that, especially in wealthy societies, "superfluous" income should be spent and capital formation attended to in ways that will help transform the world into a more equitable place. This policy orientation applies,

for example, to pension fund managers, who, following these prescriptions, would attempt to use these funds to further the development of human potential rather than simply seeking the highest quarterly return.

Historical

Mainstream economics is ahistorical; its purpose is to uncover those timeless laws that govern economic behavior at any time and in any place; it is essentially naturalistic, assuming that the natural world can be explained using mechanical concepts. This justifies a concentration on equilibrium analysis. Social economics embeds economies into their historical context and incorporates the reality of continuing institutional change and evolution. This limits the significance of equilibrium analysis, and of finding those tendencies that will produce a harmonious outcome. The reality of historical change is especially noticeable in those economists who favor an evolutionary approach to the discipline. It also makes it more appropriate for the study of nonmarket economies, for example, low income, developing economies or economies in transition from central planning.

Policy Oriented

Social economics emphasizes normative values, which is necessary for any policy application because value judgments have to be made to devise policy. That is, if policy is intended to change an undesirable reality and achieve a desirable end, the determination of "desirable" and "undesirable" is necessarily normative. Also, to state that social economics is especially concerned with social justice and welfare is also stating a normative value set. "Social justice is a set of normative values which define and specify ethically correct relationships among persons. Human welfare is a set of normative values which provide a standard for the measurement of the well being of a people" (from Hill).

One way in which this could be encouraged is by developing systems of social accountability in the private sector. This involves creating electoral systems of governance, and problem-resolving judicial systems in order to represent and further the common good. Social economists have suggested a variety of possibilities, some borrowed from actual practices in many countries. These include (but are not limited to) mutual stock ownership schemes, codetermination, workers' cooperatives, as well as community corporations (land trusts, financial intermediaries) which have a responsibility to the community. Behind all these different suggestions is the (old) idea of a self-governing, civil economy responsive to the public interest.

Historical Contributions

While there are many writers on economic topics who share many of the concerns of social economists, some can be more easily identified as "social economists." Although it may seem artificial to do so, this permits a distinction to be made between "social economists," Marxists, socialists, and other social critics and dissenters from accepted orthodox economic theory.

What follows is a suggestive listing; it by no means includes all those economic writers whose insights overlap with those of social economics, especially with reference to the present day.

Simonde de Sismondi (1773–1842)

Simonde de Sismondi was a Swiss economists who was among the first to criticize the then-economic orthodoxy, classical economics, for its reliance on the self-regulating nature of free markets, which were supposed to produce equilibrium tendencies. While in England during the early part of the 19th century, he was horrified by the appalling conditions in which a large part of the population of this wealthy country lived, which coexisted with enormous wealth of a privileged few. His argument was that because the maximization of output was unlikely to coincide with the greatest happiness of the population, state intervention to ensure a living wage for workers would be preferable. He favored greater state intervention to promote a more equitable distribution of income.

Twentieth Century Social Economists

Thorstein Veblen, the founder of institutionalism, never accepted the taxonomic, natural law-based approach to economic analysis that was common at the turn of the 20th century. Instead, he incorporated insights from other disciplines, including philosophy, history, and the natural sciences, to redefine economic activity as essentially evolutionary, and which is influenced by economic institutions, the customary and habitual methods by which societies come into contact with nature to meet their material needs.

Veblen's evolutionary approach saw contemporary American business culture as essentially wasteful, where work (and workmanship) were looked down on while wealth provided status. Affluence must be made obvious in conspicuous consumption, conspicuous leisure, and conspicuous waste (his expressions). His most popular book was *The Theory of the Leisure Class* (1899), in which he outlined his ideas of how the wealthy lived, a contrast with the neoclassical view of consumer sovereignty based on rational decision making.

Other early 20th century economists who contributed to the analysis of issues central to social economics include (alphabetically): Clarence E. Ayres, who emphasized institutional obstacles to technological change; John Maurice Clark; the historian and labor economist, John R. Commons; and Joseph A. Schumpeter.

Schumpeter's most famous contribution was his theory of creative destruction as an important explanation of both economic development and business cycles. This explains the uneven nature of economic change over time, caused by periodic clusters of innovations that require new materials, new equipment, and new methods of organizing production that make older technologies obsolete. Hence periodically, old equipment gets discarded and workers with outdated skills become unemployed, while the burst of new business investment associated with the introduction of new technologies leads to a business expansion and prosperity for those associated with the new industries and new skills. The introduction of these innovations, therefore, change not only material conditions of life, but also the distribution of political power and the institutional underpinnings of the economy.

Although not an institutionalist, Kenneth Boulding shared with them a dislike of conventional economics, and a willingness to use ideas from other social sciences to illuminate and explain economic reality as it unfolds through evolutionary change.

Similarly, John Kenneth Galbraith was, like Veblen, critical of the neoclassical conventional wisdom, and he adopted a more evolutionary approach to understanding modern capitalism. This, he wrote, was dominated by large enterprises rather than atomistic consumers, and continued prosperity for these enterprises depends on creating new wants. In this world, there is a social imbalance as the public sector is starved for funds while the output of commodities for private consumption expands, creating what he calls private affluence amid public squalor. Some key phrases of Galbraith's work include "countervailing power," which describes the way large enterprises deal with each other; the "affluent society"; and "technostructure," which refers to the new technologies that are vital to the survival of large firms and the technocrats who have more influence over operations than do owners and managers.

Some of Galbraith's policy implications are at odds with conventional thought. For example, in the United States, antitrust laws were developed to try to control if not limit the growth and behavior of large firms because of the perception that the resulting control of markets by these firms would result in high prices. Galbraith disagreed, saying that these firm's pricing policies are not in fact excessive; the real problems that are caused are those associated with an inequitable income distribution.

Contemporary Practitioners

There are many economists and related social scientists currently working in the social economics tradition. For example, working in the Catholic social thought tradition is Edward O'Boyle; representing a radical institutionalist perspective is William Dugger; and Mark Lutz is a proponent of the humanist tradition. Warren Samuels has applied the social economics viewpoint to a wide range of topics. Some other well-known social economists include David Ellerman, John Elliot, David George, Hans Jensen, Ronald Stanfield, and Charles Wilber. In addition, surveying past and recent issues of *The Review of Social Economy* gives a useful survey of both the topics covered by social economics, and of at least some of the current writers in this tradition, especially the younger ones whose names are not yet so widely known as these.

Publications

There are two main publications specifically associated with social economics, and many similar ones published by associations with overlapping memberships and interests. *The Review of Social Economy* is a quarterly publication of the Association for Social Economics. It "... investigates the relationships between social values and economics and the relation of economics to ethics, and focuses upon the social economy that encompasses the market economy. The journal is sponsored by the Association for Social Economics, by charter a pluralistic organization that accommodates different approaches to economics. Among the themes pursued are justice, need, poverty, cooperation, income distribution, solidarism, equality, freedom, dignity, community, pragmatism, gender, environment, economic institutions, humanism, economic methodology, and the work of past social economists" (from the *Review*'s Aims and Scope). The ASE also publishes the semi-annual *The Forum for Social Economics*.

The monthly *International Journal of Social Economics*'s mission statement reads as follows: "Increasing economic interaction, allied to the social and political changes evident in many parts of the world, has created a need for more sophisticated understanding of the social, political and cultural influences which govern our societies. The *International Journal of Social Economics* provides its readers with a unique forum for the exchange and sharing of information in this complex area. Philosophical discussions of research findings combine with commentary on international developments in social economics to make a genuinely valuable contribution to current understanding of the subject and the growth of new ideas. Coverage includes: economics and ethics; nuclear arms and warfare; economics of health care; the disintegration of the Soviet Union; religion and socioeconomic problems;

socioeconomic problems of developing countries; environmental sciences and social economics.

Institutions

The Association for Social Economics is the main association for those interested in social economics. It was established in December 1941 as the Catholic Economic Association, and when in 1970 it decided to broaden its focus, it renamed itself The Association for Social Economics. (The ASE was also a charter member of the Allied Social Sciences Association, the umbrella organization for various economics associations, which organizes annual meetings of these groups.) The ASE was formed "to advance scholarly research and writing about the great questions of economics, human dignity, ethics, and philosophy. Members seek to explore the ethical foundations and implications of economic analysis, along with the individual and social dimensions of economic problems, and to help shape economic policy that is consistent with the integral values of the person and a humane community" (from the ASE website).

During the 1980s, a new organization, the Society for the Advancement of Socio-Economics, came into existence, due to a large extent to the efforts of Amitai Etzioni. Both SASE and ASE share a concern that the market-efficiency oriented, individualistic, and mechanistic approach to economics of the mainstream tradition is inadequate, and both emphasize the importance of the social setting of economic behavior. However, socioeconomics sees itself as a better tool of analysis for a positivist explanation of reality. Key features include a broader sense of the individual, an "embedded market" (the economy seen as part of the surrounding society), and the central role of power relationships. Social economics adopts a normative, value-driven approach, while socioeconomics is intended to be more scientific and positive. Furthermore, the latter is intended to appeal to a broader group of social scientists, including psychologists.

Areas of Special Concern

Social Justice

An emphasis on social justice is an integral part of social economics, informing such areas of interest as income distribution, globalization, trade, poverty, and inequality in general. For example, while mainstream international economics theorizes that the opening up of world trade tends to lead to convergence—of prices, income levels and living standards—empirical evidence reveals a widening gap between rich and poor nations, and between rich and poor within any one society.

Many of those who combine social economics with Catholic social teaching emphasize studies in this area. If human material needs are not met, justice requires that action be taken, hence a concern with policy, which requires knowing where and how to intervene. Some economists in this tradition believe that strengthening the family and the community are important here, as both are where individuals spend most of their time, and are (or should be) the means by which unmet needs can be addressed. This particular focus avoids what could otherwise be a heavy-handed state intervention: heavy-handed because the state is too distant from the individual, and too often does not permit participation in the decision-making process, hence making the policy action less democratic.

An emphasis on social justice also provides an opportunity for the selective use of planning, because attempting to influence events or create institutions that will protect individuals makes democracy consistent with meeting human need. The mainstream approach is biased toward the operation of unfettered free markets, individualism, and free enterprise. However, given the realities of power relationships, and of concentrated, imperfect markets, one individual's decisions can have an adverse effect on others, which cannot be resolved by the operations of autonomous markets. But planning—giving an element of social control over society's resources—can do this, which implies the development of institutions to represent all the stakeholders in economic decisions, and which can add an element of accountability to actions.

Adherence to the economic orthodoxy encourages a policy prescription involving the extension of markets to activities that are not traditionally market based. Thus, for example, in Western Europe in the 1990s, and in the former centrally planned socialist economies in transition, the trend to privatization of state-owned enterprises is seen as the way to improve, for example, the provision of electricity, communications, and transportation services. In the United States, problems in health care especially, but also in education, have also been viewed as being candidates for transfer to market forces. While social economists obviously favor improvements in these and other areas that have an impact on human well being, they question whether treating education or health care like the production of automobiles or other commodities is justified. In all cases, the policy prescriptions compatible with this view look not just at maximizing output and income, but also at the impact on individuals' economic and noneconomic needs, on society as a whole, and on the implications for the future.

Such a consideration can also be adapted to the issues of international inequality, and question whether globalization and encouraging the development of markets

is always and everywhere the solution to problems of economic development.

Environment

Concern for ecological sustainability and the natural environment becomes of interest to social economists because it involves respect for the well being of current and future generations. If the goal of economic activity is merely to maximize something now, then future conditions—whether of scarcity or plenty—do not matter. (The implicit assumption is that, given conditions in which free competitive markets can operate, solutions will always appear through the invisible hand.) However, social economists would prefer that current needs should be met in a way that does not compromise the ability of future generations to meet *their* needs.

Standard economics approaches environmental issues in a market-oriented way. If there are externalities, in the form of pollution, resource degradation, species extinction, for example, then the rational solution is to internalize the problem, and increase prices so as to "pay" for the damage. If the future is considered at all, it is at a discounted rate, which generates the possibility that resources can become rationally extinct, and that future human lives are worth less than present lives. In contrast, social economics rejects the instrumental value of human beings and asserts that all persons living today and in the future are of inestimable worth. Once more, the aim is to transform society into a place where social justice does not come second to economic efficiency, and where human dignity, now and in the future, can be paramount.

Social Experiments, History of

Trudy Dehue
University of Groningen, Groningen, The Netherlands

Glossary

chance Lack of knowledge; whimsicality (until the late 19th century); characteristic of reality; something people can "take" (20th century).
determinism The view that the laws of human nature and society are pregiven.
liberal welfare state The version of the 20th century welfare state that emphasizes economic liberalism and is comparatively reluctant with regard to social services.
randomized controlled trial Ideal experiment in social science and medicine conducted with randomly composed experimental and control groups.
social experiment Event disturbing normal social order (19th century); social science research design (20th century).
statistical mean Measure of normalcy (19th century); also a measure of mediocrity (from the late 19th century).

Nineteenth century social researchers amply discussed the idea of social experiments. Moreover, the 19th century is known as the age of passionate measurement of social phenomena. Nevertheless, 19th century experts agreed that scientific experimentation with human beings is not feasible. It was not before the 1910s that the present-day definition emerged of a scientific experiment as comparative measurement of experimental and control groups. Also, it was not until the 1950s that the randomized controlled trial (RCT) became the ideal experiment in the social sciences (and medicine). This article compares the views of 19th century authors who denied the feasibility of active experimentation with those of 20th century social scientists to whom conducting RCTs became the ideal research strategy. Definitions of scientific social research, historians have demonstrated, form part of general belief patterns on society and politics. Understanding the 19th century pattern that excluded scientific social experiments helps to recognize the 20th century convictions legitimizing them.

Introduction: Social Experiments as Randomized Controlled Trials

The Basic Scheme

In science, the term experiment has always referred to widely varying research procedures. Historians of science have demonstrated that only loose definitions such as controlled observation cover all research designs that go for experiments. Further specifications of how precisely such general aims should be accomplished have led to a wide range of recommendations and practices.

However, in contemporary social science and psychology (as well as in medical research), a particular definition of the scientific experiment has won the day. In these disciplines, a truly scientific experiment entails comparing experimental groups that received a treatment with control groups that did not receive the treatment and, if a difference is found, calculating its statistical significance. Moreover, for the sake of statistical soundness and comparability, the groups must be composed on the basis of chance. To eliminate the possible influence of expectations concerning the outcomes, preferably both the participants and the conductors of an experiment are kept unaware of the group to which each participant has been assigned. Briefly, in these disciplines a truly scientific experiment is a randomized controlled trial (RCT; in medicine, a randomized clinical trial), and ideally it is a double-blind RCT.

Since the 1950s, social science handbooks and publication manuals have presented the RCT as the methodological standard for investigating causal relations. Many

social scientists self-evidently use the word experiment as shorthand for an RCT and consider research projects that diverge from its scheme as quasi-experiments at best. Although quasi-experiments are also conducted according to strict rules of design and statistics, social scientists regard their results as less valuable.

The Practice of RCTs

The scheme of the RCT only represents the basic design of an actual experiment. Each individual experiment has to add tailor-made supplements to the rough construction. For instance, often researchers compare several treatments and hence work with more than one experimental group. The architects of an experiment must also devise special rewards and incentives for attracting participants and assigning them randomly to the groups. Performing the RCT demands a high level of control over both the experimenters' and the participants' behavior. The designers of experiments must develop means of controlling the participants for a certain period of time and ensuring that neither the experimenters nor the participants diverge from the experimental script. The experimenters often need special training before an experiment begins. They have to learn how to work with sophisticated instruments for recording the participants' responses to the treatment. Cooperating statisticians have to manage the resulting data according to established prescriptions. Finally, research reports must be composed according to elaborate rules of publication. In addition to much methodological and professional expertise, social science experiments require large amounts of money. Nevertheless, RCTs are done on a large scale with numbers of participants that can exceed many thousands.

Social Experiments in the 19th Century

Early Definitions

The RCT is a fairly recent development. Before the 1910s, no expert on social research advanced the idea of comparing artificially composed experimental and control groups, and before the 1920s none of them proposed to compose groups on the basis of chance. However, the expression of experimentation appeared in much earlier texts on social research. The historian David Carrithers pointed out that in the 18th century eminent scholars discussed the question of experimentation as a suitable method for investigating humans and society. David Hume's "Treatise of Human Nature," first published in 1739, is subtitled "Being an Attempt to Introduce the Experimental Method of Reasoning into Moral Subjects." Hume and his Enlightment contemporaries, however, did not employ the terminology of experimentation in relation to deliberate actions by social researchers. They merely used it as a metaphor borrowed from natural science for indicating disturbing events occurring in human life. Hume, for instance, discussed "wars, intrigues, factions, and revolutions" as exemplary "social experiments." Observing such exceptional situations, 18th century authors argued, is the human science substitute of the artificial laboratory experiment in natural science labs.

Nineteenth century views on social experimentation were largely, but not completely, similar to those of the 18th century. Although the 19th century is known as the age of "the rise of statistical thinking," "the avalanche of printed numbers," and "the politics of large numbers," no social researcher at the time associated social experimentation with measurement, statistics, or particular research designs. Like their 18th century predecessors, 19th century experts used the terminology of experimentation in relation to human calamities, such as revolutions, or natural disasters, such as avalanches and floods. However, they added slight innovations to the traditional views, which in the course of time would become crucial elements of social experiments in the present-day sense.

The first novelty was that apart from the acts of God or Nature, the acts of governments also became main examples. Authors such as Auguste Comte in France, Adolphe Quetelet in Belgium, and John Stuart Mill and George Cornewall Lewis in Britain extensively discussed social legislation as social experimentation. In this respect, their definitions were akin to the present-day one. The second novelty was that these 19th century scholars explicitly preserved the label of scientific experimentation for artificial experiments with active manipulation by researchers. In this respect too, their convictions were the same as those of 20th century scholars. However, 19th century spokesmen drew the reverse conclusion, namely that if scientific experiments require active manipulation by researchers, then social experiments cannot be scientific. They categorically excluded experimentation from the useable methods of research with humans. There were two main reasons why experimentation could not be a proper research strategy.

Nineteenth Century Objections against Scientific Experimentation

The first reason was of an ontological and epistemological nature. Nineteenth century scholars regarded people and societies as organic systems in which each part is closely related to all others, and in which every event or characteristic of human life is the result of numerous interrelated causes. Because scientific experimenters have to vary one precisely delineated cause, the experimental method is not appropriate. It was mainly for this

reason that Auguste Comte, in his 1842 "Cours de la Philosophie Positive," rejected the use of scientific experimentation and why John Stuart Mill did the same in his "System of Logic" published in 1843.

According to Mill, there was "a demonstrated impossibility of obtaining, in the investigations of the social science, the conditions required for the most conclusive form of inquiry by specific experience." He illustrated his view using an important issue of his time: "the operation of restrictive and prohibitory commercial legislation upon national wealth." Such matters cannot be decided, he argued, by comparative studies of two countries that only differ as to their commercial freedom:

> *If the two nations differ in this portion of their institutions, it is from some difference in their position, and thence in their apparent interests, or in some position or other of their opinions, habits, and tendencies; which opens a view of further differences without any assignable limit, capable of operating on their industrial prosperity, as well as on every other feature of their condition, in more ways than can be enumerated or imagined.*

The second reason why the experimental method was unsuitable was of a moral nature. George Cornewell Lewis extensively discussed the latter type of objection in his 1852 two-volume "Treatise on the Methods of Observation and Reasoning in Politics." Whereas Hume more than a century ago explicitly included the "experimental method" in the title of his book, Lewis no less explicitly excluded it from his title. Regarding experimentation, Lewis maintained, is "inapplicable to man as a sentient, and also as an intellectual and moral being." This is not, he added, "because man lies beyond the reach of our powers" but because experiments "could not be applied to him without destroying his life, or wounding his sensibility, or at least subjecting him to annoyance and restraint."

Explaining the Difference

How could the notions of organic structures and multiple causes be compelling to John Stuart Mill, whereas since the 1950s "independent variables" have commonly been isolated and tested in artificial experiments? How could George Cornewell Lewis demand prudence even to the level of not "annoying" people, whereas since the second half of the 20th century massive group experiments have scrupulously been done? In 1997, the historian of science, Robert Brown, published two articles on the difference between the 19th- and 20th century views on social experimentation. Brown considers it an "incoherence" that in the 19th century there was extensive talk of social actions actually being experiments, whereas conducting them in a scientific way was deemed technically impossible and morally unwarrantable. He ascribes this incoherence to methodological ignorance due to lack of motivation. Only after social research became involved with industrial management, Brown argues, could the proper methods for social experimentation develop.

Brown offers an impressive overview of 19th century writings on social experimentation, and he raises the important question of how to explain the difference between the earlier and the later views. His answer, however, violates two interrelated principles of the historiography of science. The first one is the rule that "finalism" should be avoided—that is, that older views should not be judged from later standards of science. This rule implies that allegations such as lacking methodological expertise and zeal can be acceptable explanations only if they are justifiable in terms of contemporary norms. It is unlikely that a distinguished methodologist such as Mill, who repeatedly acknowledged the condition of comparison in science, rejected experimental comparison in human science out of ignorance. In addition, the punctilious 19th century deliberations on the feasibility of scientific social experimentation amply testify to intense motivation. Therefore, the question is open as to why notions of organic structures and fears of annoying people were once compelling reasons against artificial experiments, and why this is no longer the case. The second principle of the historiography of science is that explaining incompatible past and present ideas demands studying them as responses to other relevant beliefs of their times. The following sections apply both rules to the question at hand.

Nineteenth Century Views on Society, Politics, and Social Research

Keeping Order and Collecting Numbers

Until the end of the 19th century, determinism governed social and political thinking. The authoritative writers ascribed the facts of life to given laws of nature and society rather than to human intent and design. An essential part of the determinist philosophy was that the State could only have a very restricted role. The task of governments was mainly to safeguard the natural and normal order and not to generate permanent social change. Social legislation was directed largely at preventing the breakdown of social harmony and restoring it in cases of actual disruption. Even John Stuart Mill, who devoted much of his writings to the subject of governmental responsibility, held that central interference should be restricted to a very small range of affairs. Direct social action could at best create temporary relief and reestablishment of the natural order (Fig. 1).

Figure 1 Poverty and private charity in the 19th century. (Reprinted with permission from Elsevier Inc.)

Limited, however, as this goal may have been, in the course of the 19th century it became an increasingly demanding one. The industrialization and urbanization of Western societies resulted in the creation of large working classes that formed serious threats to social harmony. These people became the central concern of the authorities. In relation to them, governments were interested in numbers and hence employed statisticians. Theodore Porter in "The Rise of Statistical Thinking, 1820–1900," Ian Hacking in "The Taming of Chance," and Michael Cullen in "The Statistical Movement in Early Victorian Britain" vivaciously describe the strong urge of 19th century statisticians to quantify every aspect of the working classes. Statisticians not only abundantly quantified crime, misery, and suicide but also collected endless data on the number of people sleeping in one bed, the number of prints slum dwellers had on the wall, the number of wives who could knit, the number of husbands who mended furniture, and the number of parents who knew how to sing a cheerful song.

Cullen analyzes the 19th century British debates on public health reform and education as ways to counter the danger of criminality and revolutions and as means to instill "the unalterable nature of certain social relationships and hierarchies." In a history of statistics in 19th century America, Steven Kelman adds that the large-scale entrance of poor and uneducated immigrants strongly fueled the fear of social instability. Worries about instability, enhanced in the United States by the immigration problem, accounted for a spectacular extension of statistical data about crime, illiteracy, poverty, prostitution, bad housing, and ill health.

The Social Experiment Reconsidered

Experimental research in the later sense of assessing attempts at social change would have been an incoherence in the 19th century determinist belief pattern on social regularity, normalcy, and the largely peacekeeping role of the State. In times of laissez-faire, the word experiment could impossibly be more than a metaphor for indicating that careful observation of disturbances offers knowledge on the right and balanced state of affairs. Hence, the same Mill who is famous for working out the scientific method of difference argued that experimentation cannot be used in medicine and that "still less is this method applicable to a class of phenomena more complicated than even those of physiology, the phenomena of politics and history." The same Lewis who firmly objected to subjecting people to "annoyance and restraint" could simultaneously maintain that "a famine or a commercial crisis . . . has an elective affinity with the rotten parts of the social fabric, and dissolves them by the combination" and aloofly add that "the study of monstrosities, or malformations, in the animal or vegetable kingdoms, has likewise been recommended as a means of tracing the laws of organic structure."

In the 19th century pattern of beliefs, indeterminism or chance had a negative connotation of lack of knowledge and whimsicality. Using chance as a scientific instrument for drawing population samples, composing equal groups, or calculating statistical significance was therefore inconceivable. Even less imaginable was a notion of chance as something people must take in order to improve their lives. The pertinent issue, therefore, is how social experiments could change from disturbing events into instruments for assessing social progress and how indeterminism could change into something people must make good use of in both science and general life.

Turn-of-the-Century Changes

Changes in Statistics

If social misery remained the same, at least changes occurred in statistics. In the course of the century, statisticians began to distinguish lawlike regularities in their figures, which in the long term would instigate a different view of chance. Adolphe Quetelet in particular is known as the man who formulated the normal curve with the mean as a new kind of true measure of things that replaced the former notion of absolute laws. This was not, however, an indication that social phenomena were malleable. The mean gave expression to *l'homme moyen* who represented normalcy, whereas dispersion from the mean expressed aberration. Quetelet also distinguished natural forces that produce steady movement in the right direction from man-made "perturbational" counterforces. Nineteenth century statistical experts regarded the steady statistical

laws of suicides, crimes, and misery as further evidence that the State is largely powerless.

Historians of statistics generally point to the famous British statistician and biometrician Francis Galton as a crucial figure in the transition from determinism to probabilism. Building on Quetelet, Galton took an important step in the eventual conversion of "chance" into something that opens possibilities of progress instead of an indication of error. In relation to his eugenic ideals of improvement of the human race, Galton was primarily interested in the dispersions from the mean rather than the mean itself. To him, *l'homme moyen* did not represent the exemplar of the human race but the ordinary man who needs correction: "Some thorough-going democrats may look with complacency on a mob of mediocrities, but to most other persons they are the reverse of attractive" (quoted in Porter, 1986: p. 29).

Changing Views on Social Experiments

Galton was also interested in other means of establishing progress through science. In the *Fortnightly Review* of 1872, he published an article under the telling title of "Statistical Inquiries into the Efficacy of Prayer." Assuming that piety should be profitable, Galton maintained that the use of prayer can be assessed on its earthly revenues. The article is intriguing, however, for another reason. It is one of the earliest to recommend a comparative research strategy for evaluating actions. Galton stated,

> *The principles are broad and simple. We must gather cases for statistical comparison, in which the same object is keenly pursued by two classes similar in their physical but opposite in their spiritual state; the one class being spiritual, the other materialistic. Prudent pious people must be compared with prudent materialistic people and not with the imprudent nor the vicious.*

In summary, in 1872 Galton proposed to isolate a single causal variable and to establish its effects by comparing groups equal in all other relevant aspects. As he confidently added, "We simply look for the final result—whether those who pray attain their objects more frequently than those who do not pray, but who live in all other respects under similar conditions." Eight years later, Galton's countryman William Stanley Jevons, a reputed economist and statistician, suggested comparative measurement for assessing social laws. Jevons published an article in the 1880 *Contemporary Review*, titled "Experimental Legislation and the Drink Traffic," that discussed the example of the free trade of beer in shops. According to the author, the decision by the British government to legalize the selling of beer was "a salient example of bad legislation." The effects of the law should have been tested scientifically instead of passed "by the almost unanimous wisdom of Parliament." If the government would have commanded "a social experiment" first, Jevons maintained, it would have known beforehand that the beer law would only create "a beastly state of drunkenness among the working classes."

He maintained that it was possible to "experiment . . . provided we can find two objects which vary similarly; we then operate upon the one, and observe how it subsequently differs from the other." His meaning of a social experiment clearly differed from the traditional one. As far as is known, Jevons was the first author on social issues to argue that deliberate experiments should be conducted for the sake of administrative knowledge making.

Most important, apart from an advocate of active social experimentation, Jevons was also an early exponent of the late 19th century upper middle-class movement for limits on economic liberalism. In 1882, he published a book titled "The State in Relation to Labour." Although Jevons still ascribed people's success and misfortune to their own doing, he pleaded for some State intervention with regard to the supposedly fixed laws of economy. Such appeals for restrained government interference in the free-market economy provided the context in which the notion of scientific social experimentation emerged, and the rules of truly scientific experimentation gradually expanded.

Twentieth century Views on Social Politics, Statistics, and Social Research

Three Principles of Restricted Liberalism

Three mutually related principles of 20th century welfare capitalism were of pivotal importance in the emergence of social experiments as RCTs. The first one was that of individual responsibility. Social functioning and malfunctioning remained an individual affair. This implied that the degree of social care should be limited, but it also implied that ameliorative attempts were to be directed first and foremost at problematic individuals rather than at further structural change. Helping people largely meant treating, educating, punishing, or prizing individuals in order to turn them into self-supporting citizens.

The second principle was that of efficiency. Many contemporary commentators feared adverse consequences of state charity, and there was widespread distrust that administrations would squander public funds. The more hesitant a society was about State charity, the larger the fear of squandering public funds and the stronger the urge to search for singular causal factors of misery and backwardness. Ameliorative actions financed with public money had to produce instant results with economical one-dimensional means.

Figure 2 Cartoon expressing distrust in politicians.

The third principle was that of impersonal procedures. The stronger the fear of abuse of social services, the less the belief in people's own stories of needs and the more pressing the call for impersonal techniques establishing the truth behind that story. In addition, not only was the self-assessment of the interested recipients of help to be distrusted but also that of administrators providing help. Measurement also had to control administrators' claims of efficiency. As Theodore Porter expresses it in his 1995 book, "Trust in Numbers," the more resistance to centralized government in a society, the more officials have to warrant their decisions in terms of standardized or "mechanical," rather than interpretative or "disciplinary," objectivity. When Jevons ridiculed the "unanimous wisdom of Parliament" and argued that it should make way for scientific proof in the 1880s, he announced an era in which government officials increasingly had to base their authority on impersonal knowledge (Fig. 2).

It was no coincidence that these early developments took place particularly in the United States and Britain. Employing a classification introduced in 1990 by Gøsta Esping-Andersen, economists and sociologists label these countries as the prototypes of the "liberal" version of the 20th century welfare regime, which they distinguish from the "social democrat" and the "corporatist" regimes that provide more organized protection of the vulnerable. In his 1997 book titled "The Reluctant Welfare State: A History of American Social Welfare Policies," Bruce Jansson concludes that of all capitalist welfare societies the United States still spends the least amount of money on social welfare but the most on research of its effects.

From the early 20th century, administrative officials turned for help to academic experts who, on their turn, adapted their questions and approaches to the new demands. Experts on psychological, sociological, political, and economic matters also began to organize their work according to the three principles of welfare capitalism: they concentrated on help directed at individuals, the efficiency of such attempts, and impersonal procedures for assessing the attempts.

Developing the RCT

Early 20th century social scientists established a closer alliance with statisticians, who also adjusted to the social changes and increasingly adopted the teachings of Francis Galton. Statisticians now generally regarded deviations from the mean as an indication of real population differences. In "The Politics of Large Numbers," Alain Desrosières explains how the change of focus from what binds people to what separates them induced the development of random sampling for drawing conclusions on entire populations. Desrosières defies the finalist view that 19th century researchers were mistaken not to select their subjects on the basis of chance. The aim of 19th century social surveys was not to collect data for the sake of administrative actions but to describe typical situations, such as destitution in workers' communities. Only in relation to attempts at social steering could 20th century statisticians turn Galton's earlier notion of the statistical identity of random population samples into the technique of random sampling for drawing conclusions on entire populations. Desrosières, Hacking, Porter, and other historians of statistics argue that probabilistic reasoning was worked out for calculating and controlling chance rather than regarding statistical laws as mere destiny.

Initially, 20th century social scientists focused on techniques for measuring social phenomena. Subsequently, some of them proposed to use the new measurement instruments for assessing differences before and after administrative actions. These social scientists also argued that investigating only one group leaves open too much space for personal discretion with regard to the real causes of effects.

In the 1910s, the sociologist Frederick Stuart Chapin discussed the option of comparing experimental and control groups. However, in a sense, Chapin was still a 19th century aristocrat; that is, he was a "patrician–technician," as the historian Robert Bannister suitably described him. Arguing that one should not withhold treatments from needy people just for the sake of research, Chapin added a 20th century version to the former moral objections against experimentation. Furthermore, he maintained that comparing groups would be impracticable because in real life there are no identical groups.

Educational psychologists introduced the solution of deliberately composing groups for the sake of experimentation. Psychologists had a long tradition of psychophysiological and psychical experiments using small artificial groups in laboratory settings. In his book, "Constructing the Subject," the historian Kurt Danziger describes how during the administrative turn of both government and

Figure 3 "Order is heaven's first law": an early 20th century classroom.

human science, many of these laboratory psychologists offered their services to educational administrations. In the school setting, it was both morally and practically possible to create experimental and control groups. Like volunteers in laboratories, the pupils and their teachers could easily be persuaded to cooperate (Fig. 3).

In 1997, Dehue analyzed how the new educational professionals adapted their former laboratory methods to the new demands. Educational psychologists in the 1910s worked out methods for ensuring that the groups were comparable. The earliest strategy was to solve the problem by "matching." Each child was subjected to preliminary tests on factors suspected of creating bias, and then each child's ratings were used to form groups with equal results. Matching, however, collided with two of the principles that the new social science shared with the U.S. welfare state. The technique was quite elaborate and hence inefficient, and, worse, it required personal imagination regarding the variables on which the groups should be equalized.

In the early 1920s, educational psychologists at Columbia University, renowned at the time for their rigorous turn to administrative research and quantification, introduced an alternative: if chance determines the assignment of the children to the groups, each systematic difference will be automatically cancelled out. Then no personal discretion is needed with regard to the factors to be controlled, and, most important, random assignment is much more economical. Thus, these psychologists introduced the RCT in its basic form.

The RCT perfectly epitomized the values of 20th century liberalism that interventions should be directed at individuals in need of integration, instantaneous effectiveness of ameliorative interventions should be unambiguously demonstrated, and that this should be done via impersonal procedures. The assumptions of individual responsibility, efficiency, and impersonal procedures also ensured the validity of the RCT. The maxim that people are basically self-ruling rather than the product of extraindividual social processes guaranteed that it was not an epistemological problem to take them out of their natural groups and randomly rearrange them in artificial groups without social cohesion. The importance of efficiency justified focusing on a single isolated "independent variable" rather than on social and historical patterns. The belief that the discretion of responsible politicians, the subjects, or their physicians, psychologists, families, and friends should be discarded rather than taken into account justified assessment on the basis of preestablished standardized procedures only.

Ronald Fisher's 1935 book, "The Design of Experiments," prescribed random assignment as a condition to valid application of analysis of variance. This work became highly influential because it provided extra ammunition to advocates of impersonal judgment in the social sciences (and, as Harry Marks describes, for the same reason in medical research). As, over the course of time, 19th century laissez-faire capitalism was replaced by 20th century welfare capitalism, it became morally acceptable to experiment with adults too. The vast literature on the human sciences since the 1940s demonstrates that, particularly in the United States, numerous RCTs were done with students, soldiers, patients, slum dwellers, criminal offenders, drug abusers, incompetent parents, spouse beaters, people on welfare, and various other groups who were selected for an intervention and were comparatively compliant to the experimenters' regime.

Social Interaction Models

Steven Durlauf
University of Wisconsin, Madison, Wisconsin, USA

Ethan Cohen-Cole
University of Wisconsin, Madison, Wisconsin, USA

Glossary

complementarity A property of individual preferences or payoffs in which higher levels of some choice variable by others imply that higher levels of the choice variable are relatively more attractive to the individual.
contextual effects Effects determined by characteristics of an agent's neighborhood.
endogenous effects Effects determined by neighborhood members' contemporaneous behavior.
neighborhood Defined abstractly to be any group of individuals that could be considered to have a definable impact on an individual.
peer group effects An influence on an agent's behavior due to the connection to or perception of a peer group.
phase transition A model exhibits phase transition if its properties qualitatively change for a small change in a parameter value. Phase transitions are thus a way of describing when threshold effects occur in an environment.
poverty traps A situation in which the incentives for increased income or wealth are offset by other effects such that a group of agents remain poor over long time periods.
role model effect An influence on an agent's behavior due to the connection to or perception of a role model.
social multiplier The notion that connections and interactions between individuals can amplify or reinforce direct influences on agents.

Social interactions models comprise a body of recent work by economists and other social scientists that attempts to analyze formally the interplay between individual decisions and social processes. Substantively, these models attempt to answer two broad classes of questions. First, how do the characteristics and choices of others affect an individual's decision making? Second, how are these social influences reflected in equilibrium behaviors observed in a group as a whole? Substantively, social interactions models extend the domain of economic reasoning by evaluating direct interdependences between individuals. As such, these models complement the traditional economic focus on individual interdependences that are mediated via prices. Social interactions refer to these direct interdependences. During the past 15 years, there has been a renaissance of interest among economists in the social determinants of individual behavior and aggregate outcomes. A key reason for this is the potential for social interactions to help explain outstanding social questions such as the prevalence of inner-city poverty. In this regard, there is now a large body of empirical studies that attempt to measure social interaction effects on individuals in the context of residential neighborhoods. Social interactions models place such studies in a firm theoretical context. Also, methodological advances have allowed the incorporation of such effects into traditional microeconomic models. The basic structure and implications of these models suggest that these tools may have general application across the social sciences. Drawing from this basis, this article presents an overview of social interactions models and their applications, including a discussion of econometric techniques and outstanding research questions.

Social Interactions: Theory

By describing how agents' choices depend on the actions and characteristics of others in a common neighborhood,

this article provides a basis for understanding how social factors combine with the market-based and individual-specific factors that are the basis of neoclassical economic reasoning.

Following Manski, who adopts this terminology from the sociology literature, one can think of an agent's interactions with his or her neighborhood as being composed of two factors: contextual and endogenous. The first refers to those factors that are group specific and based on characteristics of the group members. The second refers to how agents are affected by the contemporaneous behavioral choices of group members. These alternative factors are illustrated in the context of residential neighborhoods, which represent an important leading case in the social interactions literature. How do residential neighborhoods affect individual educational outcomes? One source is local public finance of schools. Such a mechanism links individual educational quality to the distribution of socioeconomic status among neighborhood families. Another mechanism is role model effects. In this case, a student's school effort may be influenced by the level of economic success he or she observes among adults in the neighborhood. Feedback from the socioeconomic status of adults in a community to student behavior is an example of a contextual effect. In general, contextual effects are not reflexive: Although a student is affected by the behaviors of adult role models, he or she does not influence those role models per se. This is most obviously the case when the student is affected by a past behavior of an adult.

In contrast, endogenous effects refer to direct interdependences in contemporary choices among members of a neighborhood. For example, one might argue that the educational effort of one student is influenced by the effort of his or her friends; this type of endogenous effect is also known as a peer group effect. Unlike contextual effects, endogenous effects such as peer effects are reflexive; one student's effort influences his or her friends just as he or she is influenced. This is what is meant by an endogenous effect. Notice that both contextual and endogenous effects are influences that are not directly adjudicated by prices—that is, there is no market to compensate an adult for providing a good role model or a student for providing desirable peer effects.

Policymakers have a particular interest in social interactions research in general, and endogenous effects in particular, in that they provide a mechanism for understanding two prominent issues in social science: poverty traps and social multipliers. To understand what is meant by poverty traps, suppose that the college attendance decision is strongly related to the percentage of graduates in the community. These connections in behaviors can lead to two communities with different levels of college graduates in the long term. The mechanism for this should be clear: High (low) attendance rates of one generation lead to high (low) rates for the next generation. Communities initially composed of poor (via lack of education) members will remain poor across time. This result can be explained with intertemporal social interactions (i.e., social interactions in which choices made at one time affect others in the future).

Another conception of poverty traps derives from peer group effects. When such effects are strong, the characteristics of individuals in the group are not unique determinants of the group's action; instead, dependence on history, reactions to common influences, etc. may determine which sort of average behavior actually transpires. The emphasis here is that strong contemporaneous dependences in behavior can generate multiple different self-reinforcing behaviors in groups. Within a given configuration of behaviors, each individual is acting "rationally" in the usual sense. Note that this does not suggest that each self-consistent configuration is equally desirable from the perspective of the members of the group. One can also interpret poverty traps as a socially undesirable collection of behaviors that are mutually reinforcing and consequently individually rational.

Social multipliers arise because social interactions can amplify the effects of individual incentives. For a policymaker, this means that alterations of private incentives across a group may have far larger per capita effects than that associated with one individual in isolation. Consider the impact of providing tertiary education scholarships to randomly chosen students across various high schools versus concentrating the funds among students within a given school. If the goal is to alter high school graduation rates, then the presence of social interactions can, other things equal, mean that the concentration of the scholarships will be more efficacious. With the assumption that the direct incentive effect of the scholarships is equal for all students, the advantage of concentrating the scholarships in one school is that they will induce neighborhood effects for all students in the school, including those who have not been offered scholarships. Spreading the scholarships would have essentially no impact on any of the "neighborhoods" and would consequently impact only the students who received the funds. More generally, neighborhood effects can amplify the effects of altering private incentives; this amplification is what is meant by a social multiplier. To date, the implications for policy design of such multipliers have been little explored.

The basic implications of these effects suggest that the notion of interactions within neighborhoods may have general application in varied social science contexts. Various research agendas focus on populations of agents organized into groups in which some type of non-price-related interactions occur. Each of these utilizes, at least abstractly, the notion of neighborhood-specific social interactions. Applications range from economic growth and development to crime and land use patterns. This work

does not require that neighborhoods be defined geographically, but it does rely on some notion of proximity versus distance in "social space," a notion originally given content by Akerlof.

Formal Theory

This section summarizes the previously discussed concepts into a formal model. First, consider the abstract problem of how social interactions influence individual choices and thereby produce interesting neighborhood behaviors in the aggregate.

This model has I individuals part of a common neighborhood denoted n. Each individual i chooses ω_i from a set of possible behaviors $\mathbf{\Omega}_i$. This individual-level decision will produce a probabilistic description of the choice given certain features of the individual and his or her neighborhood. This model constructs a probability measure $\mu(\cdot)$ for the vector of choices of all members of the group, ω, that is consistent with these individual-level probability measures and relates how neighborhood effects determine its properties. To capture how others influence each agent, define ω_{-i} as the vector of choices made by individuals other than agent i.

Continuing from the previous theoretical discussion, one may distinguish between the various types of influences on individual behavior. In addition to the contextual and endogenous factors defined previously, there are also two types of individual-specific characteristics: deterministic and random. These four types of influences have implications on how to model the choice problem. For simplicity, the model labels the four as follows:

X_i, a vector of deterministic (to the modeler) individual-specific characteristics associated with individual i

ε_i, a vector of random individual-specific characteristics associated with i

Y_n, a vector of predetermined neighborhood-specific characteristics (these measure the contextual effects)

$\mu_i^e(\omega_{-i})$, the subjective beliefs individual i possesses about behaviors of others in his or her neighborhood, described as a probability measure over those behaviors (this term captures potential endogenous effects).

Each of these components will be treated as a distinct argument in the payoff function that determines individual choices. As discussed previously, the social interactions terms are the final two. Even though these may be "nonstandard" in the context of traditional economic decision problems in that they are not price driven, individual choices are still defined via the maximization of some individual payoff function $V(\cdot)$; given the notation introduced, individual choices are thus assumed to follow

$$\omega_i = \arg\max_{\omega \in \Omega_i} V(\omega_i, X_i, \varepsilon_i, Y_n, \mu_i^e(\omega_{-i})). \tag{1}$$

Next, to close this model, one must choose a method of resolving a standard problem in economics: how individuals form beliefs about the behaviors of others. The benchmark assumption is that beliefs are rational in the sense that

$$\mu_i^e(\omega_{-i}) = \mu(\omega_{-i} \mid \varepsilon_i, Y_n, X_j, \mu_j^e(\omega_{-j})\ \forall j), \tag{2}$$

where j refers to members of the neighborhood n other than agent i. The right-hand side of Eq. (2) is a conditional probability measure that describes how agent i would form beliefs that are mathematically consistent with the model, given the conditioning variables. In particular, one should note that the distinction between one's beliefs about the choices of others and their actual choices derives exclusively from the fact that agent i observes only his or her own random payoff term, ω_i. Finding an equilibrium set of behaviors in a neighborhood is thus a fixed-point problem—that is, determining what subjective conditional probabilities concerning the behavior of others correspond to the conditional probabilities produced by the model when behaviors are based on those subjective beliefs.

To make the model more tractable for analysis and interpretation, Eq. (1) is often simplified in two ways. First, since one might expect individuals to care about the average behavior of those in the group, endogenous effects can be expressed as $\bar{\omega}_{-i} = (I-1)^{-1}\sum_{j \neq i} \omega_j$. Second, one can also remove uncertainty by setting ε_i to zero for all neighborhood members; this allows expectations and realizations to coincide in Eq. (2). When these assumptions are made, individual decisions solve

$$\omega_i = \arg\max_{\omega \in \Omega_i} V(\omega_i, X_i, Y_n, \bar{\omega}_{-i}). \tag{3}$$

From the perspective of formal theory, the interesting properties of social interactions models depend on the direct interdependences that exist between individual choices—that is, the endogenous effects that are captured by the presence of $\mu_i^e(\omega_{-i})$ in Eq. (1) and $\bar{\omega}_{-i}$ in Eq. (3). Social interactions models typically assume that these interdependences between individual choices exhibit complementarity. Intuitively, complementarity means that the relative payoff of a higher value of ω_i versus a lower value is increasing in the levels chosen by others. For the payoff function described in Eq. (3), complementarity means that if $\omega^{\text{low}} < \omega^{\text{high}}$, and $\bar{\omega}_{-i}^{\text{low}} < \bar{\omega}_{-i}^{\text{high}}$, then

$$V\left(\omega^{\text{high}}, X_i, Y_n, \bar{\omega}_{-i}^{\text{high}}\right) - V\left(\omega^{\text{low}}, X_i, Y_n, \bar{\omega}_{-i}^{\text{high}}\right) > V\left(\omega^{\text{high}}, X_i, Y_n, \bar{\omega}_{-i}^{\text{low}}\right) - V\left(\omega^{\text{low}}, X_i, Y_n, \bar{\omega}_{-i}^{\text{low}}\right). \tag{4}$$

Complementarity is a fundamental property for interdependent decision making because it leads to similarity of behaviors as high choice levels by others make it more likely that an individual does the same; similar logic applies to low choice levels. In fact, the model in Eq. (3) is an example of the class of coordination models that arise in applied game theory.

What types of properties may be exhibited by social interactions models? One important property is that of multiple equilibria. A model such as shown in Eqs. (1–3) exhibits multiple equilibria when there is more than one set of choices ω such that each individual is making the choice that maximizes his or her payoff. Intuitively, when complementarities are strong enough, it permits individuals to behave similarly in equilibrium but does not specify or require particular behavior. This introduces a "degree of freedom" in the determination of outcomes as a whole. In the social interactions context, this is important because multiple equilibria create the possibility that two neighborhoods with similar observable characteristics (i.e., distributions of X_i within each neighborhood n and levels of Y_n) can exhibit different aggregate behaviors. When will multiple equilibria occur? Clearly, one factor is the strength of the endogenous social effects. If these effects are weak, then the other determinants of individual behavior play a relatively larger role in determining individual outcomes and can lead to unique equilibria.

A second property these models may exhibit is phase transition. A model exhibits phase transition if its properties qualitatively change for a small change in a parameter value. Phase transitions are thus a way of describing when threshold effects occur in an environment. Why do phase transitions occur in social interactions models? Intuitively, phase transition is related to the multiplicity versus uniqueness of equilibria. Social interaction models often have the property that for a given specification of individual and contextual effects, there is a threshold for the strength of endogenous social effects such that if the level of endogenous effects is above the threshold, multiple equilibria occur.

Brock and Durlauf provide an explicit analysis of how the strength of different factors that affect individual behavior jointly determine the number of equilibrium behaviors that may be observed at the group level for binary choice models with social interactions that illustrate these properties. In their framework, individuals choose $\omega_i \in \{-1, 1\}$. Social interactions are determined by the expected average choice level in the group, m_n. Specifically, the payoff function is such that

$$\begin{aligned} &V(1, X_i, Y_n, \varepsilon_i) - V(-1, X_i, Y_n, \varepsilon_i) \\ &\quad = k + cX_i + dY_n + Jm_n + \varepsilon_i, \end{aligned} \tag{5}$$

where k, c, d, and J are constants, and ε_i is a scalar that is independently and logistically distributed—that is, $F_\varepsilon(z) = 1/(1 + \exp(-z))$. Brock and Durlauf show that the equilibrium expected average choice for a neighborhood must fulfill

$$m_n = \int \tanh(k + cX + dY_n + Jm_n)\, dF_x, \tag{6}$$

where $(\tanh(x) = (\exp(x) - \exp(-x))/(\exp(x) + \exp(-x))$, and dF_x is the distribution of X within n. The number of equilibrium values of m_n that is consistent with Eq. (6) is determined by the value of J, holding other factors constant. For example, if each member of n is associated with the same individual effects (i.e., $X_i = \bar{X}$), then the following results holds: For each value of $k + c\bar{X} + dY_n$, there exists a threshold J^{Thresh} (which depends on $k + c\bar{X} + dY_n$) such that if $J < J^{\text{Thresh}}$, then there is only one equilibrium, whereas if $J > J^{\text{Thresh}}$, then three different values of m_n are consistent with Eq. (6).

To date, far less effort has been dedicated to analysis of econometric issues in social interactions topics than to theoretical work. Brock and Durlauf, Manski, and Moffitt provide general treatments. These studies provide a number of important results for conducting and interpreting empirical work. The following sections review the main econometric issues that arise.

Identification

To provide an illustration of the basic identification issues in social interactions research, consider that $V(\omega_i, X_i, \varepsilon_i, Y_n, \mu_i^e(\omega_{-i}))$ produces a linear representation of individual choice; that is, choices obey the following basic regression specification:

$$\omega_i = k + cX_i + dY_{n(i)} + Jm_{n(i)} + \varepsilon_i, \tag{7}$$

where X_i denotes an r-length vector of observable individual characteristics, $Y_{n(i)}$ denotes an s-length vector of contextual effects, $m_{n(i)}$ denotes the expected value of ω_i for members of neighborhood $n(i)$, and $n(i)$ denotes the neighborhood of individual i [which allows Eq. (7) to describe individuals from different neighborhoods]. This model, referred to as the linear-in-means model, was first studied by Manski in 1993. The linearity assumption facilitates interpretation as in a linear model. To put this in the context of the previous discussion, note that all endogenous effects here work solely through expectations—an assumption that might be appropriate if the neighborhoods were particularly large. To highlight one of the key econometrics issues, we first focus on the case in which $E(\varepsilon_i \mid X_i, Y_{n(i)}, i \in n(i)) = 0$, such that identification questions are intrinsic to neighborhood effects rather than the endogeneity of the neighborhoods themselves.

To understand why identification conditions arise in this model, observe that when beliefs are rational,

$$m_{n(i)} = \frac{k + cX_{n(i)} + dY_{n(i)}}{1-J}, \quad (8)$$

where $X_{n(i)}$ equals the average of the X_i's in neighborhood $n(i)$ and appears in the regression because this average is one of the determinants of $m_{n(i)}$. Substituting Eq. (8) into Eq. (7), the individual choices may be expressed in terms of observables via

$$\omega_i = \frac{k}{1-J} + cX_i + \frac{J}{1-J}\, cX_{n(i)} + \frac{d}{1-J} Y_{n(i)} + \varepsilon_i. \quad (9)$$

Equation (9) summarizes the empirical implications of the linear-in-means model. The identification problem may thus be thought of as asking whether one can recover the structural parameters in Eq. (7) from the coefficients in Eq. (9).

To complete this analysis, one need only compare the number of regressors of Eq. (9) with the number of coefficients of Eq. (7). One can see that Eq. (9) contains $2r+s+1$ regressors, whereas there are only $r+s+2$ coefficients in Eq. (7). Although it might appear that one could recover the structural parameters from a regression of ω_i onto the various regressors, in fact the parameters of Eq. (7) are overidentified. However, this conclusion fails to account for possible collinearity between the components of Eq. (9); collinearity may potentially arise because of the presence of $X_{n(i)}$ and $Y_{n(i)}$ in the equation. For example, following the case originally studied by Manski, suppose that $X_{n(i)} = Y_{n(i)}$. In this case, the researcher would be unable to distinguish between contextual and individual effects. When this condition holds and there are only $r+s+1$ linearly independent regressors in Eq. (9), the associated coefficients for these linearly independent regressors are identified, but they cannot be uniquely mapped back into the $r+s+2$ structural coefficients in Eq. (7); identification of the structural parameters in Eq. (7) thus fails. Manski termed this failure of identification the reflection problem to capture the intuition that the identification problem relates to distinguishing the direct effect of $Y_{n(i)}$ on an individual versus its indirect effect as "reflected" through the endogenous effect generated by $m_{n(i)}$.

When does the identification problem preclude identification of the parameters of Eq. (7)? The key requirement for identification is that the vector $X_{n(i)}$ is linearly independent of the other regressors in Eq. (7), (1, X_i, $Y_{n(i)}$). For this to be so, a necessary condition is that there exists at least one element of X_i whose group-level average does not appear in $Y_{n(i)}$. Intuitively, one needs prior information that at least certain individual-level effects are present whose group-level analogs do not affect individuals.

It is important to recognize that the identification problem previously discussed is a product of the linear specification. Identification breaks down when $m_{n(i)}$ is linearly dependent on the other regressors in Eq. (7); linear dependence of this type will typically not arise when individual behaviors depend on other moments of the neighborhood behavior. More important for empirical work, this argument also implies that identification will hold for nonlinear probability models of choices. For example, the binary choice model of Brock and Durlauf is identified under weak assumptions.

Self-Selection

The discussion of identification has not addressed the issue of self-selection into groups. For contexts such as residential neighborhoods, self-selection is of course important. In fact, recent theories of neighborhood composition are driven by the presence of social interactions. From the perspective of our discussion, self-selection implies that $E(\varepsilon_i \mid X_i, Y_{n(i)}, i \in n(i)) \neq 0$.

There does not exist any general solution to the analysis of social interactions with self-selection. One approach, followed by Evans *et al.*, is to use instrumental variables to account for $E(\varepsilon_i \mid X_i, Y_{n(i)}, i \in n(i)) \neq 0$. An alternative approach, developed by Brock and Durlauf, models the self-selection explicitly. We focus on the linear-in-means model. Consider the following equation to illustrate the effect of self-selection on identification:

$$\omega_i = k + cX_i + dY_{n(i)} + Jm_{n(i)} + E(\varepsilon_i \mid X_i, Y_{n(i)}, i \in n(i)) + \xi_i, \quad (10)$$

where $E(\xi_i \mid X_i, Y_{n(i)}, i \in n(i)) = 0$ by construction. Following the classic approach to selection developed by James Heckman, consistent estimation of Eq. (10) requires constructing a consistent estimate that is proportional to $E(\varepsilon_i \mid X_i, Y_{n(i)}, i \in n(i))$, call it $\delta(X_i, Y_{n(i)}, i \in n(i))$, and including this estimate as an additional regressor in Eq. (10); that is, one in essence estimates the regression

$$\omega_i = k + cX_i + dY_{n(i)} + Jm_{n(i)} + e\delta(X_i, Y_{n(i)}, i \in n(i)) + \xi_i. \quad (11)$$

The key insight of Heckman is that once this is done, Eq. (11) may be estimated by ordinary least squares. Brock and Durlauf describe how to implement this procedure in the social interactions case using two-stage methods.

Self-selection corrections have important implications for identification. Consider two cases. First, suppose that the decision to join a neighborhood depends only on $m_{n(i)}$—that is, $\delta(X_i, Y_{n(i)}, i \in n(i)) = \delta(m_{n(i)})$. In this case, Eq. (11) is now nonlinear in $m_{n(i)}$ (since $\delta(\cdot)$ is almost certainly nonlinear given the fact that the neighborhood choice decision is made among a set of discrete

alternatives) and is thus identified outside of pathological cases. Alternatively, in general $\delta(X_i, Y_{n(i)})$ will be linearly independent of $(1, X_i, Y_{n(i)})$ since $\delta(\cdot)$ is nonlinear. As such, $\delta(X_i, Y_{n(i)})$ is an additional individual-level regressor whose group-level analog does not appear in the behavioral equation (Eq. 7). Thus, identification may be achieved.

This approach to self-selection may be criticized to the extent that the self-selection correction is constructed on the basis of parametric assumptions concerning the distribution of the various model errors. We regard this as a legitimate but not critical caveat. The analysis by Brock and Durlauf that we have described should be interpreted as demonstrating that self-selection not only does not make identification of social interactions impossible but also may, if appropriately modeled, facilitate identification. This facilitation follows from the fact that neighborhood choices embody information on how individuals assess social interactions.

An equally important new direction is the development of data sets that will facilitate more detailed analyses of social interactions. One important development is the Moving to Opportunity Demonstration being conducted by the Department of Housing and Urban Development that involves creating incentives for poor families to move to more affluent neighborhoods in order to determine how they are affected; Katz *et al.* provide valuable evidence on social interaction effects. Other efforts are promising in terms of the detailed data that are being obtained. The Project on Human Development in Chicago Neighborhoods is noteworthy for the detailed information on attitudes and outcomes that is being compiled.

Social Measures of Firm Value

Violina P. Rindova
University of Maryland, College Park, Maryland, USA

Glossary

audits Research investigations conducted by specialized organizations (information intermediaries) with regard to firm performance on preselected criteria relevant to different stakeholder groups.
awards Forms of recognition for outstanding achievement in some area of firm activities, often accompanied by a monetary prize.
comparative reputational rankings Comparative orderings of organizations that compete in an industry or an organizational field.
corporate contests Direct comparisons of the performance of firms or their products, usually made by a panel of judges.
information intermediaries Organizations that monitor and certify firm performance by collecting and disseminating information about firms, and constructing social measures of firm performance.
opinion polls Surveys of stakeholder perceptions of firm performance.
stakeholders Single individuals or groups of individuals (employees, customers, suppliers, shareholders, and others) that are affected by and affect the operations of a firm.

Social measures of firm value are explicit or implicit quantitative or qualitative evaluations of the performance and ability of firms to create value along various dimensions relevant to the firms' diverse stakeholders. Valuations may be produced through audits, opinion polls, and contests. These processes can then be used to yield comparative reputational rankings and expert categorizations and ratings.

Origins and Role of Social Measures of Firm Value in Market Exchanges

Stakeholders in a business organization control the resources that are vital for the economic success of the firm. The decisions to make these resources available to a given firm depend on the evaluations that stakeholders make about the ability of the firm to create value for them. Stakeholders are single individuals as well as groups of individuals, including employees, customers, suppliers, shareholders, and others, that are affected by and affect the operations of a firm. In choosing the extent to which they will exchange their resources with the firm, stakeholders, in turn, influence the ability of the firm to create value and achieve desired economic results. However, in order to select firms with which to exchange their limited resources, stakeholders must overcome the classical market selection problem, which relates to the concepts of adverse selection and moral hazard. Moral hazard refers to the incentives of sellers to exert less than complete effort in producing and delivering products and services, and adverse selection refers to the likelihood that buyers will pick a lower quality product or service. These problems arise from the fact that sellers of products and services have more information than buyers do about the quality of the marketed products and services. This asymmetry between the information available to a particular market player (private information) and the information available to others (public information) gives rise to market selection problems. Information asymmetries and market selection problems are reduced when firms submit to certification and monitoring by outside agents.

In order to mitigate these information problems in markets, various organizations have emerged to serve as information intermediaries. Such entities specialize in collecting and disseminating information about firms. Information intermediaries may be involved in making private information public, as in the case of financial analysts, who engage business managers in discussions regarding their firm's operations. Through such discussions, financial analysts receive and make available information that supplements the information a firm has made publicly available in its financial statements. Information intermediaries can also be involved in making otherwise publicly available information more accessible and comprehensible, by issuing summary statistics and reports. This function of information intermediaries is also important to the market exchange process because, even if information about firms is publicly available, it may not be readily accessible to all market players; information intermediaries therefore potentially decrease the market players' search costs and increase the value they may derive from a particular exchange.

Information intermediaries may also "create" new information about firms by providing stakeholders with third-party evaluations of firms, in the forms of ratings, rankings, classifications, or awards. This activity of information intermediaries produces various social measures of firm value. Such measures not only facilitate stakeholders' information gathering, but also directly aid in their decision processes. The reason for this is that social measures of firm value provided by information intermediaries often carry institutional validity, because information intermediaries, in the words of management scholar Hayagreeva Rao, are "social control specialists who institutionalize distrust of agents by inspecting their performance ... and who sustain social order." Social measures of firm value therefore are outputs of organizations that specialize in the collection, dissemination, and analysis of information about firms, in an effort to reduce the market selection problem that stakeholders face.

Financial versus Social Measures of Firm Value

Financial measures of the value of a firm are quantifications of the economic value of the assets a firm controls and the expected ability of a firm to deploy these assets in generating economic returns. Whereas a systematic overview of financial measures of firm value lies outside the scope of this article, the brief overview provided here serves as a basis for distinguishing between financial and social measures of firm value.

According to finance theory, the value of a firm is the sum of the value of all of its assets. Different definitions of firm value exist and are appropriate for different situations. For example, the liquidating value of the firm can be realized if its assets are sold separately from the organization that has been using them. In contrast, the going-concern value of the firm is its value as an operating business. Further, the accounting value of the firms' assets determines its book value, while the value at which these assets can be sold determines its market value. Because the firm has both a liquidating value and a going-concern value, the higher of the two constitutes the firm's market value. The market value of the firm as a going concern is calculated as sum of the current and projected cash flows of the firm, discounted at the firm's average cost of capital. Whereas the estimation of future cash flows and the cost of capital may involve various levels of elaboration in analyses, the basic logic of financial measures of firm value is that a firm's value reflects its potential to generate economic returns for its suppliers of capital. This logic is based on the assumption that the suppliers of capital are the residual claimants, who receive their returns after all other claimants (stakeholders) have been satisfied.

Social measures of firm value differ from the financial approaches in several ways. Financial approaches are concerned primarily with evaluation of the economic assets of the firm and their productive capacity to generate economic returns for the suppliers of capital. In contrast, social approaches to firm valuation view the firm as a social agent with whom individuals and other social entities form relationships and pursue a wide range of economic and noneconomic goals, such as quality of life, social justice, professional development, and safe and clean environments. Thus, social measures of firm value are concerned with the role of the firm as a social actor, the activities of which impact a variety of stakeholders, rather than a single stakeholder group. Consequently, social measures of firm value differ from financial measures in their concern with both economic and noneconomic outcomes associated with the operations of a firm, and with the effects of these operations on various stakeholders. It should be noted, however, that financial measures of firm value are a type of social measure as well. As Ralf Hybles has explained, "The schemas of finance and accounting present an overarching set of abstract categories and decision rules that coordinate across specialties and organizations" so that "the dual functions of finance and accounting together certify the economic legitimacy of every type of contemporary organization."

Whereas financial measures are always explicit and quantitative, social measures take a variety of forms, i.e., explicit and implicit and quantitative and qualitative. Because they are quantitative and standardized, financial measures enable a high degree of comparability of firm value in dollar terms. However, they offer limited means for evaluating aspects of firms performance that are not readily measured in dollars, such as intangible assets,

employee satisfaction, and innovativeness of research and development efforts. Social measures seek to capture these aspects of firm performance and do so through both quantitative and qualitative and explicit and implicit means. Examples of explicit quantitative social measures of firm value are various reputational rankings and ratings, such as those published by *Fortune Magazine* in its "Most Admired Corporations" surveys. Examples of explicit qualitative measures are various awards, such as the annual awards presented by *R&D Magazine* to companies making technologically significant products. Implicit quantitative measures of firm value are metrics that assess specific organizational practices, rather than the overall performance of the firm and its products. For example, the Investor Responsibility Research Center (IRRC), a not-for-profit organization, offers research for portfolio screening that focuses on firm practices related to waste generation and disposal of toxic and hazardous materials, and the environmental liabilities of a firm. Examples of implicit qualitative measures are various classification schemes that categorize competing firms in an industry, in terms such as "specialty" versus "mass" or "low-end" versus "high-end" producers. As these examples indicate, social measures of firm value can take a variety of forms, including rankings, ratings, awards, and expert and lay categorizations. Because of this diversity, social measures of firm value may be less readily identifiable and available to the general public, compared to financial measures. Further, the diversity of the forms of social measures also suggests that the term "measures" may not capture precisely the nature and forms of social evaluations of firm value. Such evaluations may be better understood as summary representations of business performance that contain explicit or implicit evaluative elements. Their importance in markets and their value to stakeholders derives from the fact that they summarize, and often institutionally "certify," information about competing firms and thereby reduce stakeholder uncertainty with regard to exchanges with these firms. Therefore, the processes through which information intermediaries collect and process information about firms to generate such evaluative representations are an integral part of the validity and usefulness of such evaluations. The processes through which social measures of firm value are constructed are discussed next.

Constructing Social Measures of Firm Value

Extant research on social evaluations of firms can be organized in three main groups, based on the processes through which the evaluation takes place. In practice, these three processes are often combined, and evaluations of firms may contain elements of all of them. However, it is useful to distinguish among the processes in order to understand the variety of social measures of firm value. The three types of processes through which social measures of firm value are produced can be broadly described as expert audits, opinion polls, and contests.

Audits

Audits are research investigations about practices and outcomes based on various standardized criteria that are used to produce comprehensive evaluations. Different information intermediaries specialize in auditing firm performance on dimensions deemed of interest to different stakeholder groups. For example, Rao documented the emergence of consumer watchdog organizations in the United States; the formation of the first nonprofit consumer watchdog organization, Consumers' Research, was in 1927, and by 1995, the number of such organizations had increased to 200. If consumer watchdog organizations that operate for profit, such as Morningstar and Lipper Analytical Services, are included this number is even higher. Other examples of organizations dedicated to conducting audits of firm activities and providing stakeholders with evaluations of these activities include those dedicated to monitoring and reporting on the socially responsible and environmentally conscious behaviors of firms. For example, The Council on Economic Priorities (CEP) is a not-for-profit organization founded with the goal to provide analysis of the social and environmental records of corporations. It has published a book called *Rating America's Conscience*, which rates 130 consumer product companies on criteria such as hiring records, charitable contributions, involvement in South Africa, and defense contracts. The CEP has also published a shopping guide, *Shopping for a Better World*, which rates 168 companies and over 1800 products, and an investment guide, *The Better World Investment Guide.*

The audit process is characterized by reliance on specialized staff; its goal is to collect and process information about firms through a combination of quantitative and qualitative methods, and to produce standardized metrics, ratings, or rankings. The audit process places an emphasis on the extensiveness of data gathering, triangulation of information, and standardization of information outputs to enable systematic comparisons among competing firms. Yet, the audit process may include relative criteria, e.g., how a firm performs relative to its industry peers, as well as data on absolute standards, such as government-mandated or industry-sponsored standards and guidelines. For example, information intermediaries screening firms for environmental performance tend to rate and rank firms for their performance on the Toxic Release Inventory (TRI), which is mandated by the Environmental Protection Agency (EPA).

Whereas organizations that employ an audit process to produce social measures of firm value seek to demonstrate the social rationality of their criteria and the rigor of their methods, they tend to approach firm evaluations from a particular ideology, which guides the selection of criteria on which firms are evaluated, as well as the allocation of resources in collecting and processing information about firms. Also, despite their use of statistical and other scientific methods in processing the data, these organizations are subject to a very limited degree of social control with respect to the validity and the reliability of the measures they generate. For example, *US News & World Report* publishes annual rankings of the top business schools in the United States. These rankings are based on information concerning input characteristics (e.g., for a student earning a Master's degree in business, the average Graduate Management Admission Test score, and the grade-point average of the entering class), throughput characteristics (such as teaching methodologies used), and output characteristics (such as percentage of students with job offers at graduation, and average starting salaries of graduates). The aggregation of such diverse data increases the noise in rankings, thereby reducing their validity as measures of underlying quality. Further, these rankings are based on self-reported information by schools, the veracity of which has come into question. Together, these arguments suggest that the validity of social measures of firm value that are based on audits can improve significantly if well-developed auditing and data analytical techniques in the field of accounting and social sciences, in general, are deployed more systematically. Further, to the degree that multiple information intermediaries undertake audits with similar purposes, they will be subject to the discipline of the market.

Opinion Polls

Opinion polls do not strive to examine and assess the practices of firms and their relative performance. Instead, they seek to capture stakeholder perceptions of firm performance. The rationale underlying opinion polls is to capture and make explicit the collective consensus about a firm's performance and abilities to create value for various stakeholders. Social measures of firm value derived from opinion polls are important in market exchanges because individual stakeholders are ultimately the ones who form expectations and who make buying and selling decisions. Further, whereas the audits of expert organizations tend to espouse a particular ideology, which influences both the criteria of the audit and the final evaluations derived from the data analysis, opinion polls can capture the diversity of stakeholders beliefs and evaluations of firms. For example, whereas some investors are socially responsible, others are not; whereas some customers are "green," others are "price-shoppers"; and whereas some employees consider the pro-bono activities of a firm an important part of its identity, others focus only on personal benefits. Therefore, the construction of social measures of firm value that account for the diversity of a firm's stakeholders is an important issue for both research and practice.

Though researchers agree about the importance and value of opinion polls as an approach to capturing stakeholder perceptions of firms, they disagree about the appropriate methodology for doing so. Research on "public opinion" has long wrestled with the problem of how the viewpoints of the general public can be captured and observed. Currently, public opinion research efforts have adopted the perspective that the public point of view is best captured through an aggregation of individual opinions. Anchored in a pluralistic worldview, this perspective adheres to the democratic principle of "one person, one vote," advocating systematic random polling as a way to unearth the opinions of a diverse polity. The critical concern when employing this approach is to create samples that are "representative" of the population at large. As Charles Roll and A. Hadley Cantril have explained, "Respondents ... are not selected because of their typicality or of their representativeness. Rather, each sampling area and each individual falls into the sample by chance and thus contributes certain uniqueness to the whole. It is only when these unrepresentative elements are added together that the sample should become representative." Much as opinion polls are used to construct a profile of "public opinion" on a particular topic, so can stakeholder evaluations of firms be uncovered by systematically polling a company's stakeholders.

Methodologically, opinion researchers advocate random sampling as the preferred means of polling a diverse constituency, because this method produces the closest approximation of all of the constituency's characteristics. This method also allows for efficient use of resources; for example, a sample of about 500 to 1500 people is considered sufficient to represent national public opinion in the United States, with a margin of error of 3–5% at a 95% confidence level. If this methodology were systematically applied, a comparably small sample could be used to capture the diversity of perceptions that stakeholders hold. In the case of the *Fortune* survey, the Most Admired Corporations, survey data are collected from some 8000 executives and analysts annually. This sample size far exceeds the sample size needed to conduct a valid poll of all of a company's evaluators. Despite its big sample size, the *Fortune* survey has been criticized for its lack of representativeness. Heeding the warning of public opinion researchers that the validity of a poll hinges on avoiding sampling from "typical individuals" and on using subgroup quotas, more valid polls of stakeholders may be obtained by targeting

a random set of external observers rather than a circumscribed group of constituents. Recently, the Harris–Fombrun Reputation Quotient (RQ) standardized survey instrument has been developed and administered to capture the perceptions of various stakeholders, including consumers, investors, employees, and key influentials. The annual RQ is a survey of the most visible companies in the United States, and it has been conducted annually since 1999. The survey is conducted in two stages. For example, in the 2001 survey, 10,038 survey respondents (4063 by telephone and 5975 online) were interviewed to nominate two companies that stand out as having the best and the worst reputations overall. In the second "ratings" phase, 21,630 randomly selected online respondents were asked to do a detailed rating of one or two companies with which they were "very" or "somewhat" familiar. As a result, in this poll, each company was rated by an average of 600 randomly selected respondents who had indicated that they were either "very" or "somewhat" familiar with the company.

Another methodological issue that has been posed with regard to measures generated through opinion polls is whether stakeholder evaluations should be reflected in terms of average scores or distribution of opinions. It has been argued that stakeholder evaluations of firms should not be measured by averaging responses by all members of a collectivity and generating a single composite measure. Instead, stakeholder evaluations should be captured as distributions of opinions that can be represented in tables and figures as frequency distributions.

Corporate Contests

A growing body of research in sociology and management has begun to focus on a third type of process through which social evaluations are constructed. This process has been characterized as corporate contests, in that it directly pitches the performances of rivaling firms against one another. Researchers view these contests as a mechanism through which actors are evaluated relative to one another and high performers are identified and made highly visible to stakeholder publics. Victories in such contests make the value of competing firms appear self-evident, because of, as Rao put it, "the taken for granted axiom that winners are 'better' than losers and the belief that contests embody the idea of rational and impartial testing." Rao provided an interesting example of the use of contests: in the early U.S. automobile industry (1895–1912), contests were used to increase the perceived value of the new vehicle—the automobile—and to establish the reputations of its producers. The first contest was the *Times-Herald* race organized in 1895, in which five of the 11 entrants actually participated and two completed the race. An example of a modern-day corporate contest is the annual competition for the Industrial Design Excellence Award (IDEA) sponsored by *Business Week*.

Corporate contests may have some limitations in the comprehensiveness of the evaluations they afford. Rao warned against such limitations: "Contests structure search in crowded and confused markets and circumvent the issue of measuring capabilities." Two types of errors associated with contests: they foster artificial distinctions between equivalent participants; and they may lead to nonequivalence of capabilities being awarded the same level of acclaim, because winners in one year may have lesser capabilities than winners have in other years. Another key issue in organizing contests is the composition of the rival group. At one extreme, all firms, without regard to size or type, can be compared with each other on common dimensions of performance, such as progressiveness of work–family practices. Such contests, however, are likely to be dominated by size, because there is much information available about large, publicly traded firms. At the other extreme, firms could be compared only with rivals producing identical products. Though this narrows the relevant set considerably, it reduces the difficulty of making comparisons of firms across product groupings.

Forms of Social Measures of Firm Value

The different processes through which the ability of firms to create value is assessed tend to generate different forms of social measures of firm value. More specifically, the outcomes of audits and opinion polls are usually comparative reputational rankings of firms. Audits also generate expert categorizations and ratings, whereas corporate contests usually identify award "winners." Just as the three processes often coexist and are combined by information intermediaries, so the three forms are often interrelated. For example, expert ratings can be used as primary inputs for granting awards, thereby converting an audit process into a corporate contest.

Comparative Reputational Rankings

Reputational rankings are comparative orderings of organizations that compete in an industry or an organizational field. Because they juxtapose rivals in an industry in a hierarchical fashion, rankings specify the prestige ordering of the industry. The ordering reflects a firm's relative success in meeting the expectations of the industry's stakeholders. Thus, rankings are useful because they combine the judgments of different individuals on uniform criteria and enable summary comparisons of firms.

Whereas reputational rankings provide convenient direct comparisons among firms in an industry, they also pose a number of questions about their validity. One set of

questions relates to the degree to which a given set of rankings represents the evaluations of a single stakeholder or multiple stakeholder groups. This issue can be more easily addressed in evaluations based on opinion polls, which, as discussed earlier, can be designed to capture the diversity of firm stakeholders. In the case of audit processes, assuring such diversity may significantly increase the costs of information gathering and may contradict the ideology espoused by the information intermediary conducting the audit.

Recognizing and addressing the issue of the perspective of which stakeholder group a set of rankings represent has important implications for the usefulness and validity of the rankings. Much of the dispute surrounding the rival rankings of business schools presented in the press may be due to the different groups they survey and the different criteria these groups apply. The rankings of business schools published by *Business Week* are based on surveys of recruiters and alumni, but exclude faculty, students, donors, and local communities. The rankings of business schools published by *US News & World Report* include survey data from business school deans, but not survey data from any other informants. Ilia Dichev analyzed the two sets of rankings issued by these two journals between 1988 and 1996 and concluded that "the correlation between concurrent changes in *Business Week* and *US News* rankings is close to zero, even in the long-run. Thus, the cross-rankings correlation results suggest that the two rankings are largely based on different information. Since both rankings seem to reflect relevant information, it appears that neither ranking should be interpreted as a broad measure of school quality and performance . . . , but rather . . . as useful but noisy and incomplete data about school performance."

The issue of stakeholder diversity and social measures of firm value is not simply an empirical issue, but also a theoretical one. Some scholars argue that stakeholder evaluations of firms are necessarily disjointed because they reflect the contradictory interests of self-interested constituents. Others argue that stakeholder evaluations converge because constituents incorporate into their assessments implicit judgments about whether the firm is meeting the interests of other key constituents. These theoretical differences clearly spell different prescriptions about the processes through which social measures of firm value should be constructed. Empirically, the *Fortune Magazine* survey asks respondents to nominate leading companies in an economic sector and to evaluate each company on eight dimensions: (1) quality of management, (2) product/service quality, (3) long-term investment value, (4) innovativeness, (5) financial soundness, (6) ability to attract, develop, and keep talented people, (7) community and environmental responsibility, and (8) use of corporate assets. Early studies based on these ratings assumed that they were eight distinct dimensions, but Charles Fombrun and Mark Shanley have found that these dimensions were highly correlated and loaded on a single factor. They therefore concluded that when respondents rated firms on these seemingly distinct dimensions, they were in fact assessing a stable underlying construct, which could be called "reputation." In their analysis of those rankings, Fombrun and Shanley also found that, although the ratings were best predicted by financial performance variables, they were also influenced by media prominence, advertising, and charitable contributions, suggesting that respondents may unconsciously factor other constituents' concerns into their judgments. In recent years, *Fortune* appears to have recognized the unidimensionality of the construct and now no longer stresses the disaggregated ratings.

To overcome some of the problems with constructing comparative rankings, researchers have also attempted to uncover "natural" forms of status orderings in industries. In the investment banking industry, for example, the hierarchical status ordering of firms in the industry manifests itself on tombstone announcements. A tombstone announcement is a listing of a pending public security offering, which identifies the investment banks participating in the syndicate that underwrites the securities. On the tombstone, banks are listed in hierarchically arranged brackets. Listing a bank in the wrong bracket is a cause for withdrawal from the syndicate, either by the bank, or by other banks in the bracket. Using tombstones, scholars have developed an index of the relative standing of over 100 investment banks.

Awards

Unlike comparative reputational rankings, corporate awards have attracted rather limited research. Fombrun provided one of the most comprehensive treatments of the subject. He identified five major types of awards (product, process, social and environmental performance, and leadership awards). Product awards are given to recognize innovative or quality products that outperform industry standards. Many product awards are sponsored by trade journals, such as *Popular Mechanics* and *Motor Trend* in the auto industry. Process awards recognize importance organizational practices. For example, *Personnel Journal* gives the Optima Awards to companies with innovative human resource management practices. In the area of environmental performance, the United Nations environmental program sponsors the Global 500 Roll of Honor for Environmental Achievement. In the United States, over 16,000 awards are given annually to individuals and organizations by more than 6000 donors. These diverse types of awards perform common functions. From the perspective of the donors and sponsors of the awards, they highlight achievements in order to encourage others to imitate them, thereby elevating the

level of performance in an industry as a whole. From the perspective of the recipients, the awards designate some firms as "winners," thereby conferring to them a special status in their industry, as well as significant visibility relative to competitors. In addition, some awards are associated with attractive monetary prizes. The pervasiveness of awards as a form of social evaluation of firms and their significant impact on stakeholder perceptions of these firms suggest that they warrant significant future research.

Expert Ratings

Expert ratings often tend to be confused with comparative rankings. The difference between the two lies in the standard of performance that is used as a reference point for making evaluations of firms. Rankings use a relative standard and evaluate the performance of a firm relative to the performance of others firms. In contrast, ratings use an absolute standard and compare the firm to a preset performance index. This difference is important, because changes in a firm's ranking result not only from changes in its own performance on the set of criteria used by the rankings, but also from changes in the performance of other firms on those criteria. In contrast, changes in ratings indicate absolute increases or decreases in performance.

Expert ratings are often used as inputs in the construction of comparative reputational rankings or in selecting winners in contests. Yet, they can also exist independently and function as a distinct form of social measures of firm value. Examples of such measures are "star" ratings of wines, hotels, restaurants, and movies. Expert ratings are a prevalent form of product evaluation in service and entertainment industries, based on the experience of using goods, the quality of which cannot be ascertained with advance inspection.

Conclusion

Overall, social measures of firm value offer a powerful way for drawing attention to the relative success of firms at meeting stakeholder expectations. Social measures of firm value are an important feature of the institutional and competitive environments of firms because they reduce stakeholder uncertainty and search costs, during the process of selecting firms with which to exchange the resources that stakeholders control. Although most social measures of firm value have some limitations with regard to their validity, they offer the tantalizing possibility that the performance of firms can be evaluated systematically, in terms of both economic and social dimensions. The growing interest in including social measures in firm valuations suggests that they are an increasingly important area of social research and management practice.

Glossary

personality Traits and/or temperaments that characterize an individual or category of individuals.
self The organization of thoughts, feelings, and/or social roles of an individual that lend meaning to the individual from the individual's and others' perspectives and that generate expectations for the individual's behavior.
social cognition How individuals perceive, interpret, remember, and recall information about the social world and information used to understand the social world.
social environment The context in which social interaction occurs, consisting of real, implicit, or imagined others, the actions taken by one's self and others, and the symbols and objects associated with one's self and others.
social interaction Any encounter (real, implicit, or imagined) between one or more persons or directed toward one or more persons by one or more others.
social perception The processes through which individuals use information to generate impressions of others and to form inferences regarding the causes of their own and others' behaviors.
social structure Cross-cutting patterns of relations between social groups that are guided by normative conventions in institutionalized domains of social life.

Social psychology is the scientific study of the interplay between social interaction, social structure, and human thoughts, feelings, and behaviors.

Introduction

The field of social psychology focuses on the interplay among three components of social life: human thoughts, feelings, and behaviors; social interaction; and social structure. Human thoughts, feelings, and behaviors include attitudes, opinions, beliefs, emotions, cognitive processes, perception, aggression, helping, persuasion, and conformity. Social interaction encompasses interpersonal relationships, collective behavior, and inter- and intragroup processes. Social structure refers to the cross-cutting patterns of relations between social groups that are guided by normative conventions in such institutionalized domains of social life as work, family, and education. Thus, social psychology can be formally defined as the scientific study of the interplay between social interaction, social structure, and human thoughts, feelings, and behaviors.

The field of social psychology is a broad one that is a common component of the curriculum in a range of disciplines, including psychology, sociology, management and organizations, education, industrial engineering, nursing, social work, marketing, and economics. In most higher education institutions, however, social psychology is represented primarily within psychology and sociology departments. Other reviews of the field of social psychology have focused on trends in the theoretical perspectives that characterize psychological and sociological social psychology. This article primarily focuses on the kinds of topics that social psychologists in the disciplines of psychology and sociology study by examining the topics around which social psychology textbooks are organized and the topics that are reflected in published reports of social psychological research. This overview of social

psychology begins, however, by assessing its professional and intellectual background.

Social Psychology's Professional and Intellectual Roots

American Psychological Association

Division 8 of the American Psychological Association, the Society for Personality and Social Psychology (whose membership is approximately 3500), portrays its focus as follows:

> *How do people come to be who they are? How do people think about, influence, and relate to one another? These are the broad questions that personality and social psychologists strive to answer. By exploring forces within the person (such as traits, attitudes, and goals) as well as forces within the situation (such as social norms and incentives), personality and social psychologists seek to unravel the mysteries of individual and social life in areas as wide-ranging as prejudice, romantic attraction, persuasion, friendship, helping, aggression, conformity, and group interaction. Although personality psychology has traditionally focused on aspects of the individual, and social psychology on aspects of the situation, the two perspectives are tightly interwoven in psychological explanations of human behavior (Society for Personality and Social Psychology Web site, 2002, http://www.spsp.org/what.htm).*

American Sociological Association

Compare the above to how the Social Psychology Section of the American Sociological Association represents its focus:

> *Our emphases have been on the effect [of the] organization of social life on people's thoughts, feelings, and behavior, and how face-to-face interaction reproduces society. The Social Psychology Section of the ASA works to keep the spirit of social psychology alive in sociology. Today we represent over 600 scholars whose interest include self-conceptions and identity, social cognition, the shaping of emotions by culture and social structure, the creation of meaning and the negotiation of social order in everyday life, small group dynamics, and the psychological consequences of inequality. Many section members also identify with other areas of sociological research. But all bring to their research and teaching a special interest in the individual as both a social product and a social force. The common desire is to understand the many connections between individuals and the groups to which they belong (Social Psychology Section Web site, 2002, http://burkep.libarts.wsu.edu/SPNews/Purpose.htm).*

Clearly, there is much overlap across the two representations. For instance, both illustrate an emphasis on human social behavior and both reflect an interest in longstanding social concerns such as aggression and inequality. Yet these representations also reflect subtle differences between psychological social psychology and sociological social psychology, as, for example, in the former's emphasis on explaining individual outcomes and the latter's additional emphasis on the individual as a reflection of society. These different foci may, in turn, reflect the different intellectual roots that led to the development of social psychology within each field.

Intellectual Roots of Social Psychology in Psychology and Sociology

Generally, psychological social psychology recognizes three important intellectual influences: psychoanalytic theory, behaviorism, and Gestalt psychology. The psychoanalytic tradition, associated with Sigmund Freud, links an individual's behavior to psychological conflicts the individual experienced as a child within his or her family. Thus, (1) early social interaction plays a critical role in subsequent adult behavior, and (2) psychological conflicts that arise in these interactions generate motivations for subsequent behavior. The role of individuals as determinants of a focal actor's behavior is also found in behaviorism. Behaviorism, associated with John Watson and B. F. Skinner, demonstrates how behaviors are learned, primarily through the reinforcing and punishing responses of others to an individual. This line of research illustrates the important role that external stimuli (including others) have in eliciting behavior and portrays individual behavior as responsive to external forces. Finally, Gestalt psychologist emphasize how individuals think about people and objects. Central to Gestalt psychology is the notion that actors experience and understand the world in holistic, dynamic, subjective terms, rather than discrete, objective events and units. That is, the context of a unit contributes to how it is understood and experienced. While this perspective has had a strong impact on cognitive psychology (in terms of influencing theories of perception, memory, and recall), it has also led psychological social psychologists to attend to the effects of the environment (including other social actors) on human behavior. In this regard, the influence of Kurt Lewin and his field theoretical approach, emphasizing the interdependence of physiological, psychological, and social forces on social behavior, has been far reaching. In sum, these intellectual traditions each convey the importance of the social environment in determining an individual's behavior.

In contrast, although sociology is often associated with the study of macro social issues, early sociologists also

noted that social patterns reflected in individual actions, like deviance, could be attributed to social forces rather than individual motivations. These insights encouraged attempts to document effects of social forces and patterns of individual actions and emphasis on collective outcomes and group processes by early researchers such as Georg Simmel, who argued that interactions generate social reality. Social interaction among individuals, according to this work, produces society; an insight shared by Charles H. Cooley in his portrayal of society and the self as equivalent. Along similar lines, a unique form of behaviorism, social behaviorism, was being conveyed by George H. Mead through lectures in the philosophy department at the University of Chicago. The influence of social behaviorism on sociological social psychology can be contrasted with the influence of Watson's and Skinner's psychological behaviorism, described earlier. The influence of psychological behaviorism within sociological social psychology led to the development of social exchange theory, which portrays social outcomes as the product of actors' rational attempts to maximize rewards (both social and material) and minimize costs in their interactions with one another. This line of work also draws heavily on seminal theorizing on social structure by Georg Simmel, who emphasized the importance of group compositions and the configuration of relations among group members. Early sociometric research, pioneered by Jacob Moreno and developed today in the form of social network analysis, has also been an influential intellectual tradition. Social network analysis examines social outcomes as the product of relations between individuals (e.g., exchange relations) and how relations within collectives of individuals are configured. By comparison, social behaviorism casts human action as the outcome of membership in social groups, or more specifically, as the result of particular roles one assumes in different groups, and the interactions with others that those roles engender. Action, in turn, can alter the social environment. Thus, human behavior is a consequence, cause, and reflection of the social environment developed through interaction with others. This orientation toward human social experience led to the development of an important sociological perspective, symbolic interactionism, which traces human thoughts, feelings, and behavior to interaction with others in which meanings and expectations are conveyed through the exchange of symbols (e.g., words, gestures, signs). From this perspective, social environments are situations that are proactively constructed by individuals, rather than situations to which individuals react. As a result of both strains of behaviorism, sociologists gained interest in micro-level dynamics of social interaction, leading to a distinct orientation toward social psychology that emphasizes the effect of social structure on patterns of interaction between individuals and ultimately human behavior.

As this brief overview of a few key influential intellectual streams reveals, psychological social psychology and sociological social psychology can both be traced to shared acknowledgment of the embedded nature of human behavior. Yet, psychological traditions tended to steer the study of this embeddedness toward a focus on how it motivates human behavior, while sociological traditions began to treat the embeddedness as indicative of how human behavior reflects society. As a result, it is not surprising that social psychology is represented in slightly different ways by psychological and sociological professional associations. There are similar subtle differences in the organization of the curricula in the two disciplines.

Organizing Topics in Social Psychology

The landscape of social psychology is reflected in the organization of how it is taught. Table I depicts the organization of three textbooks that were commonly used by faculty teaching undergraduate social psychology courses in top-ranked sociology and psychology departments and psychology departments in 2001 and 2002. Some of the differences across the two orientations are not surprising. For instance, all three sociology textbooks give explicit attention to collective behavior, group behavior governed by norms that spontaneously emerge within the group (rather than the norms of the society in which the group is embedded). In contrast, this topic was not an organizing topic for psychology textbooks. This, however, appears to be consistent with the more macro orientation of sociological social psychology. Likewise, deviance, which is defined as behavior that violates the norms of a group or society and is thus a societal concern, is treated explicitly through dedicated chapters in textbooks used in sociology, but not those used in psychology.

Perhaps more surprising, at first glance, is that sociology textbooks dedicate chapters to communication, social structure and personality, socialization, and social power—seemingly micro-level areas of interest—while these are not given focal attention as organizing areas of the field in psychology textbooks. Also, psychology textbooks differentiate the study of social cognition and social perception, according each topic separate chapters, while sociology textbooks tend to treat both topics within a single chapter. These patterns correspond to a key difference between sociological and psychological treatments of social psychology. Each focuses on a different mechanism as a critical determinant of human experience. Throughout the sociological discussions of social psychology, the concept of social structure is given a prominent role, while throughout psychological discussions of social psychology, the concept of information processing is accorded prominence.

Table I Organization of Three Commonly Used Social Psychology Texts in Social Psychology Courses in Psychology and Sociology Departments[a]

	Textbooks used in psychology			*Textbooks used in sociology*		
Chapter topics	*Aronson, Wilson, and Akert (2002)*	*Taylor, Peplau, and Sears (2002)*	*Franzoi (2002)*	*Michener and DeLamater (1999)*	*Wiggins, Wiggins, and Van der Zanden (1994)*	*Stephan and Stephan (1990)*
Intro to social psychology	1		1	1		1
Theory		1	1	1	1	2
Methodology	2	1	2	2	1	3
Social cognition	3	2	5	5	6	9
Social perception	4	3	4	5	6	9
Communication				7	5

Applications		[c]			[c]	17

[a] Numbers in table cells correspond to chapter numbers. Top-ranked programs were those listed in *U.S. News and World Report's Guide to Graduate Programs*, 2001. Three textbooks were used by 90% of the top-10 programs in each discipline. Parentheses indicate that the topic is given cursory treatment in the chapter.

[b] Entire textbook is developed around a theme of social influence (i.e., individuals are affected by others).

[c] Applications of social psychology are given specific explicit treatment in each chapter.

The influence of these mechanisms is also reflected in differences in the conceptualization of common terms. For instance, sociological social psychologists conceptualize personality somewhat differently than psychological social psychologists. Within sociological social psychology, personality refers to psychological attributes and values that differentiate groups of people. Within psychological social psychology, personality refers to traits and motivations that determine individual behaviors. As noted by House in 1990, sociological interest in personality emerged from cross-national comparisons in which researchers found that values, beliefs, and experiences of people were relatively consistent within a nation state, yet varied across states. Furthermore, within a nation state, systematic differences in the values and attitudes of groups are associated with social structural

positions. For example, researchers using a social structure and personality perspective have found that the occupational positions, socioeconomic status, and educational attainment of individuals (i.e., the categories individuals occupy in the social structure) account for their attitudes and beliefs. In summary, while the term personality reflects a group-level phenomenon in sociological social psychology, it is largely considered an individual-level phenomenon within psychology. In fact, two of the three psychological social psychology textbooks present social psychology as an alternative to personality psychology for explaining human thoughts, feelings, and behaviors. Moreover, psychologists tend to study personality as an independent variable that determines behavior, whereas sociological social psychologists tend to view personality as a dependent variable, arising from one's position within the social structure.

The topics of communication, social power, and socialization, unique to sociology textbooks, are also linked to the concept of social structure. For instance, communication, the exchange of ideas, feelings, and information between individuals, is studied in terms of (1) how meanings are constructed within and vary across cultural groups, and (2) how communication styles vary according to one's position within the social structure. Social power, the ability to induce compliance on the part of another, even when the person resists the attempt, is understood as a function of an individual's control over resources (i.e., valued commodities). Resource control, in turn, depends on one's position within a social structure; more specifically, the extent to which one is socially connected to others who possess resources, as represented by social exchange theory. Sociological social psychologists also study socialization, the process by which individuals learn social norms, values, and beliefs, from a structural standpoint. Socialization is a function of interaction with others, and interaction is determined by one's position in the social structure. Indeed, sociological social psychologists recognize socialization as a recurring lifelong process, as indicated by unique attention given to the topic of the life course in sociology textbooks. The life course is the study of patterned changes in the positions an individual occupies in the social structure that lead to the adoption of new norms, values, beliefs, and patterns of behavior emanating from these changes throughout one's life.

Additionally, as noted previously, the topics of social cognition and social perception are treated separately within textbooks used with psychology programs, whereas they are treated within the same chapter in textbooks common to sociology programs. The emphasis of psychologists on these two components of information processing may reflect the intellectual roots of this strain of social psychology in gestalt psychology, as was described above. Social cognition refers to how individuals perceive and process information related to the social world, while social perception refers more specifically to how information is used to form impressions of other people and generate inferences regarding the causes of others' behaviors. Within the field of cognition, psychological processes of attention, memory, and recall are central topics of concern, and researchers offer detailed accounts related to how information is mentally organized (e.g., categorically through schemata) and remembered (e.g., through heuristics, or mental shortcuts). These processes, in turn, generate biases that affect how the information is used. Thus, the study of cognition has important implications for social perception insofar as information that is biased through cognitive processes can become the basis for impressions that individuals form of others and inferences that individuals make regarding the causes of their own and others' behaviors.

Despite these differences, however, it is clear that there is substantial overlap in the topics that sociologists and psychologists study in the context of social psychology, as represented by the organization of textbooks. In particular, the nature and content of the self is a central concept in social psychology. However, consistent with differences in the two strains of social psychology, the self assumes a different theoretical role. The self as the embodiment of a person's knowledge of who he or she is (i.e., the self-concept) is a variable to be explained within psychological social psychology. In contrast, drawing primarily on the intellectual traditions of Mead and Cooley that were described earlier, sociologists conceptualize the self as a capacity for reflexive action. Reflexive action, behavior that is guided by one's ability to view oneself as an object in the same way one is viewed by others, represents an important cause of social behavior within sociological traditions.

The remaining overlapping topics share common conceptualizations across psychologists and sociologists. Both psychological and sociological social psychology textbooks portray attitudes as relatively enduring evaluations of people, objects, or events. Attitudes have been a topic of ongoing concern among both psychological and sociological social psychologists, dating back to Louis Thurstone and Rensis Likert's important work on attitude measurement in the 1920s and 1930s, and subsequent work by Leon Festinger and others on attitude change. Conformity is conceptualized in both sociology and psychology as behavior that is determined by the norms (i.e., rules for behavior) that are set by others. Persuasion involves the intentional use of information to change the beliefs or attitudes of another. Conformity, persuasion, and social power (discussed earlier) are subsumed by the more general concept of social influence, which refers to the effect of others on an individual's thoughts, feelings, or behavior.

Interpersonal attraction, another topic common to both psychological and sociological social psychology

textbooks, involves the study of factors that lead individuals to develop strong positive attitudes toward others that foster a desire for increased interaction with the others. The related topic of interpersonal relationships refers to the study of interactions that are based on a high degree of interdependence and strong emotional bonds between the individuals. Two behaviors of particular interest to social psychologists, aggression (behavior intended to harm another) and pro-social behavior (behavior intended to benefit another) receive primary attention in both sociological and psychological social psychology textbooks, as does prejudice (enduring negative attitudes toward members of a social group based on their membership in the group).

Not only do social psychologists in both sociology and psychology share common topics of concern; they also share a variety of research methods. As noted in the textbooks, experimental methods are a common research strategy in social psychology, but their use tends to be more dominant among psychologists, while survey methods are the most common research methodology used by sociological social psychologists. Also, observational methods receive attention in the discussion of how social psychological research is conducted, though observation is less common to research conducted in both psychological and sociological social psychology.

In summary, psychological and sociological social psychology textbooks used in top-ranked departments suggest substantial commonality with respect to the topics that are studied by both psychologists and sociologists. Differences arise primarily in the focus of each discipline on different mechanisms that explain human social experience: while psychologists focus on information processing, sociologists focus on social structure. These differences are also reflected in research articles that appear in the top psychological and sociological social psychology journals.

Research Areas in Social Psychology

Areas of research in social psychology were studied by examining the subheadings listed in the PsycINFO database for articles in the social psychology journals sponsored by the American Psychological Association (*Journal of Personality and Social Psychology*) and the American Sociological Association (*Social Psychology Quarterly*) from 1997 through 2001. The subheading assignments for some articles were more specific than others. For example, one article might be categorized under the subheadings social schema, attention, and human information storage, while another article might be categorized under the single subheading social cognition. Consequently, the categorizations of all the articles were examined, and the more specific subheadings were reclassified under the more general ones (details regarding the procedures used for this reclassification are available from the first author on request). In addition, despite the clear distinction between social cognition and social perception that characterized psychological social psychology textbooks, these subheadings appeared to be used interchangeably in the categorization of articles for both *JPSP* and *SPQ*. Thus, articles with subheadings referring to either social cognition processes or social perception processes were reclassified under the more general term social cognition and perception. The top-10 subheadings in terms of their commonality for *JPSP* and *SPQ* are given in Table II.

Overall, the list reveals striking similarities and a few notable differences. Just 12 subheadings capture the top-10 subheadings of both journals, suggesting a strong degree of overlap across sociology and psychology in the areas that garner the most research attention. Note also that the topic of social cognition and social perception is the most common for articles in both *JPSP* and *SPQ*, but it is about twice as common in *JPSP* as in *SPQ*. In fact, *JPSP* appears to be dominated by the top three or four topics, while differences in the frequency of one topic to

Table II Rankings of Ten Most Common PsycINFO Subheadings for Articles in *Journal of Personality and Social Psychology* and *Social Psychology Quarterly* from 1997 through 2001 (Commonality in Parentheses)[a]

Subheading	*JPSP (number of articles = 906)*	*SPO (number of articles = 122)*
Social cognition and perception	1 (0.430)	1 (0.205)
Personality	2 (0.253)	17 (0.074)
Self and identity	3 (0.207)	3 (0.197)
Social group differences	4 (0.199)	8 (0.148)
Emotions	5 (0.194)	9 (0.131)
Attitudes	6 (0.179)	1 (0.205)
Interpersonal relationships	7 (0.108)	5 (0.164)
Social interaction	8 (0.099)	10 (0.115)
Group processes	9 (0.097)	7 (0.156)
Sex and gender	10 (0.089)	3 (0.197)
Status	31 (0.028)	5 (0.164)
Social power	72 (0.006)	10 (0.115)

[a] Commonality is the frequency of the subheading divided by the total number of articles in the journal from 1997 to 2001. The analysis of *SPQ* articles was replicated in the Sociological Abstracts database using the descriptors assigned by this database to articles. For nearly every article, the subheadings assigned by PsycINFO were also assigned as descriptors by Sociological Abstracts. Thus, the analysis using Sociological Abstracts did not generate different results with respect to the rankings of the different topics.

the next are smaller in *SPQ*. There are a few other differences. For instance, differences arise in the prominence of status in *SPQ* (ranked fifth), and the lack of attention this area received during the same period in *JPSP* (ranked 31st). Status, the degree of social value (usually assessed in terms of prestige and esteem) accorded to actors, is generally linked to an actor's position in the social structure and is an important precursor of social influence. The processes linking status to influence (status generalization processes), detailed in status characteristics theory, describe how attributes valued in the larger society in which a group is nested become important determinants of reward allocations, competency expectations, and action within the group. Social power (which ranked 10th in *SPQ* and 72nd in *JPSP*) is also tightly coupled with the concept of social structure, and is a central concept in social exchange theory. Personality is ranked second in *JPSP*, but only 17th in *SPQ*. Its high ranking in *JPSP* likely reflects the fact that the journal is a forum for both personality psychologists and social psychologists. Given that sociological social psychologists consider personality in the context of social structure (a major area within sociology), the relatively low ranking in *SPQ* may seem curious at first. However, an examination of articles in *SPQ* adopting the social structure and personality perspective reveals that most were classified in terms of social group differences without reference to the term personality. This is not surprising, because the sociological researchers who adopt this perspective rarely invoke the term personality and instead refer to social groupings and the attitudes and interaction patterns that correspond to different social groups.

One area that characterizes a substantial amount of research, emotion, was not accorded a central organizing role in textbooks, perhaps reflecting its emerging importance in social psychological research. Emotions, the feelings of actors toward themselves, others, and events, affect and are affected by a wide array of social psychological processes. For instance, both psychologists and sociologists have proposed that emotions are socially constructed and governed by social norms. Also, sociologists have proposed that emotions play an important role in the development of one's sense of self. Yet both sociologists and psychologists recognize the biological and physiological dimensions of emotions, in addition to their social psychological dimensions.

Conclusion

Social psychology is a far-reaching field with implications for every facet of human life that gains attention in any discipline concerned with social and behavioral sciences. The fact that both psychologists and sociologists accord social psychology a prominent place in their disciplines indicates the interdisciplinary nature of the topic. Additionally, it suggests that bringing different intellectual orientations to the study of social psychological phenomenon can generate important insights for the social and behavioral sciences. Some reviews of social psychology have decried the lack of integration of psychological and sociological perspectives and research. However, as noted in our assessment of both textbooks and research articles, there is an indication that such integration is occurring, as represented by the striking overlap in research topics. Furthermore, all three sociology textbooks and one of the psychology textbooks explicitly note that social psychology is a branch of both sociology and psychology.

The strategy used here for systematically assessing the field in terms of sociological and psychological orientations may have unintentionally led to the illusion that there are more differences than similarities across these approaches to social psychology, or that any differences may be counterproductive to the growth of social psychological knowledge. To the contrary, the differences contribute important new insights and critical avenues of integration, which may lead to an enhanced body of knowledge that informs the social and behavioral sciences. Moreover, we believe that shifts in the technological and research landscape are likely to catalyze integration across the two disciplines. For example, as online databases such as PsycINFO continue to archive both sociological and psychological sources, researchers are more likely to stumble upon useful insights of others from a different orientation. Additionally, print and online journals with explicit interdisciplinary orientations (such as *Journal of Social Psychology* and *Current Research in Social Psychology*) may also facilitate the flow of knowledge across disciplinal boundaries. Likewise, increased attention to the importance and value of interdisciplinary research by higher education institutions and organizations that support research in the social and behavioral sciences may motivate further collaborations by researchers trained in different orientations. These promising shifts make it all the more important to continue to represent the interdisciplinary nature of social psychology and the topics that are covered in both sociological and psychological research. As noted by Michener and DeLamater in 1999 (p. 5; italics in the original), "*Social psychology* bridges the gap between sociology and psychology . . . As we might expect, this leads them to formulate different theories and to conduct different programs of research. Yet, these differences are best viewed as complementary rather than conflicting. Social psychology as a field is the richer for them."

Social Work

Stephen M. Marson
University of North Carolina, Pembroke, North Carolina, USA

Glossary

action system A social entity (micro, mezzo, or macro unit) that participates in an effort of planned systematic change for a client system.
change agent system A social worker or other social entity that spearheads a planned change for a client system.
client system A social entity (micro, mezzo, or macro unit) that establishes a contract for a positive change with a change agent. Client system is often abbreviated with the term "client."
Council on Social Work Education (CSWE) The organization held responsible by the Council for Higher Education Accreditation for establishing and maintaining educational standards for professional degrees in social work.
formative measures Usually a qualitative-based measurement or observation that attends to the process of a change.
operationalization A process by which a social worker or researcher moves from the abstract (concepts) to the concrete (variables).
single system design Based on statistical concepts found in control charts, it is the systematic measurement of change over time that usually includes a statistical conclusion regarding the effects of an intervention.
social worker A person who has successfully completed a baccalaureate or master's degree from an academic program accredited by the Council on Social Work Education.
summative measures Usually a quantitative-based measurement that attends to the outcome of a change.
target system A social entity (micro, mezzo, or macro unit) that is the focus of a change by a change agent and other social systems.
total institution An organization that mandates rigorous interaction patterns among its participants. Total institutions are particularly effective at maintaining accurate records that can be used for measuring baselines. The term was coined in Erving Goffman's *Asylums*.

Social work has a rich history upon which social measurement is an important foundation. Although the general public often perceives social work as the delivery of services to individuals, it is much more than that. Graduates of Bachelor of Social Work (BSW) programs and most Master in Social Work (MSW) programs receive instruction in providing a wide range of services to highly diverse client systems. The term client system is used to stress the notion that clients can be individuals, social groups, or organizations. Social measurement is a critical dimension of all social work practice, regardless of the sizes of client systems (micro, mezzo, or macro). In studying social measurement in the history of social work, it can be seen that the emphasis 100 years ago was placed on all types of client system problems. In the last three decades, micro and/or clinical practice dominate the literature of social work measurement. This recent trend does not suggest that social measurement fails to be a critical issue in macro practice; it merely indicates that less is written in the area. Most importantly, recent trends and future projects hint that social workers will see more social measurement literature with an emphasis on macro practice.

Introduction

Since the beginning of social work in the 19th century, assessing change with client systems has been an integral aspect of professional practice. Two dimensions of measurement are at the heart of assessing social problems. First is process. Here, social workers must gain insight into the steps involved to resolve a social problem. The measurement of a social problem can be addressed within

the client system, change agent, or target system. Currently and historically, process has been the most problematic issue to address in terms of measurement protocols. More creativity among social work practitioners and academicians is required within this arena.

Second is the issue of outcome. Unlike process, outcomes are easily conceptualized in terms of quantity. Thus, measurement of outcome is less problematic than the more "qualitative" process. The tools for demonstrating effective outcome measurements are available and learnable by social workers. This information comes to social work from psychometrists and their literature of tests and measures. In essence, social workers apply psychological principles of reliability and validity to the measurement of change within social problems.

History (Measurement Themes)

When first envisioning social work, one does not immediately think of social measurement; rather, one is most likely to picture the dissemination of welfare checks or removal of children from an unsafe environment. More recently, the delivery of psychotherapy as part of an agency service or in private practice may be envisioned. However, none of these visions captures the historical foundation of social work. The birth of professional social work practice can be found in social research and social measurement.

Three phases or themes in the historical development of the profession's linkage to social measurement exist. In the first theme, the measurement of social problems was the hallmark of social work activities. In the late 19th and early 20th centuries, pioneer practitioners could not conceive of their budding profession without the systematic measurement of social problems at its heart; this was a unifying theme. Second, as academic institutions became the focus for the education of the social worker, the departmentalization of knowledge arose. Splitting or dividing a curriculum into educational components or sequences has always been thought to make the educational experience more palatable for students and more manageable for faculty. Thus, the importance of social measurement and research was conceptually disconnected to the delivery of social services to needy clients. Third, the final phase includes the realization that the conceptual disconnection between social work practice and social measurement is a fatal flaw in the education of social work professionals. This is the current stage in which the profession finds itself. Today, professionals are beginning to realize that social work must reestablish itself to promote the idea that social measurement and social work practice must go hand-in-hand. Thus, social workers are beginning to realize that we must return to the original vision espoused in the later part of the 19th century. Each of these three themes is briefly discussed in this article.

Unified Theme (Amos Warner and Mary Richmond)

To understand the historical relationship between measurement and the emergence of professional social work practice, the contents and contributions of the first social work text books, three in particular, must be reviewed. The first social work textbook was Amos Warner's *American Charities*, published in 1894. Warner received his Ph.D. in economics from Johns Hopkins University. His background led him to create a classification system for establishing priorities for the delivery of social services based on statistical measurements. Thus, this first widely used textbook adopted by the first social workers was empirically based on and emerged from the systematic measurement and analysis of social problems.

The second widely used textbook was Mary Richmond's 1898 *Friendly Visiting Among the Poor*. Compared to *American Charities*, Richmond's book is considered to have had less of a social science influence. Richmond questioned the reasons for frequent failures found in social work intervention. Her effort was to systematically review failures on a case-by-case basis and draw conclusions to improve the delivery of social work services.

This effort led to Richmond's landmark social work textbook of 1917, *Social Diagnosis*. Within the pages of *Social Diagnosis*, Richmond shifted her priorities and took a strong stand on the use of social science inquiry to identify and resolve social problems. Specifically, she advocated the systematic measurement of social problems. She warned her readers of the problems of social measurement (e.g., illiteracy of clients, cultural differences that produce different meanings for the same item on a measurement scale). However, she unambiguously contended that social measurement is a critical tool for the social work practitioner. To emphasis this point, she included a wide range of measurement protocols that could be employed by the social worker for the identification and resolution of social problems, including general family issues, the immigrant family, widows with children, neglected children, unmarried mothers, blind persons, homeless men, persons with intellectual limitations, and persons with a mental illness.

Disunified Theme (Academic versus Practitioners)

Although Richmond can be seen as a pivotal figure in emphasizing social measurement for social work practitioners, she is also a pivotal figure in a movement to disengage from measurement as an integral aspect of

social work practice. With the publication of *What Is Social Case Work?* in 1922, Richmond neglected to note the importance of measurement, but rather placed emphasis on casework as a method of practice. Why do we see this major shift in Richmond's approach?

The answer to this question may lie in the unspoken prestige that existed in the academic community at that time. For example, during the first meeting of the American Sociological Society in 1905, a discussion on whether to prohibit membership to "practical sociologists" (social workers) can be found in the minutes. In the minutes of the second meeting, there is a continuing discussion of liabilities and merits of allowing social workers to join. Eventually, social workers were permitted to join, but they took a subordinate role in the society. At this point in social work history, lines of division between academic and practicing social workers began to form.

Lurie continued this theme in the *Social Work Year Book*, published in 1929. Research completed by social work practitioners was criticized for merely focusing on specific needs of the agency. In addition, the quality of the information generated by the representative agency was based on its prestige within the community rather than "measurement methods, process and results" (p. 418). Lurie also contended that some of the worst studies ever published came from practitioners rather than academicians, stating that such studies were "statistically dubious and showed an amazing ignorance of logic and of the scientific method" (p. 418). These strong words unintentionally led to a rift between the academic community and the community of practicing social workers.

The issue becomes more apparent as one examines the type of research being published by academicians. The research questions relate to social problems, but do not capture the essence of what was needed by practitioners. The central problem, of course, was an issue first introduced by Richmond—measurement of social problems. Academicians were selecting research questions that included elements in which measurement protocol achieved social scientific standards. Practitioners wanted research in areas in which concepts were difficult, if not impossible, to measure. For example, Lurie cited a wide range of research contributions produced by academicians that were thought to be important to practicing social workers. All of these cited studies offered a degree of theoretical value, but offered little to no use for the typical social worker, who asked the question, "What should I do with this client [system]?"

Unified Theme (Integration of Academic and Applied)

Issues of social measurement appear to be at the heart of the schism between practice and scholarship. However, three significant pieces of writing began to change the direction of both social work practice and social work scholarship. The first is a landmark textbook entitled *Social Work Practice: Model and Method*, written by Pincus and Minahan in 1973, which introduced a major paradigm shift in conceptualizing social work practice. Not since the publication of Richmond's *Social Diagnosis* has a text had such a dramatic effect on the practice of social work. In addition, Pincus and Minahan gained international attention and influenced the conceptualization of service delivery in both clinical psychology and psychiatry. In terms of measurement, the central focus of this textbook was outcome. The authors noted a distinction between client system process and client system outcome. In addition, they suggested that the system process is not measurable. Thus, the authors asked social workers to concede that some of the central ideas of measurement and evaluation introduced by the founders of the profession were misdirected.

Although Pincus and Minahan's observations do not seem dramatic by today's standards, their framework rejuvenated intellectual excitement within social work circles. In terms of measurement, these authors gave the profession a coherent direction to follow. Following this lead, *Evaluating Practice: Guidelines for the Accountable Professional*, by Bloom and Fischer, was published in 1982. These authors began to systematically apply concepts introduced by Pincus and Minahan. By employing single system designs, they produced a tight focus on the systematic measurement of outcomes in social services. Single system designs gave practitioners what they needed. First, these designs enabled practitioners to systematically assess outcomes, resulting in a common standard of successful outcomes. Such a standard never existed in the history of social work. Second, subjective impressions of successful outcomes were stripped away from the social worker and/or supervisor. In the past, the successful change of a target system was primarily based on perception of the change agent. With single system designs, successful outcomes were based on rejecting a null hypothesis. The scientific dimension of social work practice was no longer merely lip service. Change agents were given a tool to apply the scientific method to social work practice.

There are several serious drawbacks, however, in the employment of single system designs. First, measurement tools are necessary for the employment of single system designs. Although counting problematic behaviors is an appropriate approach for measuring, counting certainly cannot be considered the only option available for practitioners; rather, more sophisticated methods are required. Social scientific standards related to reliability and validity must be met. These standards are necessary not only for proper identification of a social problem, but also as a basis for ethical intervention. Social work

practitioners do not have the time, energy, or resources to develop a measurement that complies with social scientific standards. This problem can be seen within Richmond's *Social Diagnosis*; she was aware that her proposed measurements lacked scientific rigor.

To address this problem, in 1987 *Measures for Clinical Practice: A Sourcebook* was published. The authors, Corcoran and Fischer, searched the literature for instruments that demonstrated practical and research applications. They studied and reported on the calibration issues for each instrument that included scoring, sampling, reliability and validity. They offered enough information for the change agent to answer the question "Should I use this measurement for my client?" To support this critical practice question, most social work research textbooks include sufficient instruction for BSW and MSW graduates in the area of reliability and validity analysis. Although there are numerous monographs that achieve the same goal as the work of Corcoran and Fischer, their work included instruments that both are directly relevant to social work practice and research and have a great deal of practical application. Social workers have demonstrated such strong support that the book is in its third edition; it now offers approximately 342 instruments for clinical practice.

In terms of measurement, the introduction of single system designs for social work practice has two major drawbacks. First, the most worthy single system designs require a baseline measure. In the real world of social work practice, baselines may be either unethical or not possible. For a victim of severe depression, the change agent would be irresponsible to institute a baseline measurement. Clearly, such a strategy would be a foundation for a malpractice lawsuit. Second, real measurement (this excludes *ex post facto* or reconstructive measures) is rarely available for agencies that operate on an out-patient basis. On the other hand, these designs and associated measurements are clearly appropriate and most effective in total institutions, such as schools, nursing homes, prisons, and hospitals.

Regarding the state of the art of measurement in social work, the profession today seems to be facing a measurement problem nearly identical to the one faced at the beginning of the 20th century. In addition, one important conclusion from measurement in social work history can be drawn. The profession has made little to no contribution to the social measurement knowledge base. Essentially, social work researchers/academicians and change agents have been adopting measurement ideas (mostly from psychology) and applying these concepts to social work research and practice. However, in projecting from the past and examining current trends, it appears that social work is on the threshold of making a significant contribution to the social measurement knowledge base. Perhaps this is the beginning of another paradigm shift.

Current Standards of Practice and Scholarship

Currently, there are two trends related to measurement in the professional education of social workers. These trends focus on research methods and the educational outcomes for BSW and MSW graduates as articulated by the Council on Social Work Education. On the BSW level, the central focus is twofold. First, BSW social workers are trained to be consumers of research. BSW graduates are expected to use research findings of others to advance their skills as a change agent. Thus, students are introduced to social science research vocabulary and concepts such as reliability and validity. Second, they are expected to employ social science methods to the evaluation of practice. Evaluation is measurement. On the MSW level, we also see a twofold focus. First, MSWs are trained to be research producers and are considered leaders of the profession. Second, like the BSW students, they are expected to apply social science knowledge to practice evaluation. If research professors are earnest in their efforts, the profession will witness huge cohorts of budding professionals developing strategies for the measurement of social problems.

Operationalization

In teaching research methods with the focus described above, professors stress the concept of operationalization. In practice situations, social workers rarely intellectualize on the concrete or variable level. However, funding sources and record audits are demanding measurable outcomes. In nursing homes, failure to comply with this standard can lead to a penalty (fine). Thus, measurement of social problems is a critical issue, and social work professors attempt to address this issue by using models similar to Fig. 1. Here, students are taught the relationship between theory and research, concepts and propositions, and variables and hypotheses, and how to move from abstract thought processes to concrete measurable social problems. Without the discipline of thought processes, social workers cannot demonstrate that client systems are improving.

However, a critical problem remains. The focus of the social work research curriculum assumes that social problems must be quantified to be measured. In the real

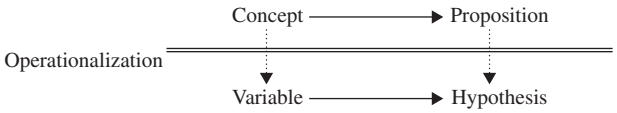

Figure 1 Central problem of measurement for social work practice.

world of social work practice, this assumption is seriously flawed. Two strategies from the academic side of social work attempt to address the issue. In the first, DePoy and Gitlin in 1998 introduced a non-traditional relationship between quantitative and qualitative research methods. They stated that the difference is not discrete, as most other authors suggest, and took the position that there is an interactive property. These authors made an obvious point that is often disregarded by most social work researchers: The nature of the research question guides the method of measurement. Taken to its extreme, one can assume that the various research strategies outlined in their book will have an impact on conceptualizing measurement of client system processes. As stated earlier, the measurement of process was conceived as out of the realm of possibility. Social workers need a new comprehensive framework.

In 1991, Alter and Evans provided such a framework, as shown in Fig. 2. This figure illustrates a common perspective shared with DePoy and Gitlin. Alter and Evans discarded the notion that outcome is the only measurable entity; rather, the change agent can measure introspectively in the realm of process and outcome (Fig. 2, right column). In addition, the change agent can measure client and target system change in terms of both process and outcome (Fig. 2, left column).

Alter and Evans advocated two different approaches to achieve their goal. First, they endorsed the position of DePoy and Gitlin. Here, they suggested that the issue of the systemic analysis of qualitative information should be revisited. Both DePoy and Gitlin and Alter and Evens stressed that social workers have not spent adequate time addressing the importance of qualitative analysis. However, Alter and Evens provided a slightly different twist when they contended that qualitative and quantitative data are not discrete entities; rather, they fall on a continuum. Second, they made systematic efforts to quantify qualitative information, advocating the use of target problem scaling and goal attainment scaling as methods of measuring process. Both of these methods have the unique characteristic of placing a numerical value on qualitative data (usually ordinal, but sometimes nominal) in an effort to measure change over time. The great strength of Alter and Evens and DePoy and Gitlin is that their work has strong implications for measurement for all social work practice—not just clinical and/or micro practice.

		Central focus of measurement	
		Client system or target system	Change agent system
Measurement strategies	Formative	Observations that monitor process or activities of client or target systems (usually qualitative)	Observations that monitor the actions/ performance of the social worker (usually qualitative)
	Summative	A measurement of the outcome of intervention (usually quantitative)	A measurement of the level of success achieved by the social worker (usually quantitative)

Figure 2 Measurement options in social work practice. Adapted from Alters and Evens (1990), p. 29.

Current Trends in Measurement

Three patterns of measurement strategies are commonly employed among practicing social workers and social work academicians: consultation, construction, and counting.

Consultation

Thousands of instruments are available and published today. The developers of such instruments have calibrated them to reach respectable levels of reliability and validity. Social workers are trained to identify when an instrument is usable for social work practice. Most importantly, many of these instruments can be found in books and on the Internet with a minimal investment of time, effort, and cost. If traditional social work citations fail, the *Mental Measurements Yearbook* can be explored. It is rare for a social worker to employ a concept that has not been operationalized.

Construction

Although it is unlikely that a social work practitioner or researcher cannot locate an instrument that is needed, that event is a distinct possibility. In addition, an instrument may be available, but the level of reliability and validity may be unacceptable. Reliability and validity of instruments become a critical issue for judges during a hearing. In such a case, the social worker must design an instrument. Instrument construction is an academic enterprise. Under normal circumstances, it takes well over a year for an instrument to reach a threshold of reasonable level of reliability and validity. Construction of new instruments is not recommended for full-time practitioners, but in some cases, no other alternative will be available.

Counting (Monitoring Designs)

For decades, social workers have been counting observations over time. Summaries of the reliability and validity of this strategy can be found in the behavior modification literature. Counting or monitoring is completed by the change agent (includes agency staff), the client system, or a combination of both. Although counting is normally an exercise to assess an outcome, if creative, a change agent

can employ monitoring to address issues of process. Following is a case illustration:

A nursing home patient was referred to a social worker because of a severe and life-threatening weight drop for which medical staff could not identify a cause. The social worker completed a psychosocial assessment that included the geriatric depression scale. There was no indication of depression or terminal drop. First, as illustrated in Fig. 3, the social worker examined the pattern of weight loss over time. From the data, it is clear that significant weight loss occurred between March 3 and April 4. To assess eating patterns, Fig. 4 was constructed. Several graphs were developed prior to Fig. 4. The earlier versions were difficult to read because of the huge amount of data. In Fig. 4, the mean percentage of food consumed per day is presented (an example of data reduction). From Fig. 4, it can be seen that March 22 and March 31 are the last dates on which acceptable levels of food were consumed.

Examining every event that occurred within the time frame (March 22–31) eliminated a psychosocial cause for the weight loss. Every note in the patient's chart was examined. Finally, the staff discovered that the patient received a new prescription to reduce blood pressure. *The Physician's Desk Reference* stated that the drug worked as an appetite suppressant for some patients. The critical weight loss problem was resolved by simply changing medications. No one realized that the medication was the cause of the life-threatening problem until food intake and weight were measured over time.

This example illustrates that in some cases, the measurement of client process is a fruitful endeavor. However, many of the rules for graph making were violated. In Fig. 3, for example, the *x* axis does not include equal intervals of time. A student would have received a poor grade on such a graph. However, in the non-academic world, data is not clean. Despite the problematic data housed in the graph, the measurement was helpful in solving a real problem.

Measuring Social Work Competence Nationally

Currently all 50 states, Puerto Rico, the District of Columbia, and Canada regulate the professional practice of social work. Most of these political entities employ the use of an instrument to ensure that these professional social workers attain a minimum level of competency. Since 1983, the Association of Social Work Boards (ASWB) has been developing and maintaining respectable levels of validity and reliability of such an instrument. ASWB has four social work examinations that test BSW graduates, MSW graduates, and MSWs with two years of post-graduate experience, both generalist and clinical. For each exam, ASWB employs a national job analysis to determine relevant skills and knowledge of currently practicing social workers. From the job analysis, a blue-print for items is developed. Items are formulated in the proportion and frequency as indicated by the blueprint. From there, each item undergoes five to eight stages in which content validity is assessed. The minimum standard for establishing a respectable level of content validity costs the agency approximately $900 per item. With a test bank that includes several thousand items, attaining respectable levels of reliability and validity (for any measurement) is not only an intellectual enterprise, it is also a costly one. ASWB does the most thorough job of addressing measurement issues of reliability and validity for the practice of social work.

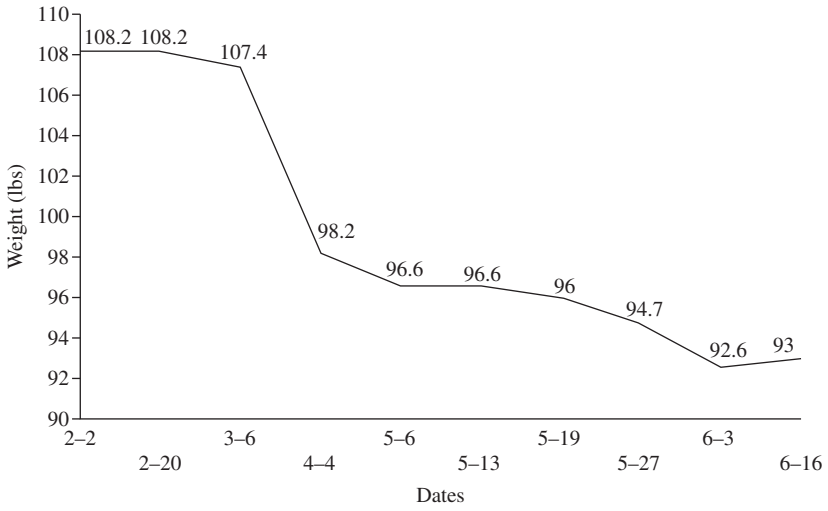

Figure 3 Weight change.

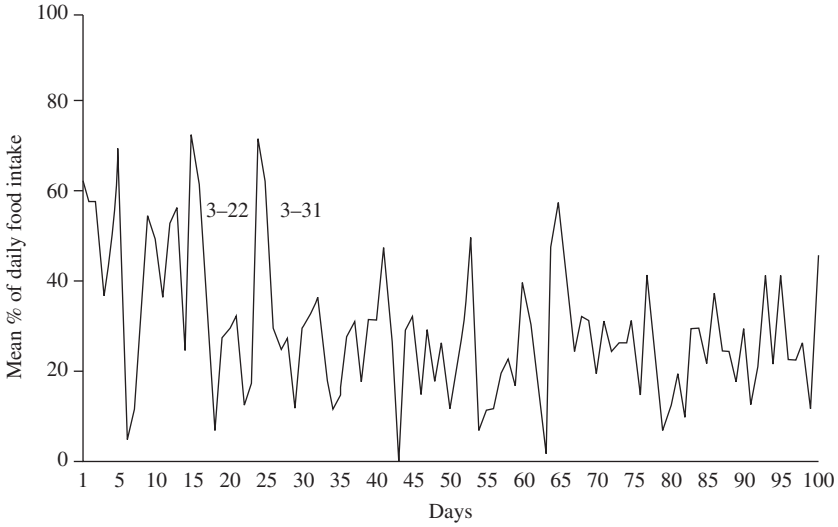

Figure 4 Food intake.

Other Issues

Issues of reliability and validity will always emerge in social work practice. For example, there is a surprisingly skewed distribution among 50 surveys addressing client satisfaction. It would be expected that the distribution of satisfaction among social service clients would be normally distributed. Among these 50 studies, the mean percentage of satisfaction is 78%. Essentially, this means that all 50 social service agencies are doing an excellent job. While this outcome is certainly possible, it is highly improbable. To most observers, such a finding is highly unlikely and probably is a result of the wording of the items. This, of course, is an issue of face validity. It should be acknowledged that the stakeholders are constructing the measures.

To address this and other issues related to measurement, the profession is moving to examine measurement in a more systematic manner. Two strategies are currently employed. First, the Council on Social Work Education is requiring BSW and MSW accredited programs to focus on the evaluation of practice. Such a program objective traverses the social work curriculum and facilitates resolving the problem noted earlier in our discussion of history of measurement in social work. With each succeeding cohort of graduates, greater insight into measurement problems will be solved.

Second, education is not enough. Professors and practitioners must have a forum to systematically address issues related to measurement. In this respect, social workers lag behind other academic disciplines and professions. During the fall of 2000, the inaugural issue of *The Journal of Social Work Research and Evaluation* was published. This journal focuses on issues of measurement and instrument development related to the delivery of social work services. The editors emphasize the importance of accepting manuscripts that include both quantitative and qualitative themes. If the journal remains true to its mission, there will be advances in the quality of measurement and in turn, the quality of service delivery.

Future of Measurement in Social Work

The best manner in which to assess the future of measurement in social work is to look at the profession's history. Several themes in this history are apparent. The first theme emerges from the work of Richmond. At the end of the 19th century and the beginning of the 20th, Richmond was well aware of the importance of accurate measurement in the effective delivery of social services to the indigent. Initially, she did not departmentalize measurement skills until the academic community demonstrated the lack of scientific rigor found in the measurements developed by practitioners. Although tension between the academic and practice arms of the profession still exists, the advent of inexpensive personal computers is diminishing its effects. However, unlike in the past, quantitative analysis of measurement may not be the central issue in social work.

The problem of social work measurement rests in the systematic examination of process. This includes client system process and change agent process. Over the past 100 years, very little work has been accomplished in this critical aspect of social work measurement. In fact, process only began to receive serious consideration during the 1990s. At this point, there is a consensus among researchers. Qualitative analysis is a legitimate approach for scientific

inquiry. The profession will move forward with increased interest and energy measuring social processes by employing qualitative methodologies. One critical area of analysis is the social history. The study of the social worker's social history is a desperately neglected area of study. The value of the qualitative measurement must receive greater scrutiny among practitioners and academics.

In terms of quantitative methods, social work will continue on its current path. Academicians will pursue social work concepts and operationalize them for use in practice, and practitioners may do the same. The Council on Social Work Education must continue its standards in the area of evaluation of practice. Social work scholars must provide a venue for the discussion and dissemination of measurement research.

Glossary

accuracy Validity or correctness of the measurement.
hard data Data that can be obtained through direct observation by measurement or counting.
metrics Measurements of interest to the entities—parts of the universe/environment/population—to be used for gaining insight, decision-making, policy formulation, performance evaluation, etc. In some cases, metrics and raw data coincide, e.g., they are the same. In general, however, metrics are the result of some analytic procedure or algebraic relationship/combination involving two or more raw-data variables/elements.
precision Obtaining a measurement value within a given range in a large number of observations. Precision is sometimes indicated by a margin of error expressed in (+/−) percentage points.
raw data Facts and figures that are, or have been, collected/extracted from some relevant entity—a part of the universe/environment/population—and stored to be used for providing information needed to gain insight, for decision-making, policy formulation, performance evaluation, etc. Most data are numeric.
socioeconomic aspects of social measurement Consideration of any and all, intended or unintended, environmental impacts on society as a whole, or any relevant subset thereof, resulting from the dissemination and/or use of a given measurement.
soft data Data representing estimates or subjective judgment extracted from individual persons or from groups.

This article addresses the socioeconomic aspects of social measurement. Raw data are differentiated from metrics (standards of measurement) as is collection/measurement done on an *as-needed* versus on a *just-in-case* basis. Precision is differentiated from accuracy with all its ramifications. The economic and social consequences of collecting the "wrong" data, or evaluating the "wrong" metrics are discussed. The article then addresses the need for serious deliberations regarding the end-uses of data/measurements invoking, but not limited to, the use of systems analysis techniques. These allow one to clarify such issues as: the potential uses of collected data/metrics, the needed levels of aggregation and precision, the stakeholders involved, and "soft" data as surrogates for "hard" data. Several real-world examples are invoked to illustrate all of the above. The article concludes with a number of admonitions regarding the socioeconomic aspects of social measurement.

Introduction

Considerations of social measurement encompass raw data to be collected as well as metrics (standards of measurement) to be used. As will be shown, the two may well be quite different. Socioeconomic data/metrics are collected as-needed, on a just-in-case basis/philosophy, or both. When raw data are collected or metrics are measured, calculated or evaluated as they are needed, the client/customer is typically identified and the end-use is fairly well defined. This leads more easily to defining the raw-data/metrics sought and the processes to be used. However, many questions must still be asked and answered. These require much deliberation with the need to set aside conventional wisdom and/or intuition. The consequences of collecting the wrong data or

evaluating the wrong metrics may prove to be costly in economic, and disastrous in social, terms. The remainder of this article will address most, if not all, of these issues.

Importantly, the "just-in-case" situation presents, or should present, cause for serious deliberations including, but not limited to, some serious systems thinking/modeling, where such thinking can be of either the "soft" or "hard" variety.

Discussion

Unlike data, metrics may well be multi-dimensional, involving several attributes. They may be simple ratios of two attributes, for example, Labor Productivity, or they may involve a multiplicity of dimensions as in the World Competitiveness Index (WCI). It should be noted albeit parenthetically that the WCI is jointly produced and maintained by the World Economic Forum (Geneva) and the Institute for Management Development (Lausanne). It ranks selected countries in terms of their competitiveness. It depends on a number of qualitative factors, which, in turn, depend on perceptions of executives. Moreover, in 2002, Ulengin *et al*. statistically replicated the WCI by using publicly available socio-economic data for selected countries. Their data represented 61 different objective attributes grouped as; demographics, health, education, environment, technology/infrastructure, economy, and military power.

Metrics may be more directly responsive to questions of evaluation, and this may lead to executives' compensation, corporate/institutional resource allocation decisions at the microeconomic level, and to national policy at the macro level. Given human nature as it is, and when such is the case, great thought must be given to what is being measured. The various civil and criminal indictments and judicial decisions involving executives of the Enron, WorldCom, Health-South, and Tyco corporations as well as senior auditors at Arthur Andersen LLP, bankers at Credit Suisse–First Boston, and influential analysts at a number of "prestigious" Wall Street firms during the early years of this century poignantly attest to that.

The resulting measurement should direct the behavior of all actors involved in a desired direction. Deciding on what is desired is a nontrivial question as it often depends on a multiplicity of stakeholders and their respective goals and objectives. These may well prove to be (often are) conflictual. So, metric(s) considerations must, at a minimum, include answers to: Who seeks (or might seek) the information? Why is (or might be) the information needed and toward what end will it be used? What is to be measured, and at what level of aggregation? How it is to be most meaningfully measured?

Some Well-Known Metrics with Serious Untoward Consequences

The hard-data-based, easily understood, widely disseminated (US Department of Labor among others), accepted, quoted and used *labor productivity* statistics are misleading indeed; particularly so, when used to make comparisons over time or across borders or industries. One can easily make the case, for example, that the problems of America's steel industry during most of the 20th century were at least as much due to the quality of managerial plant investment decisions as they were to the quality of American labor.

The payback period is an easily understood rule for investment decisions. It is widely accepted and used by managers in plant or process modernization decisions. It has many variants but they all seek a response to the question of how long will it take to recoup the money invested. The wisdom used in applying this metric in decision making is "the shorter the payback period, the better." Any project showing payback in more than a year or two is often "axed" from further consideration. But, this rule says nothing about the magnitude of incomes, simply cumulated or discounted and then cumulated following the payback.

One can make the case that reliance on the payback period as a guide to plant modernization investments by several generations of America's steel industry executives was as much the cause of the industry's demise as were the labor unions. Needless to say, over many decades, its use in management decision-making contributed to maintaining the American steel industry's low levels of labor productivity statistics. Since payback period is a prospective decision rule, the inputs (metrics) typically used are more or less subjective estimates.

Social Measurements

Hard Data/Soft Data Tradeoffs

Some data/metrics can be secured in hard form, i.e., transactions that are counted or measured. Examples include patients serviced, personnel trained, unit costs of personnel, space, and supplies, the number of people staffing a particular department, the number of departments or clinics, and the investment in plant or equipment.

Importantly, it is not uncommon to find that such data/metrics are uncollectible and/or unavailable in hard form. Some typical examples include the cost of patients' waiting time, quality of social services, and performance of government agencies.

In between the preceding two extremes, there is a broad spectrum of data classes that can be collected in hard form, but at a cost. The costs range from trivial

to prohibitive. Also, there are classes of data which, although collectible at some cost, require time for collection. The time span may be prohibitive from the points of view of the project and/or the organization for which the data are needed. Then, there are data or metrics which, by their very nature, simply cannot be counted, measured, etc., irrespective of time and cost. Yet, these inputs may very well be key. In this category are the relative or absolute values that an organization places on various performance criteria, for example, budget balance, service level, and public image.

Also in this category are evaluations of "softer" intangible criteria, for example, institutional drawing power for quality providers and patients, and "sex appeal" (public image), as well as less soft, pseudo-tangible criteria, e.g., the reliability, maintainability, safety, and operator comfort of plant and equipment. The analyst should thus be quite flexible and broad based in designing the data-collection process.

Subjective Judgments

When data are, by nature, not collectable, then recourse is made to obtaining subjective judgments from the most knowledgeable available sources. One approach is to solicit the view(s) of a single expert. An alternative path seeks a formal consensus from a well-designed panel of knowledgeable people. This could employ some formal, interactive, consensus-seeking process, such as the Delphi method. Clearly, interviews, questionnaires, etc., taken on either a census or a survey basis, are midrange possibilities. Moreover, these highly subjective inputs that cannot be measured, nor counted, can be quantified depending on the research instruments used.

In 1979, Reisman presented various techniques of data collection within the objective/subjective spectrum for purposes of system description, evaluation, and/or valuation, forecasting demand for services, cash flows, and so on. For purposes of evaluating the outputs of services provided by a network of disparate human service agencies, several types of data, and the sources for each, are required. Some of the data can be obtained in hard form from agency records. Others require estimates, evaluations, or valuations. A real-world case involving all of the above was also provided.

Stakeholders

Stakeholders are those individuals, institutions, and other entities that have a vested interest in the issues/matter for which the data are to be collected. They have, in one way or another, some leverage and influence on the use of the data/metrics to be collected. The success or failure of data usage thus depends on the attitudes and behaviors of relevant stakeholders. In a sense, stakeholders are the data's clients. Consequently, it is important to identify the stakeholders for the data/metrics to be collected. This, as a process itself, will likely generate highly pertinent information about the perceptions and values of "clients" regarding the original problem situation.

In 1981, Mason and Mitroff reinforced this point in saying that identifying stakeholders is an easy way of generating the prevalent assumptions about a problem situation for, "while it could be difficult to 'see' assumptions, most people can rather easily generate a set of stakeholders that bears on their perspective. From the stakeholders, it is but a short step to assumptions." Identifying the stakeholders thus appears to be a prerequisite for developing models having acceptable levels of conceptual and operational validity, hopefully leading to successful model implementation.

Levels of Aggregation

As previously indicated, socioeconomic data and/or metrics are collected/measured to serve a variety of needs. Among such end-uses might be policy formulation, perfomace evaluation, resource allocation, and compensation. There may well be a number of intermediate steps that would involve models, decision rules, and related quantitative or quantified dimensions. These should be as simple as posible, yet, often, completeness contradicts simplicity. The problem is thus to decide what level of detail to include in the overall model, and what quantities to approximate and incorporate as aggregate components. This encounters a tradeoff between manageability and descriptiveness. However, in order to be complete, one needs the formulation of the model to be as detailed as possible. On the other hand, this tends to make models large and complex.

Furthermore, it is critical that the model be implementable, that is, a good representation of the situation, as well as communicable in order to enhance chances for successful implementation. (The term *representation* is emphasized as it incorporates the notion of approximation).

No model will be 100% accurate. However, the difference between a large, complex 90% accurate model and a simpler 80% accurate model may be large in terms of implementability. Experience indicates that one should err, during the earlier phases of the study, on the side of descriptiveness. However, it is often necessary in later phases to combine variables and aggregate parameters/metrics to make models manageable and, therefore, more implementable. This aggregation process should not be viewed as a compromise action. On the contrary, it requires a high level of competence. The end result's cost/benefit ratio is improved. This aggregation process often takes place as a result of data collection attempts. The latter should not be interpreted as the data are unavailable, but rather, that

the data are too costly to collect, or that earlier tests indicate the model/decision rule is insensitive to such data.

For instance, in the early phases of a systems study involving a federation of a number of disparate communal agencies, seven client groups (based on age) were identified. However, after preliminary data collection it was discovered that the differences between both the values and evaluations of the services offered to high school and junior high school groups were not sufficiently great to justify the separation of these two groups. Consequently, the two age groups were combined. Similarly, it was found that one of the agencies operated on a minimal budget as compared with all others. It was therefore decided to eliminate this particular agency from the study.

In summary, the level of aggregation employed in a model/decision rule may well be a decisive factor in the success of its usage. Simpler models are more easily managed, communicated, and understood. The user thus feels more at ease with the resulting model structure and solutions, thereby favoring the chances for successful implementation.

Levels of Precision

If the distance between point A and point B, provided within a kilometer or two, is satisfactory to the end user, there is no need to use a measuring tool accurate to plus or minus one millimiter. The additional precision comes with an increase in cost and time required for collection. This also applies to socioeconmic data/metrics.

Precision with which data are acquired is often directly related to the cost and time required to collect that data. At the same time, the precision of data/metrics must not be confused with the accuracy of the end result. If data/metrics groupings collected at differing levels of precision are then combined, the resulting entity can only be claimed to be as precise as that of the least precise grouping.

Although this concept is well established in engineering, and even more so in land surveying, accountants often count petty cash down to the penny and add such precise and hard data to rough estimates of other asset values in the millions of dollars so as to establish corporate balance sheets. Yes, over many years, a world-renowned audit firm called Arthur Andersen did indeed show that the assets and the liabilities of one of their clients, a company called Enron, did balance, to the very last cent. Great *precision* indeed. Most of the stakeholders bought into it; at least up to the point that officers of both firms began to be criminally indicted for "megafudging" on the *accuracy* of these very precise-looking figures. History has recorded the fact that this "fudging" seriously impacted many pension funds for many years, and many retirees for life, and that it was the result of unmitigated greed not only among Enron executives but also at a number of very prestigious banks, brokerage houses, and at least one law firm. None of this would have happened had more meaningful metrics been in place for evaluating performance and rewarding personnel at each of these interrelated enterprises. One could go further and query the various relevant regulatory agencies and institutions as to what metrics were being used as sensors given that such monumental and widespread wrongdoing was missed.

Levels of Accuracy

Often, though clearly not always, it is possible to check the accuracy of data or information obtained by having individuals or groups make subjective judgments against the actual events that occur. Some examples include estimates of costs and time to completion, person-hours required, task times, height and weight, as well as predictions of usage of supplies, demand for services, and manpower availability. Whenever such judgments can be validated, clearly they should be. (Some methods of validation are discussed in the work of Reisman.)

Surrogates

Measures

Often in socioeconomic systems/situations it is impossible by any means or at any cost to obtain values for the most direct measure of a variable. Consider for example, the quality of social or health care services provided. It is necessary to evaluate such phenomena using surrogate measure(s) that can be more readily quantified, albeit subjectively. Surrogate measures for the quality of food might, for example, be looks, freshness, texture, and taste. Surrogate measures for the quality of health care delivery, if measurable, might be mortality and morbidity rates, length of stay in hospital, laboratory tests performed, specialists consulted, and availability of trained nurses. Some surrogates for social welfare might be number of clients seen by professional workers, "service time," or the number of hours workers spend with, or on behalf of, clients. Others include effectiveness of services as perceived by clients, workers within the agency, and outside evaluations. Selected surrogates for education include number of trainees completing the program, starting salaries of graduates, and number of graduates going on for further studies in quality institutions.

Sources

Similar to those problems encountered in obtaining the most direct measures of a variable, it is often difficult, if not impossible, to obtain a measure, be it hard or soft (that is, subjective), from the most direct source. It is thus impossible to query certain patients regarding the quality of social service or health care received. Some patients, for example, may be too young to evaluate what they get,

while some may not be sufficiently coherent to respond. In either of the preceding cases, however, it is possible to obtain some expression of quality from the client's natural or legal guardian.

It may also be difficult to have members of the board of trustees and/or the lay community leadership to invest the time required to reach consensus on issues on which they, and only they, should act. In such cases, it has been shown possible to use surrogate panels acting on behalf of recognized leaders in seeking consensus on questions of concern using such techniques as Delphi.

Multiple Data Sources

Whenever it is possible and economical to obtain data, especially subjective estimates, from several independent sources, attempts should be made to do so. Moreover, the results of such collections should be compared and/or statistically analyzed for similarities and differences. In the case of social welfare services, for example, a high correlation was found between the level of professionalism among workers providing a service and their own estimates of effectiveness of their services vis-à-vis estimates by outside experts and clients. This finding was obtained within a highly professional institution (most, if not all, workers held advanced degrees in their specialty, and their supervisors were acknowledged leaders in the profession) for educating emotionally disturbed youngsters. Workers rated their effectiveness in the 60 to 70 range on a 0 to 100 scale. The same services were rated in the 70 to 80 range by outside experts, and by those acting on behalf of the patients, that is, parents or legal guardians.

However, in another part of the same study, a supplementary parochial school run by a husband, wife, and daughter team showed great disparity in effectiveness ratings, for example, 95 to 100 by "workers," 70 to 75 by students, and 40 to 50 by outside experts.

Checks on the Quality of Data

As indicated above, in the communal federation study, surrogate panels acted on behalf of recognized leaders in obtaining consensus on questions of concern via the Delphi method. In that study, a stratified random sample of the questions was put to the true leaders for consensus. These results, and those obtained from the surrogate panels, were then statistically analyzed to determine the level of agreement. It was found that similarly designed panels of knowledgeable people provided statistically similar responses.

An Expanded Illustrative Example

The following retrospection will illustrate many of the above issues. Lessons learned are outlined following presentation of the example (which is based on the work of Pollack-Johnson *et al.*, and Reisman).

Background

Ph.D.-granting programs in American universities became a focus of national concern in the post-Sputnik era. The number of doctorates granted during the 1960s exceeded the total production prior to 1960. During the late 1960s, however, the sitting U.S. Commissioner of Education found himself in a serious predicament. He had charge of the National Center for Educational Statistics (NCES). At the time, this was the world's most comprehensive database on educational statistics. The NCES staff statisticians included Ph.D. holders from the world's best graduate programs. The NCES continued turning out rosy projections for the demand for Ph.D.s in the sciences, and for elementary and secondary school teachers. This drove many universities to expand their graduate programs and to start new ones. The same was true for schools or departments of education. At the very same time, the *Washington Post* reported that over 30,000 Ph.D.s were unemployed or driving cabs. To make matters worse, it was reported that many an open position for grade-school teachers attracted over 400 applicants.

In consequence of the above, several efforts to forecast the supply and demand for doctorates in the sciences through the year 1980 and the supply and demand of elementary and secondary school teachers were undertaken in 1970 and 1971. Such studies were performed by government related agencies such as the NCES itself and the National Science Foundation (NSF), by private foundations such as the Commission on Human Resources and Advanced Education (CHRAE) of the Russell Sage Foundation, and by independent faculty members.

After reliable data on the actual outcomes became available, it was discovered that unlike the others, one of these forecasts was extremely accurate. Moreover, this was also true on a year-by-year basis.

It is rare to have so many concurrent forecasts of the same phenomenon for which the recency, predictability, and time horizon are all comparable. Such a similarity of conditions reduces the number of independent variables involved and makes a comparison of methodologies more meaningful. Consequently, a study of the various methodologies used and the differences between them was undertaken to see what lessons might be learned.

First, all but one of the forecasting teams relied strictly on hard data and employed various objective statistical extrapolative methodologies. One team, however, enriched what could be learned from the hard and, therefore, historical, data with subjective forward-looking inputs from a panel of knowledgeable and diverse

individuals using Delphi. The panel assigned subjective probabilities to each of a set of mutually exclusive future scenarios defined by several socioeconomic and demographic dimensions. Whatever hard data were found to exist were used to make projections under each of these scenarios. The expected outcome was then calculated by summing the products of the respective scenario-specific outcomes and their probabilities.

Identification of Data Needs

Questions of data needed and data available were addressed by first creating a relatively deaggregated feedback model to track those people flows into, and through, the educational system network. Feedback, at various levels of educational attainment, and between the educational system and the rest of society, was facilitated by having a counterpart network. Together, the two interrelated networks comprised 60 nodes. These nodes specified the educational levels and corresponding employment segments. The network model is shown in Fig. 1. Significantly, the model was established without regard to data requirements. It was based on the 1965 Bolt *et al*. framework, a forerunner to Reisman's.

Sources of Data

Extensive efforts were made to determine where and how the data required for the model of Fig. 1 could be collected. Among the agencies contacted were the National Center for Educational Statistics, National Research Council, National Academy of Science, National Science Foundation, Bureau of Labor Statistics, Bureau of the Census, National Education Association, Institute of

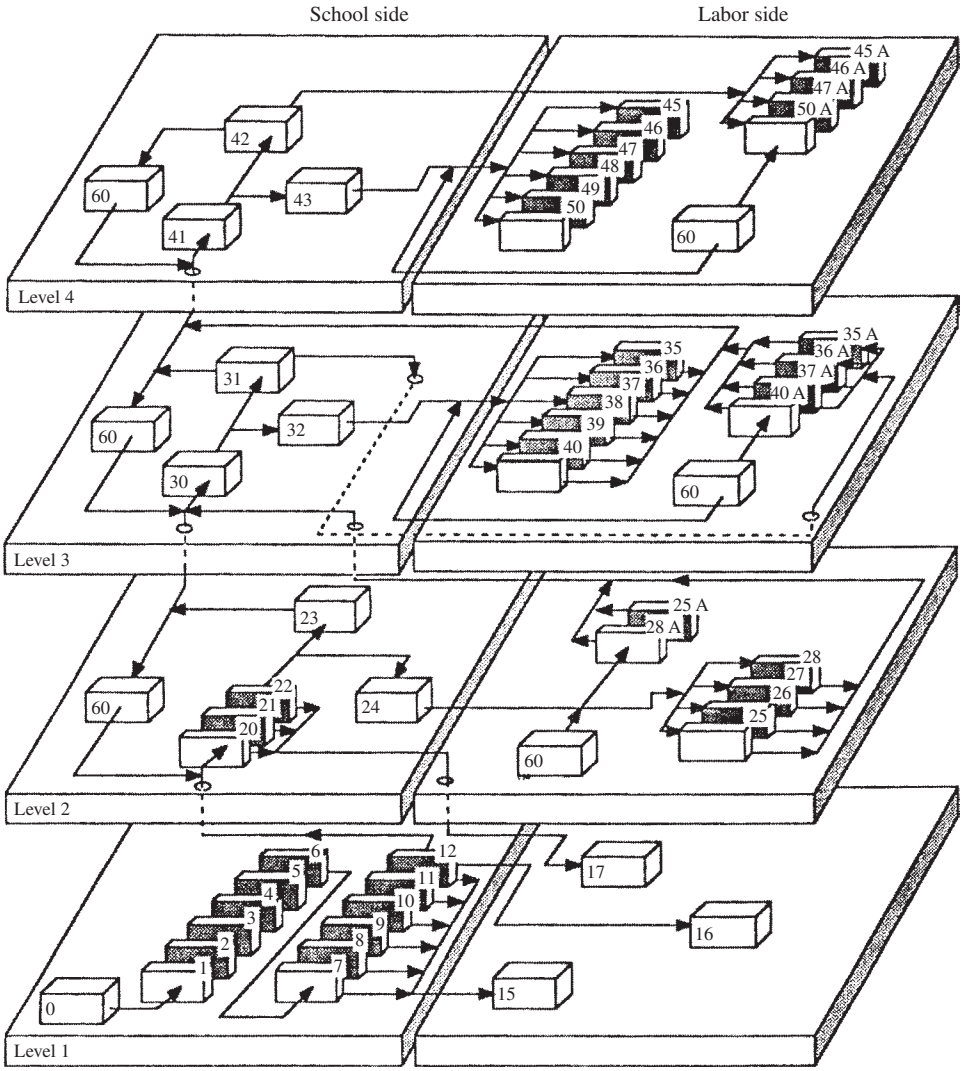

Figure 1 A highly deaggregated model of the education and use of human resources.

International Education, U.S. Department of Defense, U.S. Department of Justice, U.S. Department of State, John Mitner & Associates, Association of American University Professors (AAUP), and departments of education in a number of states. These agencies were truly helpful and generous with the data that they had in hand. On some occasions, if the data were found to be nonexistent within the agency's files, referrals to other agencies or organizations were made. Figure 2 illustrates the nodes that communicate with each other. If node i communicates with node j, either a "1" or a "0" (zero) is placed in the (i, j)th cell. A "1" indicates that flow data are available, whereas a "0" indicates that no flow data are available.

For each communicating pair of nodes, historical flow data are required. For example, node 23 (senior college students) communicates with nodes 23 (itself), 25A (labor force with at most a college degree and without teacher certification), 28A (people not in the labor force with at most a college degree and without teacher certification) and 30 (first year master's degree students). This implies that the model requires historical data (yearly) on the number of college seniors that (a) do not graduate but repeat their senior year, (b) move on to the labor sector, (c) move into the "not in the labor force" sector, and (d) move into graduate school.

Data are typically not available in flow form. Rather, the aggregated numbers of people at each node are available. Indeed, much of the aggregate numbers are often available by sex, age, or other characteristics. Using these data, the flows can, in a few instances, be reconstructed. In most cases, however, the flows have to be estimated. The "0" entries in Fig. 2 indicate that either (a) the flow data were not available, or (b) the aggregate numbers themselves could not be broken down fine enough to reconstruct the flows. As can be seen in Fig. 2, a large number of nodes have "0" entries.

The Model

The model shown in Fig. 1 required as input school-age populations. Each cohort was then pushed through the network. Using historical data, the transition probabilities

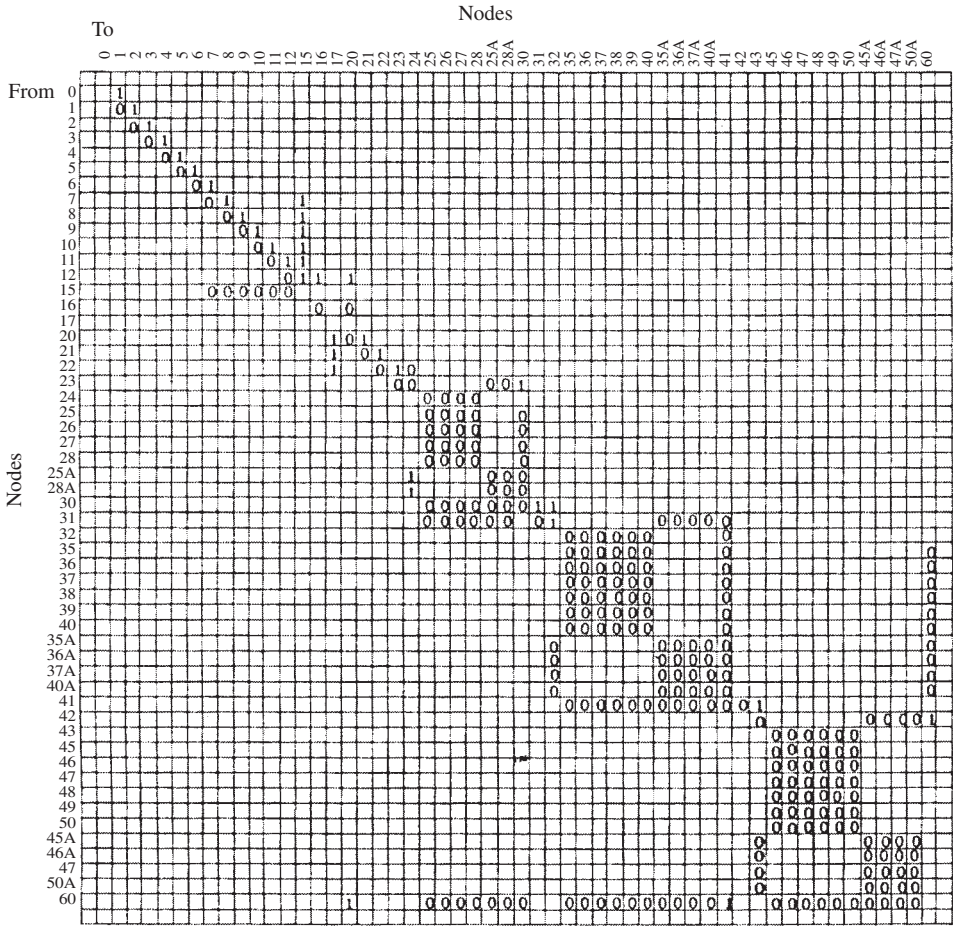

Figure 2 Data needs: data availability matrix for forecasting the education and use of human resources in the United States.

were estimated. For example, consider the node, grade 7. For a given cohort group, the proportion of students who go to the next level (in this case, grade 8) or repeat grade 7, or drop out, was determined. By tracking the transition probabilities over time and at each node, it was possible to characterize the aggregate behavior of individuals throughout the network. As a second example, consider the nodes at the master's degree production level. Enrollment in the master's degree program would come from foreign students, recent college graduates, and/or from working people with college degrees. Using the transition probabilities and the probability distribution of the time it takes to obtain a master's degree, it was possible to predict how many master's degree students reach their final year, graduate, go on for a Ph.D., go back to the labor force, and/or apply for a teaching certificate.

Nodes at the lower educational levels are more homogeneous with respect to age than are those at higher levels. Also, the choices for future movement are greater at higher levels. The statistical methodology for estimating transition probabilities differed for nodes at different levels. Estimation of such probabilities at the lower level was based on the push-based Markov chain theory. Thus, given a successful investment in education at a particular grade, the probability of moving into the next grade is well defined. In contrast, the estimation procedure of transition probabilities at the higher educational levels was based on the pull-based Renewal theory. That is, opportunities for advancement are based primarily on vacancies becoming available at the next higher level.

Clearly, the Markovian and Renewal approaches are not the only methods for modeling the flow of people through an educational network. However, to be useful, the Markovian and Renewal approaches require historical data on the flow of people among communicating nodes over time. Typically, these types of data are not directly available. In practice, data usually reflect a count of the number of individuals at given node. These data must be converted into flow data. In many instances, this is simple. For example, knowledge of the number of individuals in grade 7 in year 1984 and grade 8 in year 1985 can be used to determine the number of students who moved from grade 7 to grade 8. If the number of ways of entering grade 8, or if the number of destinations for students leaving grade 7, were high, then estimation of the flows from grade 7 to grade 8 would be difficult. To be useful, the Markovian and Renewal models require extremely disaggregated data. If flow data are not available, transition probabilities cannot be estimated and nodes must be redefined (aggregated).

Other representations of the educational network can be postulated. For example, nodes characterized by age and or sex could be important, especially beyond the bachelor's degree. In this study, separate networks were developed for males and females.

Lessons, Both General and Specific, That Can Be Learned from This Example

This example demonstrated that:

1. Even under the best of circumstances not all hard data needed are available.
2. In the matter of long-range socioeconomic forecasting, usage of subjective metrics outperformed usage of hard data.
3. In the matter of long-range socioeconomic forecasting, usage of "[non]conventional wisdom" techniques outperformed conventional techniques.
4. Use of a representivive panel/sample of stakeholders in securing subjective metrics via consensus-seeking techniques provided good metrics.
5. Usage of systems thinking and/or modeling defined the data needed as well as their availability.
6. Usage of systems thinking and/or modeling defined the levels of aggregation of the data needed as well as their availability.
7. A number or practical suggestions for long-range forecasters, especially those working in the fields of education and human resource policy and planning, resulted from this retrospective review. They can be summarized as follows:
    a. First and foremost is the importance of core assumptions: being aware of them, avoiding "assumption drag" by making sure that assumptions are current, testing them when possible, and reconciling them with known theory from disciplines beyond the immediate topic at hand.
    b. Avoiding biases due to one's institutional affiliation.
    c. Of great importance is the question of possible structural changes in the system. The form of forecasting approaches used should depend on the likelihood of achieving feasible levels of system stability. Overall, a forecasting method should be as objective as possible, as causal as it can be, and broken down into segments where appropriate. It should be as simple as needed to model the most crucial factors, and as eclectic as possible in order to be robust and to synthesize as much information as possible.
    d. In forecasting doctorate production, and other forms of human resource forecasting, it is imperative to recognize the importance of economic forces on enrollments and degree production. (Pollock-Johnson *et al*. discuss these issues at some length.)
8. Unfortunately, there are no large decision support systems for human resource planning in the educational arena.
9. Current data are dispersed across a large number of agencies.

10. Typically, data exist in the form of simple time-series, although, in some cases, cross-tabulated data are available.

11. Little attention was given to the management of this information. As a result, the nature of information varied by network level. Detailed information existed at some levels, with fundamental information missing at other levels. Census information at the lower levels, for example, was available. Survey information, however, was not generated on a regular basis. Further, the results were not monitored in longitudinal studies. Missing and conflicting data are not uncommon occurrences. Moreover, nonuniformity or changing definitions of time-series were likely problems.

12. Human resource policy formulation objectives at the national level vary from administration to administration. However, a commitment to collect and manage needed information for a decision support system (with respect to information content and quality) is in order, and long overdue. Without such attention, sophisticated educational planning models at the national level will be less well accommodated.

13. Finally, the study served to illustrate the data voids in national education statistics. It did not attempt to segregate educational disciplines, e.g., science versus humanities, nor professions, e.g., engineering versus law; and, within the teacher model, no attempt was made to distinguish between specialities, e.g., science versus mathematics versus physical education. This kind of segregation in, or de-aggregation of, the data is clearly needed to aid in the formulation of policy at the national level.

A Recent Methodology for Forecasting Social or Political Outcomes

The most recent methodology for forecasting business success as well as social, political, and foreign policy outcomes and, yes, perhaps even coups d'etats, involves Internet-based marketplaces for futures trading. This approach is certainly resonating in the business world and is beginning to be used by large corporations. As with earlier Delphi-based methods, forecasting the model's efficacy depends on inputs from knowledgeable individuals. Unlike before, however, this methodology provides financial incentives to those individuals in position to influence the outcome. Therein, one might argue, lay a serious danger.

Developments in Converting Data into Useful/Meaningful Metrics

As indicated earlier, simple metrics used for setting policy and for operational decision making are often simplistic and may result in significant, adverse, socioeconomic effects over time. Though they are intuitively satisfying and easy to use, more often than not, their long-term effects are self-evident only to those who look or want to look beyond what is immediate and obvious. In recognition of the fact that unidimensional, or even bi-dimensional (ratio form) metrics generally do not capture the complexity of the systems involved, the literature concerned with analysis for decision-making has recorded a number of multi-attribute or multi-criteria methodologies. These include, but are not limited to *Decision Tables*, and, more recently, *Data Envelopment Analysis*.

Data Envelopment Analysis

Data Envelopment Analysis (DEA) is a technique that allows for measurement of relative efficiency of organizational units. The methodology's main strength lies in its ability to capture the interplay between multiple inputs and outputs, a process that cannot be satisfactorily probed through traditional ratio analysis.

Significantly, applications of DEA have a high rate of implementation. DEA applications of record range, sector-wise, from: banking to the not-for-profits; from welfare agencies to the military; from health services to manufacturing; from education to policing. The objectives served include: organizational design, organizational effectiveness, credit evaluation, privatization, insurance underwriting, benchmarking, productivity analysis, modernization policy analysis, scale and performance measurement, physician report cards, environmental regulation, pollution prevention, facilities/equipment planning, and evaluation of macroeconomic performance.

The following web site at Warwick University, UK, provides state-of-the-art information on data envelopment analysis: www.DEAzone.com.

Data Mining

Advances in data collection and storage technology have made it possible to store large collections of data. This is especially true regarding customer and business transactions in retailing, e.g., at the point of sale. Data mining research deals with the extraction of useful and valuable information that cannot be otherwise (via standard querying tools) uncovered from large collections of data. The tools thus created allow uncovering of interesting patterns deeply buried within the data. Such patterns facilitate the making of strategic decisions.

In the context of data mining itself, the interesting problems can be categorized as classification and clustering. These partition the data items into disjoint groups or classes such as associations, which seek correlations among data items, and sequences which, as the name

implies, find the sequencing among data items. Data mining thus offers many possibilities for learning actual behavior at a point in time. Clearly, if collected from the same sources over extended time periods, and correlated with more macro data/parameters, it may offer tangible evidence of the effects of, say, business cycles on customer behavior. The following website, at the National Center for Data Mining, University of Illinois, Chicago, provides state-of-the-art information on this subject: www.ncdm.uic.edu

Concluding Remarks

There are many admonitions regarding the socioeconomic aspects of social measurement. Among these are:

1. "*Be careful what you measure' cause what you measure you will get*." Humans adjust. Some examples justifying this admonition have been provided above. Some others follow:
   a. The stock market's, and many pension fund managers', preoccupation with short-term profitability (based on various metrics) has shortened many a corporate lifespan and, with it, the jobs paying into the pension funds.
   b. Teachers, schools and, indeed, school districts (under pressure from parents and public officials) have, over time, adopted what was being taught to what was being measured on the output side, e.g., Massachusetts' statewide school-leaving test, a School Leaving Certificate examination in Nepal, and the nationwide college entrance examination in Turkey (taken at the same time by over a million students each year). Obviously the exam does not include any essays, compositions, etc. Hence, Turkish high schools, both public and private, hardly emphasize essay writing.
   c. Many a hospital has avoided accepting very serious cases after mortality statistics began appearing in community news media.
2. "*Statistics don't lie. Statisticians do*." Statistics are often used to divert attention from real problems. As an example, a president of a university in serious academic decline announces that applications are up when he should have been saying that freshmen go elsewhere, enrollments are down, and, so, let's look for internal problems.

Summary

End uses of socioeconomic data/metrics must often rely, at least in part, on data which are not measurable, countable, or, in general, "hard." Even when such data are obtainable, there are situations when they can only be secured at great monetary or human resource costs.

There are, of course, many situations where hard data cannot be obtained at any cost; hence, subjective or "soft" data may be used. The literature has recorded a number of techniques for securing such "soft" data. It behoves the data collector or metrics evaluator to choose the "right" technique to do this. The collector/evaluator must therefore identify the feasible alternative techniques, state the benefits and costs associated with each in the context of the problem at hand, and then choose the best one based on some cost-benefit analysis. In data collection or metric evaluation, consideration must be given to the level of aggregation, to cost-representative tradeoffs, as well as to end-use sensitivity to the measurements' precision. However, experience shows that it is easier to aggregate data in hand than not to have collected it in sufficient detail in the first place. So, once again, "*Be careful what you measure, cause what you measure you will get*."

Sociology

Joseph W. Elder
University of Wisconsin, Madison, Wisconsin, USA

Glossary

aufhebung German term used by Marx to refer to pressing contradictions to achieve transcendence, through the sublation of error and preservation of truth.
geisteswissenschaft German term for the disciplined study of products of human consciousness.
ideal type Unambiguously defined, internally consistent, meaning-directed mental construct used heuristically to compare with social behavior.
idiographic explanation Interpretation of a unique event.
nominal definition Statement that a word or group of words is synonymous with another word or group of words.
nomothetic explanation Interpreting an event by describing it as one of a set of regularly recurring events.
noumena Subjects/events as they are in themselves.
operational definition Statement defining a set of empirical operations to be used to identify a word or group of words.
phenomena Subjects or events as they appear to observers.
qualitative research Drawing on the subjects of study to define the terms of the study.
quantitative research Applying researchers' categories systematically to large numbers of subjects.
reliability The extent to which procedures of measurement produce the same results in repeated trials.
validity The extent to which measuring procedures actually measure what they purport to measure.
verstehen German term for understanding; sympathetic reliving of the experiences of others.

The 18th-century founders of sociology envisioned a "science of society," discovering "laws" that would enable social engineers to produce improved societies, just as other engineers produced improved machinery or effective cures for diseases. Concepts and the measurement of concepts lie at the heart of the sociological enterprise. Complicating those concepts and their measurement is the fact that societies (and other social groups) are collectivities of individuals. Is referring to societies as collectivities actually engaging in reification? Do collectivities have identifiable attributes as collectivities, or are their attributes basically the sums of the individual parts? If collectivities are meaningful units of analysis, how can they—or their causal processes—be defined and measured? And how is the accuracy or generalizability of those causal processes established? Over the years, sociologists have devised a number of strategies of social measurement to address these questions. Although the 18th-century vision of a law-based science of society soon faded, the idea of observing society and social behavior scientifically has persisted, generating the academic discipline of sociology.

Sociology and the Measurement of Collective Phenomena

One ultimate philosophical problem that must be addressed when dealing with the empirical world is the problem of definitions. What terms are used to describe what is perceived? In most instances, the everyday language within a family provides individuals with their initial definitions of the world. The loosely structured sets of near synonyms and antonyms of the many everyday languages around the world define the empirical world in diverse ways for the speakers of each language. When clarification of a specific word or words is called for, the word or words to be clarified (the *definiendum*) may be matched with a word or set of words (the *definiens*) describing what the original word or words mean. In such cases, a nominal definition is created—i.e., a word or group of words is declared to be synonymous with another word or group of words. Nominal definitions are neither true nor false; they are merely

statements of proposed equivalency. A word may have several nominal definitions. For example, a Marxist's nominal definition of social classes might be "groups of people occupying the same position in relation to the means of production." W. Lloyd Warner's nominal definition of social classes might be "groups of people ranked together as having the same social status." For purposes of clear communication, it is important to know which of the nominal definitions is being used. Once that has been established, the major requirement for an intelligent dialogue is consistency. As a field of knowledge expands, the number of nominal definitions within the field typically increases. In the early days of urban sociology, Louis Wirth defined cities as communities characterized by large and heterogeneous populations living within relatively small areas. A few years later, Roderick McKenzie, extending the field of urban sociology, identified four different types of cities based on their central economic functions: primary-service cities, distributive cities, industrial cities, and cities lacking any specific economic base. Sociologists could then direct their efforts at discovering similar and different patterns of human interaction in the four different types of cities.

When evidence is to be gathered from the empirical world, a nominal definition is more useful if it is accompanied by a set of empirical operations measuring that nominal definition. Ethnic groups, capitalists, the working poor, criminals, peasants, homosexuals, revolutionaries, etc. can be nominally defined. But until the identity can be determined, through some measuring procedure, precisely who out there in the empirical world is and who is not an ethnic group, a capitalist, the working poor, a criminal, etc., it is hard to make unchallenged statements describing what they are doing or what is being done to them. The set of empirical operations identified as synonymous with a word or group of words is called an operational definition (or a corresponding definition). Taking the nominal definition of social classes, for example, to be "groups of people ranked together as having the same social status," it is necessary to find a way to operationalize such groups. For example, everyone in a community could be asked to rank everyone else in the community as having higher, lower, or about the same social status, compared to themselves. The information gathered through the operational definition would enable a sociologist to group together people who felt they shared the same social status—in other words, to group people according to their social classes.

The history of sociology is a history of nominal definitions, operational definitions, and strategies for gathering data according to the operational definitions. All three are elements of sociological measurement. But none of them overcomes an ultimate philosophical problem: the impossibility of establishing an absolute identity between nominal definitions and operational definitions. Validity has been defined as the degree to which an empirical procedure actually measures what it purports to measure. Validity has also been described as the *sine qua non* of measurement; without it, measurement is said to be meaningless. Validity has been regarded as constantly evolving, as a matter of degree, as ascertained only indirectly. In the final analysis, no way has yet been found to establish some ultimate form of validity. Words and actions are not identical. Nominal definitions and operational definitions are not the same. The best that can be achieved are collectively agreed-upon approximate matches between operational and nominal definitions, recognizing that the agreement regarding the extent of the approximate match may vary between collectivities and over time.

Another ultimate problem that must be addressed when dealing with the empirical world is the problem of particulars and universals. Particular events are observed at particular times in particular places. However, the scientific exercise often requires generalization from particulars (bound by time and space) to universals (not bound by time and space). Links between particulars and universals remain open to debate. Was the 1992 Los Angeles violence following the release of the officers who beat Rodney King a particular instance of a race riot, an antipolice protest, or a class uprising? Universals are often socially defined. For example, some sociologists have stated that behavior, in order to be criminal, must be labeled criminal by an officer of the law. Does that mean that a particular theft on a particular day is not an instance of criminal behavior until it is labeled criminal behavior by an officer of the law? What happens if, after the behavior has been labeled criminal, the thief is found not guilty? Is that theft no longer a particular instance of criminal behavior? At times, it is difficult to establish linkages between particulars and universals other than collectively agreed-upon inclusion or exclusion of a given particular within the scope of some designated universal.

One way sociologists have dealt with the problem of universals and particulars is to begin with the universals (e.g., all families with annual incomes less than $20,000; all women under the age of 65) and then to take samples of particulars from the pool of universals. By operational definition, this solves the problem of linking particulars with universals. Sampling is one of the most frequently used techniques by which sociologists measure collective phenomena.

Founders of Sociology and Problems of Social Measurement

A French essayist, Auguste Comte (1798–1857), is often credited with naming and launching sociology. In his writings, Comte proposed identifying social processes of

resemblances and succession in order to identify laws of social statics and social dynamics. By establishing policies based on these laws, Comte believed that, in time, societies could be organized according to rational principles rather than religious doctrines. He envisioned the day when a hierarchy of sociologists would replace the church hierarchy and would follow empirically based processes of inquiry and application. As an alternative to calling this new process of inquiry and application social physics, Comte called it sociology.

Although the idea of administering societies scientifically according to laws of human behavior soon faded, the idea of studying societies scientifically did not. Another Frenchman, Emile Durkheim (1858–1917), advanced the new discipline of sociology by defining its parameters. Sociology was the study of "social facts" that emerge from individual facts. Social facts are exterior to individuals, they constrain individuals, and they cannot be modified by individual will. Group rates (e.g., marriage, divorce, and suicide rates) are social facts, in that they exist apart from the individuals comprising the group. Durkheim believed that social laws exist in the empirical world and that they can be discovered, like other laws, by using scientific concepts (i.e., nominal definitions created by sociologists rather than by lay people). Durkheim wrote about a society's collective conscience (its shared beliefs and sentiments) and what happened to that collective conscience as societies moved from "mechanical solidarity" (characterized by low division of labor and high collective conscience) to "organic solidarity" (characterized by high division of labor and low collective conscience). For his operational definition of collective conscience, Durkheim observed the extent to which a society enforced "repressive" laws or "restitutive" laws. "Repressive" laws inflict suffering or loss directly on violators of a society's rules. To Durkheim, this reflected a strong collective conscience with widely shared beliefs and sentiments. "Restitutive" laws merely require violators to return things to what they were before the violation. To Durkheim, restitutive law reflected a weak collective conscience and an absence of widely shared beliefs and sentiments. According to Durkheim, laws are collective phenomena (i.e., social facts); therefore, they can be used to measure other collective phenomena, such as a society's collective conscience.

One of Durkheim's most well-known studies explored relationships between three collective phenomena: suicide rates, group integration, and within-group regulation. Durkheim's operational definition of group integration included membership in a religious community (according to Durkheim, Jews had the highest group integration, followed by Catholics, Protestants, and the religiously unaffiliated). Durkheim's operational definition of group integration also included marital status (according to Durkheim, membership in a family with children provided the highest group integration; absence of family ties provided the lowest group integration). Durkheim's operational definition of within-group regulation included stability or termination of marital bonds and stability or change in economic well being. Using these operational definitions, Durkheim identified four different types of suicide: egoistic, anomic, altruistic, and fatalistic, each configured by different combinations of social facts. Although, over the years, details of Durkheim's studies (including his operational definitions) have been criticized, his approach to the study of social behavior has played a significant role in the history of sociology as a discipline that attempts to measure and explain collective behavior in the empirical world.

One of Europe's most-recognized 19th century intellectuals was Karl Marx (1818–1883). According to Friedrich Engels, who spoke at Marx's graveside, Marx had discovered the "law of development of human history" just as Darwin had discovered the "law of development of organic nature." Marx, while a student in Berlin, had been affected by the philosophical writings of Georg Friedrich Hegel. Hegel maintained that human thought provided the dynamic for constant change in human history. Hegel's unit of analysis was an entire nation, or *geist* (culture, spirit, cultural phenomenon, product of human consciousness). According to Hegel, history was a movement of cultures from "pure being" (devoid of human thought or consciousness) to the "absolute idea" (the entire historical unfolding of complete consciousness). At the core of this movement of cultures was the dialectical process whereby one concept generates an alternative concept, from which emerges a new concept. The German term for this meeting of concepts was *aufhebung* (pressing contradictions, leading to transcendence through the sublimation of error and preservation of truth). According to Hegel, ideas embedded in the *geist* generated evolving institutions, such as the sovereignty of the monarch and the state.

Marx's reading of Ludwig Feuerbach profoundly reordered his thinking. Feuerbach argued that humans and their material conditions—not abstract ideas—are the source for change. Monarchy, sovereignty, and the state were not abstract ideas emanating from the *geist*. Instead, monarchs and states existed in the material world; they sanctified their existence by concepts such as sovereignty. According to Feuerbach, Hegel had mislabeled the antecedent and the predicate. Through a "transformative method," the antecedent and consequent should be reversed.

Marx found Feuerbach's arguments convincing. He accepted Feuerbach's idea that the momentum for historical change comes not from abstract ideas but from the material conditions of existence (humans must have food and shelter before they pursue politics and religion). Marx, however, retained Hegel's concept of

historical movement through pressing contradictions. Instead of ideas generating alternative ideas from which emerged new ideas, Marx now held that material conditions generated alternative material conditions from which emerged new material conditions of existence. Using this as his framework, Marx produced a corpus of materials identifying the underlying components of the material conditions of existence and tracing their changes through history, especially European history. Key components of these material conditions included the primacy of productive forces, the formation and existence of classes, class consciousness, class conflict, exploitation, the labor theory of value, pressing contradictions, and radical transformations. As Marx introduced these concepts, he generally provided nominal definitions. Indeed, in his lifetime, he produced a lexicon of terms specifically associated with his frames of reference. However, Marx provided few operational definitions to accompany his nominal definitions.

A German contemporary of Durkheim, Georg Simmel (1858–1918), tried to define and justify the field of sociology as Durkheim had done. Simmel acknowledged that sociology's claim to be a science was challenged on the grounds that "societies" do not in reality exist, only individuals exist. Simmel argued that intellectual abstraction is an essential part of scientific thought. In reality, for example, only color molecules, letters, and particles of water exist. Yet scholars usefully study their abstractions, i.e., paintings, books, and rivers. According to Simmel, reality is studied through socially constructed categories; the choice of categories depends on the intentions of the observer. Turning to the abstraction of "society," Simmel reasoned that society emerges from multiple processes of sociation (interaction) between its component parts. Therefore, sociology might usefully pay less attention to society and more attention to the forms of sociation that occur in wide varieties of groups. Forms of sociation include competition, subordination, representation, solidarity, exclusiveness, etc. Simmel held that the relationship between sociation and social behavior paralleled the relationship between linguistics and language. Sociologists should proceed like grammarians, identifying the underlying, often "invisible" regularities in human interaction. According to Simmel, through studying sociation, criminologists might learn about the psychology of mass crimes by observing the behavior of theater audiences. Students of religion might learn about the willingness of individuals to sacrifice for the group by studying the behavior of labor-union members. Simmel introduced no special ways of measuring sociation other than commonsense observations. He deduced his most well-known descriptions of sociation not from observations, but from aspects of their definitions. In his essays, he addressed questions such as how group size affects group behavior, the point at which several conniving rogues become a delinquent gang or a social gathering becomes a party, and how three-person groups differ in essential ways from two-person groups.

In Germany in the latter half of the 19th-century, scholars were debating whether those methodologies used to study nature (*naturwissenschaft*) could be used to study cultural phenomena (*geisteswissenschaft*). The German sociologist Max Weber (1864–1920) concluded that cultural phenomena differ from natural phenomena in several fundamental ways: cultural phenomena have meaning, but natural phenomena do not. Natural phenomena occur regularly and repetitively; cultural phenomena do not. Furthermore, cultural phenomena will continue to change as long as humans are capable of raising new questions to the "eternally inexhaustible flow of life." Because cultural phenomena differ so fundamentally from natural phenomena, the methodology used to study natural phenomena cannot be used to study cultural phenomena. Students of cultural phenomena must develop their own methodology.

In his essays *The Meaning of "Ethical Neutrality" in Sociology and Economics* and *"Objectivity" in Social Science and Social Policy*, Weber outlined a methodology for studying cultural phenomena. His methodology required social scientists to understand (*verstehen*) human conduct within the cultural expressions (*ausdruck*) of its times. *Verstehen* could be achieved by placing oneself empathetically in the positions of subjects being studied and trying to relive their experiences. According to Weber, after social scientists understood subjects' behaviors and attitudes, they had a responsibility to explain those behaviors and attitudes interpretively to others. This was not a responsibility of scholars dealing with the natural sciences. Continuing his methodology for studying cultural behavior, Weber suggested that sociologists must create unambiguously defined, internally consistent "ideal types" of those cultural phenomena. Ideal types are not hypotheses (although they may help construct hypotheses). They are not descriptions of reality (although they provide unambiguous means to help describe reality). They are not an average. Ideal types are constructed by one-sidedly accentuating one or more aspects of a cultural phenomenon while synthesizing many other aspects of that phenomenon. A sociologist's own interests and value preferences determine which aspects of the phenomenon will be accentuated. Sociologists with different interests and value preferences are able to construct markedly different ideal types of the same cultural phenomenon. Ideal types (as unambiguously defined, internally consistent, meaning-directed constructs) exist nowhere in reality. Ideal types have only a heuristic value. They provide limited artificial models with which historical realities can be compared. Weber, during his career, constructed ideal types of a wide variety of cultural phenomena, including

social action, church, sect, the Protestant ethic, the spirit of capitalism, modern capitalism, classes, status groups, parties, and imperatively coordinated groups (*verband*), including those groups legitimized on the basis of "rational authority," "traditional authority," or "charismatic authority." Weber also wrote that the terms Karl Marx used to describe the material conditions of society were most useful if they were regarded not as descriptions of reality, but as ideal types—concepts with which historical realities could be usefully compared.

"Phenomenology" was the name assigned to a school of philosophy initiated by several German scholars in the first third of the 20th century. Edmund Husserl and Alfred Schutz drew on Immanuel Kant's distinctions between subjects/events as they appear to observers (phenomena) and subjects/events as they are in themselves (noumena), independent of forms imposed on them by observers' categories. Acknowledging the futility of studying noumena, Husserl and Schutz focused on the study of phenomena. According to Schutz, if social scientists are to deal objectively with the subjective meaning of human actions, they must build their constructs—including their ideal-typical constructs—on actors' common-sense constructs of their own actions. As with the *Geisteswissenschaft* movement and Max Weber, the phenomenologists held that the study of human behavior called for a methodology different from that required for the study of natural and physical phenomena.

Robert E. Park (1864–1944) is frequently identified as the founder of the Chicago school of sociology. Park's essay, *The City—Suggestions for the Investigation of Human Behavior in the Urban Environment*, presented multiple research agendas associated with the study of cities: What competing forces shape urban population patterns? What unique urban occupations emerge out of the extensive division of labor in cities? Why do crime and vice increase in cities? What excessive forms of human nature appear in cities, stimulated by the social contagion of divergent types of people who congregate in cities? The Chicago school sociologists observed that, in cities, secondary groups were replacing primary groups. Primary groups were small, face-to-face groups characterized by mutual trust and cooperation. Secondary groups were larger, more hierarchical groups that increasingly relied on coercion rather than cooperation for social control. According to the Chicago school, as primary groups were replaced by secondary groups in cities, social disorganization increased, indicated by family breakdown, divorce, drug use and alcoholism, youth gangs, vice, and criminal behavior. Terms such as "primary groups," "secondary groups," and "criminal behavior" called for nominal definitions and operational definitions. Data needed to be gathered, and statistics were increasingly called for to measure collective phenomena and test hypotheses. Sociologists specializing in sampling and survey techniques and focusing on demographic and ecological variables began developing new methodologies to meet their research needs.

Sociology and the Measurement of Causality

Measuring collective phenomena is one thing; measuring causal relationships between collective phenomena is another. The Scottish philosopher David Hume (1711–1776), in his *An Enquiry Concerning the Human Understanding*, challenged the concept of causality when he presented the following metaphysical premises: Humans derive all their ideas from their perceptions of the world in which they live. Many regularities exist in that world. Nevertheless, humans cannot observe cause and effect. At most, humans perceive spatial and temporal contiguity, temporal succession, and constant conjunction. To say they observe cause and effect adds nothing but a mystical quality to their otherwise straightforward observations. Therefore, efforts by humans to establish causality are doomed to failure.

The German metaphysician Immanuel Kant (1724–1804) maintained that reading David Hume "awakened" him from his "dogmatic slumber" and led him, ultimately, to write his *Critique of Pure Reason*. In his *Critique*, Kant distinguished between phenomena (things as humans perceive them) and noumena (things as they actually are), noting that noumena can never be known except as they are perceived. Kant observed that humans imposed conceptual categories (such as time, space, quantity, quality, relation, and modality) onto things they perceived. Kant noted further that such categories were not obtained by reflecting on the empirically given. Instead, such categories existed before, and were separate from, experienced events. They were pure intellectual constructs—universals. Individuals had to understand the universals before they could understand the particulars. Furthermore, it was by means of such categories that humans could perceive the empirically given and communicate with each other about it. But they could never actually know the empirically given. Reality would always be filtered through perceivers' conceptual categories.

Georg Friedrich Hegel (1770–1831) endorsed Kant's view that empirical events, including historical events, are filtered through human consciousness. According to Hegel, history is shaped by what humans think. One concept generates an alternative concept from which emerges a new concept through the process of *aufhebung* (pressing contradictions, leading to transcendence through the sublimation of error and the preservation of truth). The world is constantly changing. The past will never recur; the present will always generate a new

future with new ideas, until there is no further room for new ideas. Karl Marx (1818–1883), drawing on (but inverting) Hegel's perspective, applied the concept of *aufhebung* (pressing contradictions) to the material world. According to Marx, the world of material production generates pressing contradictions capable of producing changed material conditions. But such changed material conditions do not occur on their own. Humans must initiate them through praxis (the transformation of collective social perceptions into collective social action). Marx held that through the power of the owning classes, most people acquired a false consciousness of their historical conditions—historical conditions in which they were oppressed and exploited. This false consciousness led people to interpret their historical conditions as inevitable or unchangeable and to engage in social actions that reproduced, rather than transformed, the historical conditions that exploited them.

Marx identified a complex series of interrelationships between deterministic and voluntaristic elements in human history. He wrote that "no social order ever disappears before all the productive forces for which there is room in it have been developed." According to Marx, humans must evolve accurate interpretations of the social order in which they live before they can change that social order. He further argued that the juxtaposition of a social order ripe for change and accurate collective social perceptions transformed into collective social action (praxis) could produce an *umschlag* (an abrupt inversion) of the previous order and the introduction of a new social order. To test the accuracy of social perceptions, humans had to engage in praxis. Only praxis would reveal if the social order were indeed ripe for change, i.e., if all the productive forces for which there was room had been developed. If all the necessary causal factors were in place, praxis would generate an *umschlag*. If not, praxis would fail to generate an *umschlag*. In either case, causal verification required collective social action.

As a young scholar in Germany, Max Weber, found himself and his mentors surrounded by a methodological controversy: should the search for causal relationships between cultural phenomena follow the same, or different, methodologies as the search for causal relationships between natural phenomena? In addressing this question, Weber identified two different approaches to the study of causal relationships: nomothetic and idiographic. The nomothetic approach (used extensively in the study of natural phenomena) observed recurrent instances of particulars in order to develop general laws about universals. Empirical observations (including time sequences) were the core of the methodology, as was the use of conceptual or empirical controls. Following the nomothetic approach and the establishment of general laws, causes of given events were explained by "covering laws" (the reason that X was followed by Z was that X was a particular instance of Y, and Y was always followed by Z). The covering law was that Y was always followed by Z.

According to Weber, the idiographic approach (used extensively in the study of cultural phenomena) tried to explain unique historical events that could not be explained by covering laws. This called for a different methodology. In order to understand why a person acted in a certain way at a given moment in history, a sociologist had to relive empathetically what that person was experiencing at that moment. This required *verstehen* (reliving or reexperiencing) by the sociologist. If the person were living in a different culture or time period from that of the sociologist, the sociologist had to take special care to understand the expressions (*ausdruck*) of that person's time and culture in order to provide a meaningful explanation of his or her behavior. In such instances, there was no ultimate way in which it was possible for a person to validate an individual causal explanation. A description could be offered to peers about how a causal explanation was derived, but the validity of the explanation depended on how widely the explanation was or was not accepted by peers.

Max Weber also described how ideal types could be used to provide causal explanations for historical events. By definition, ideal typical actors are constructed to be clearly motivated, rationally directed non-real persons. Like a jurist in a court case, it would be possible to hypothesize how such clearly motivated non-real persons would behave in a given historical situation. Then, how actual people behaved in that same historical situation could be examined and comparisons made concerning the actual people's behavior and the non-real ideal-typical actor's behavior. The degree to which the people's actual behavior matched the non-real ideal-typical actors' behavior would suggest how closely the real meanings of the actual people matched the constructed meanings of the non-real ideal-typical actors. For example, if Max Weber's non-real ideal-typical predestined Calvinists engaged in worldly activities in order to obtain a hint of their souls' salvation, and actual historical Scottish Calvinists inaugurated extraordinary industrial activity, it could be inferred that a cause of the actual Calvinists' extraordinary industrial activity was their desire to obtain a hint of their souls' salvation. According to Weber, "In order to penetrate to the real causal interrelationships, we construct unreal ones."

Max Weber identified two different kinds of ideal types: historically individual complexes and developmental sequences. Historically individual complexes were created by accentuating certain distinctive features of some empirical phenomenon and making it into an analytic construct (e.g., church, sect, feudalism, individualism). Developmental sequences were created as a series of ideal-typical events conceptualized in space, time, and causal relationship (e.g., the routinization of charisma, the dynamics of

bureaucratization). The main purpose of both kinds of ideal types was heuristic—to compare with empirical reality. Regarding developmental sequences, Weber warned against a popular belief that sociology's goal was to produce laws of human behavior. Developmental sequences looked like such laws. They might even be mistaken for such laws. Were such to happen, ideal types would cease being heuristic and would become pernicious.

The English philosopher and economist John Stuart Mill (1806–1873), in his *A System of Logic*, outlined five "canons of inductive inference" that he believed enabled observers to agree on causes and effects in the empirical world. These canons included the method of agreement, the method of differences, the joint method of agreement and differences, the method of residues, and the method of concomitant variation. Mill based his canons on the ways in which observers found laws in the physical and natural world. According to Mill, these worlds were most effectively studied through "hypothetico-deductive" procedures that involved proposing, empirically testing, and continually refining hypotheses regarding regularly recurring events.

Considerable debate occurred, primarily in Europe, about the applicability of hypothetico-deductive procedures to the study of human behavior. "Logical positivism" was the name given to the philosophical positions associated with the Vienna Circle of the 1920s and 1930s that included such luminaries as the economist Otto Neurath, the physicist Philipp Frank, and the philosopher Moritz Schlick. The basic tenets of logical positivism included a desire to develop precise and unambiguous languages incorporating mathematical and logical symbols to refer to the empirical world, and the requirement that any proposition, causal or otherwise, must provide a method for its own verification or falsification. Logical positivists insisted on the unity of all sciences, because all sciences study the empirical world, components of which they try to link together by identifying relations of similarity and contiguity. According to the logical positivists, sociologists should use the same methodologies as physicists, astronomers, and biologists.

By the 1940s, the logical positivist movement had begun to decline, at least in part because some of its assumptions led to conclusions that were incompatible with its assumptions. One such assumption was the requirement that any proposition must be capable of verification or falsification. Efforts to establish unambiguous criteria for verification or falsification ran into serious problems. The philosopher Karl Popper, in *The Logic of Scientific Discovery*, argued that, on philosophical grounds, neither verification nor falsification could ever be attained. In their place, Popper substituted the vaguer (but possibly more attainable) criterion of "corroboration." Subsequently, Thomas Kuhn, in *The Structure of Scientific Revolutions*, described how, in the earliest stages of any field, the accumulation of knowledge was *ad hoc* (or preparadigmatic). However, as knowledge of any field accumulated, collectors of that knowledge began to operate within a paradigm (a multiple set of problems and solutions accepted by a community of scholars). Over time, those scholars would ignore an increasing number of negative instances challenging the validity of their paradigm. Finally, the negative instances would overwhelm that paradigm's credibility. At that point a new paradigm would be identified, one that accounted for many of the anomalies that had accumulated (and been ignored) under the old paradigm. In time, the majority of the scholarly community would come to reject the old paradigm and accept the new paradigm. A paradigm shift would occur, producing a scientific revolution. The new paradigm (solving some of the problems unsolved by the old paradigm but lacking some of the capabilities of the old paradigm) would generate a burst of new scholarly activity. According to Kuhn, scientific revolutions had occurred when Copernican astronomy replaced Ptolemaic astronomy, Newtonian dynamics replaced Aristotelian dynamics, and Darwinian evolution replaced teleological evolution.

Responses by sociologists to Kuhn's concepts of paradigms and scientific revolutions varied widely. Some sociologists doubted the existence of any shared sociological paradigm and suggested that sociology was still preparadigmatic. Others held that sociology had several paradigms, each with its own methodologies and causal explanations. Some scholars distinguished between revolutionary science and normal science and suggested that most scientists (including sociologists) practiced normal rather than revolutionary science. During the final decades of the 20th century, the focus of inquiry shifted from the philosophy of science to the history and sociology of science. What principles of rhetoric did Galileo use to convince his critics that their Earth-centered view of the universe was wrong and his Sun-centered view of the universe was right? How do any scientists (including sociologists) state their claims regarding facts and causal relationships, and how do they convince other scientists that their claims are valid? From a philosophical perspective, the methodology of sociology decreasingly meant strategies used by sociologists to validate their propositions and increasingly meant strategies used by sociologists to convince their peers to accept their propositions.

Sociology and Methods of Research

Sociological Training

Most undergraduate and graduate programs in sociology in the United States insist that students complete one or

more courses in statistics and research methods. The required statistics courses typically cover topics such as means, medians, modes, correlations, regressions, two-way tables, sampling distributions, confidence intervals, tests of significance, statistical inferences, probability theory, logistic models, likelihood functions, goodness of fit, binomial distributions, analyses of variance, strategies for handling missing data, and procedures for conducting special forms of analysis (such as path analysis, network analysis, factor analysis, and time-series analysis). The required research methods courses typically cover topics such as operationalizing variables, constructing hypotheses, identifying independent and dependent variables, recording observations, interviewing, drafting questionnaires and interview schedules, constructing scales, testing validity and reliability, sampling, and cleaning data after they have been collected but before they are processed. The requirement that sociological training will include courses in statistics and methods reflects a widely shared perspective in the United States that methodologies used to study natural or physical data can be applied equally well to sociological data.

The Use of Secondary Data

Because gathering data can be difficult, time consuming, and expensive, sociologists often use data that have been collected by other researchers. In 1962, the Inter-University Consortium for Political and Social Research (ICPSR) was established in Ann Arbor, Michigan to acquire, preserve, and make available to researchers wide-ranging bodies of social science data, many of them "social facts" as identified by Emile Durkheim. These data include national and international census, election, and financial information (e.g., gross domestic products, per-capita incomes, and income-distribution inequalities), opinion polls, household surveys, health information, longitudinal surveys, and statistical abstracts. During the first 40 years of its existence, more than 500 institutions joined the ICPSR. Benefits that member institutions received included access to the ICPSR's ever-expanding archives, its abilities to transfer data into new storage media to keep pace with technological changes, and the training it provides in quantitative methods of data analysis. Sociologists studying crime and criminal behavior can benefit from secondary-data sources such as uniform crime reports, prison records, and the national crime victimization survey. Sociologists interested in demography can obtain mortality and morbidity data from a wide range of secondary sources, including state and national census offices, the Centers for Disease Control and Prevention in Georgia, and relevant branches of the United Nations and the World Health Organization. As informational websites become increasingly available through the Internet, sociologists have expanding access to secondary data, with the caution that website data have not necessarily undergone professional or peer review.

The Use of Primary Data

Qualitative Research

As American sociologists generally define it, qualitative research differs from quantitative research in its greater dependence on the subjects of study (rather than on the sociologists studying the subjects) to define variables, historical sequences, and causal relationships. Qualitative research tends to focus on human agency (and hence widespread individual variability) rather than on structural agency (and hence recurrent comparability). Qualitative research is often used in case studies, including comparative case studies and extended case studies. Qualitative research is also sometimes used in pilot studies and the early stages of inquiry, when research problems and relevant variables are being initially identified.

Interviewing is one of the principal methodologies of qualitative research. Like anthropologists and psychologists, sociologists engaged in interviewing are generally trained to be sensitive to response bias and to be aware of how their rapport with their subjects, their ways of phrasing initial and follow-up questions, and their own verbal and nonverbal cues can distort the information they receive. Other methodologies used in qualitative research involve collecting oral histories, other kinds of oral productions, written materials, and visual productions. Further methodologies can include phrase-completion exercises, recording "natural" conversations, forming focus groups, and conducting various types of observations (structured and unstructured, participant and non-participant, obtrusive and unobtrusive) of individuals' behavior. Because of potentially sensitive information being obtained from individuals through such qualitative methodologies, sociologists engaged in primary research are often required to conform to certain ethical standards, including the informed consent of the participants and their own guarantees of record destruction to protect the anonymity of individuals.

Data gathered through qualitative research methodologies often require special forms of storing and retrieving, as well as of processing. Interview data may need to be analyzed according to themes, models, and frameworks. Unspoken materials, as well as spoken materials, from interviews should be reviewed. Premises and logical structures of narrative and performance data may require content analyses as well as cultural and historical contextualizations and criticisms of sources. Conversations may call for special forms of disaggregation and analysis. The skills required for dealing with qualitative data correspond in many ways to the skills of *verstehen* and *ausdruck* mentioned by Max Weber in his essay *The Meaning of "Ethical Neutrality" in Sociology and Economics*. The

perception is shared among many sociologists that qualitative researchers are more likely than quantitative researchers to question, as Max Weber and the phenomenologists did, the applicability of physical/natural science methods to the study of social behavior.

Quantitative Research

For sociologists, one of the main purposes of quantitative research is to make statements with some degree of confidence about sizable human groups. Such statements typically accept the hypothetico-deductive premises of regularity and recurrence seen to be present in the natural and physical sciences. Quantitative research often begins with the researcher selecting the population (or universe) to be studied, based on the nature of the questions to be answered. The selected universe could be all the citizens of a designated nation, laborers in a sweatshop, or the homeless in a large urban center. It could be women chief executive officers of *Fortune 500* corporations, or children raised in homes with same-gender parents. If the universe is large, the researcher might wish to select a manageable-sized sample from which to gather data. The sample could be selected in such a way that every unit in the universe has an equal likelihood of being selected (a probability sample). Or the sample could be structured in a way that guarantees the inclusion of certain subsectors (e.g., genders, ages, locations, ethnic groups) of the universe. An initial sample could be selected on the basis of convenience (a nonprobability sample) and then expanded by "snowball" referrals to additional units of the sample. The manner in which the sample is selected directly affects the confidence with which findings from the sample can be generalized statistically to the universe. A researcher can introduce additional degrees of sophistication by engaging in time-series sampling, paired-comparative sampling, and longitudinal panel studies.

The hypothetico-deductive approach calls for examining statements of purported invariant relationships (hypotheses) between antecedent (independent) variables and consequent (dependent) variables, presented so that the relationship is capable of falsification. In order to be capable of falsification, such statements must be nontautological and without empirically continuous antecedents or consequents, and they must specify the relationships between the antecedents and consequents (e.g., as necessary conditions or sufficient conditions). If, after the data have been collected and examined, the hypotheses have not been falsified, it can be stated that the data demonstrate the hypotheses. But it cannot be stated that the hypotheses have been "proved." "Proving" invariance requires evidence that has yet to be gathered.

In order for a statement of invariance to be examined, the variables in the statement must be operationalized (i.e., made capable of observation and measurement). If, for example, the statement refers to domestic violence, democracy, or intelligence, instructions must be provided for how data are to be gathered as evidence of domestic violence, democracy, or intelligence. Furthermore, the case must be made that the data obtained by following the instructions are valid indicators (i.e., actually provide evidence) of domestic violence, democracy, etc. This case must be made rhetorically, because it cannot be made empirically.

Comparisons are at the heart of sociological research: comparisons of sociological phenomena at two points in time, comparisons of dependent variables following changes in independent variables, and quasi-experiments in which treatment effects on dependent variables are compared with control effects on comparable dependent variables while accounting for experimenter effects. Quantitative research tends to focus on structural agency (rather than human agency) and hence recurrent comparability. The goal of such research is to demonstrate empirically supported sociological relationships, often in sizable human groups. In order to gather systematic information from large numbers of people, sociological researchers frequently conduct surveys for which they prepare data-gathering instruments, such as questionnaires (for written responses) and interview schedules (for oral responses). The questions asked in these instruments may be close ended (with limited fixed choices) or open ended. The major advantage of close-ended questions is the ease of final tabulation. The major advantage of open-ended questions is the possible acquisition of useful unanticipated information. If replies to open-ended questions are to be used systematically, they must be coded. Raters who code the open-ended answers must be trained so as to minimize differences in their coding patterns and to maximize their interrater reliability.

Prior to using questionnaires or interview-schedules in the field, it is essential to pretest them with a sample of respondents who will not be included in the final survey. Pretests may uncover problems of question clarity and accuracy. Because the phrasing of questions can alter respondents' answers, efforts are usually made to ask each respondent identically worded questions. At times, however, wording equivalency may be more important than wording identity. In a survey of sexual behavior, for example, alternative words were substituted for certain sexual practices so that respondents from different social backgrounds could understand what sexual practices were being referenced. Designers of questionnaires and interview schedules can prepare scales (such as Guttman scales, Likert scales, or Thurston scales) to measure relative degrees of attitudes or practices. Interview schedules require trained interviewers to gather data in face-to-face conversations or over the telephone. One advantage of using interview schedules rather than questionnaires is the possibility of asking respondents to answer follow-up questions for clarification or additional

details. Advantages of using questionnaires generally include greater speed and lower cost of data collection.

Reliability (the extent to which questionnaires or interviews give the same results in repeated trials) is desirable in survey instruments. Asking the same question in different ways can test a procedure's reliability. In a survey of sexual behavior, for example, differently worded questions were asked at different points in the interview about the number and gender of the respondent's recent sexual partners. Afterward, the respondents' replies to each of the different questions were compared for consistency, and hence for procedure reliability. Another technique for testing a survey's reliability is to reinterview a random selection of already interviewed subjects. The reinterview can achieve two ends: it can establish the fact that the subjects were indeed interviewed, and it can identify differences between the ways subjects originally answered the questions and the ways they answered the questions the second time. The narrowness of differences between the first and second answers would be a measure of the survey instrument's reliability. Arranging for questions to be asked in multiple languages requires special care. A useful technique is to have one translator convert the English questions into Spanish (for example) and a different translator convert the Spanish questions back into English. Comparing the original English with the "back-translated" English could identify words or phrases needing to be retranslated.

The heart of the sociological enterprise involves concepts and the measurement of concepts. Over the years, increasingly sophisticated statistical procedures have refined researchers' abilities to analyze data. But sociology's fundamental philosophical problems remain the same: How are social collectivities accurately defined and measured, and how are their causal relationships established?

Software

Micah Altman
Harvard University, Cambridge, Massachusetts, USA

Glossary

algorithm A precise set of instructions, in an abstract programming language, describing how to solve a problem.
compilation The translation of instructions in a programming language into a machine language.
machine language The set of instructions directly executable by a particular type of computer hardware.
program A sequence of instructions, written in some programming language, that a computer can execute.
programming language An artificial language used to write computer programs that can be translated into a machine language.
pseudocode A notation resembling a programming language but intended for pedagogy, not translation into machine language.
software engineering The discipline engaged in systematic study and practice of designing and implementing software.
software rot The tendency of software to fail as it becomes older. Usually this is because of changes in the operating environment or limitations in the design assumptions and not because of changes to the software.

Software, generally defined, is a set of instructions designed to be executed by a computer. Practically every modern method of quantitative and statistical analysis relies on software for its execution. Despite its ubiquity, software is usually regarded (when considered at all) as necessary, but preferably invisible, infrastructure for such research. In fact, an understanding of software is essential to correct and efficient application of many quantitative and statistical methods.

Introduction

How Is Software Used?

The use of software in social science research is extensive and wide ranging. Software is used at every stage of the research process, from collecting, organizing, and analyzing information to writing and disseminating results. The mathematically demanding nature of modern statistical analysis makes the use of relatively sophisticated statistical software a prerequisite for almost all quantitative research. Moreover, the combination of increasingly powerful computers, ubiquitous computer networks, and the widespread availability of the software necessary to take advantage of both has made practical on a hitherto unprecedented scale the application of many complex methods, such as maximum likelihood estimation, agent-based modeling, analytic cartography, and experimental economics.

Brief History

The idea of the algorithm, which is basic to all computer software, dates back as far as 825 CE to the Persian mathematician Abu 'Abd Allah Muhammad ibn Musa Al-Khwarizimi. The invention of the computer program is much more recent: Ada Lovelace is usually attributed with creating the first theoretical computer programs in 1843, to be used with Charles Babbage's analytical engine (which was never physically constructed).

The modern form of "software," a set of instructions that is separated from the physical computer, originated in 1945 when John Von Neumann first proposed the "stored program." This stored program (now known as a "computer program") would comprise a set of instructions for a general-purpose computer that would be stored in the computer's memory, along with the data, rather than being physically "wired" into the computer hardware. (The Eniac, the first general-purpose, programmable, electronic digital computer, had to be rewired in order to run different programs; subsequent digital computers have followed Von Neumann's design.)

```
function Standard_deviation (X: vector ) {
  variables x_sum, x_mean, x_std, : real ; n ,
   count: integer;
  x_sum = 0;
  n = length(X) ;
  for count = 1 to n {
    x_sum = x_sum + X[count];
  }
  x_mean = x_sum/n;
  x_dev = 0;
  for count = 1 to n {
    x_dev = x_dev + (x_mean - X[count])^2;
  }
  x_dev = sqrt(x_dev/n);
  return (x_dev);
}
```

Figure 1 Pseudocode for computing the standard deviation.

In the earliest period of digital computing, from the construction of the Eniac in 1945 through the mid-1950s, software was developed either by the end user or by the manufacturer. Typically, the vendor delivered, at most, low-level utility programs. The end user would have to write whatever software that he or she needed, or copy it from another user.

A market for software contracting first developed in the mid-1950s, but application software remained entirely custom written: The vendors of the mainframes of the day would supply freely the operating systems software needed to run the system since such software was coupled so closely to that particular type of hardware that no one else had the experience or the time to develop it. All other software was written by the end user or by contractors, who would write custom software tailored to the needs of that user and application.

It was only in the 1960s that generalized software packages products first emerged and not until the late 1970s that software became a "shrink-wrapped," standardized, stand-alone, mass-market commodity. Today, much of the software used in social science research is of the shrink-wrap variety: a stand-alone package capable of performing a wide variety of functions and written in a programming language that permits portability across different types of computer hardware. However, although software has become much more standardized, social scientists sometimes find it necessary in the course of their research to write their own programs. In addition, despite the increasing standardization of software, its intrinsic complexity is such that even standardized, widely used commercial software may occasionally yield wildly incorrect or inaccurate results.

```
function standard_deviation_2 (X: vector ) {
  variables x_dev, x_sum_sq, x_sum : real; n,
   count: integer;
  x_dev = 0; x_sum = 0; x_sum_sq = 0;
  n = length(X);
  for count = 1 to n {
    x_sum = x_sum + X[count];
    x_sum_sq = x_sum_sq + X[count]^2;
  }
  x_dev = sqrt((n*x_sum_sq - x_sum^2)/n^2);
  return (x_dev);
}
```

Figure 2 A single-pass algorithm for the standard deviation.

Algorithms, Computability, and Computational Tractability

What Is an Algorithm?

The idea of the algorithm is fundamental to software. An algorithm is a sequential set of steps that can be used to solve a well-defined problem. More strictly, an algorithm is a finite, deterministic set of instructions written in an abstract syntax that, when executed, completes in a finite amount of time and solves a specified problem. An algorithm is said to solve a problem (or to be effective) if and only if it can be applied to every instance of that problem and is guaranteed to produce an exact solution for each instance.

Consider the problem of computing the standard deviation of a population, $\sigma = \sqrt{\left(\sum(x-\bar{x})^2/n\right)}$. Pseudocode for one algorithm that computes this is shown in Fig. 1. A cursory examination will show that this algorithm is effective for any vector of real numbers and will complete in an amount of time roughly proportional to the length of the vector.

This is not, of course, the only algorithm that solves the problem. The mathematical expression could be expanded and rearranged to yield $\sigma = \sqrt{\left(n\sum x^2 - (\sum x)^2/n^2\right)}$, which computes the standard deviation in a single pass, without first computing the mean. Directly translating this expression into pseudocode yields a different algorithm, as shown in Fig. 2.

Algorithmically, the two methods of computing the standard deviation are similar in structure, and the execution time for either is a linear function of the length of x. As we shall see in the next section, however, straightforward implementation of each of these algorithms may differ greatly in real accuracy and speed.

As stated previously, the term algorithm, when not otherwise qualified, denotes a deterministic, finite set of steps guaranteed to produce results with well-defined

properties. Other categories of algorithms exist: approximation algorithms, randomized algorithms, and heuristic algorithms. These qualified classes of algorithms, especially heuristics, are used most frequently to approach problems for which no tractable deterministic, finite, effective algorithm is known.

Approximation algorithms produce results that are guaranteed to be within some formally defined distance (usually given as a relative measure) of the optimal solution to a problem. For example, approximation algorithms are sometimes used for the traveling salesperson problem (TSP), which is stated as follows: Given a list of cities and the cost of travel between each, find the cheapest route that visits each city once and returns to the starting point. No algorithm solves the TSP efficiently, and it can be proved that no approximations exist for the general TSP problem. However, if the cost of travel between cities satisfies the triangle inequality, approximation algorithms (such as the minimum spanning tree algorithm) exist that are guaranteed to yield solutions that are no more than twice the optimal cost. For other problems, approximation algorithms may exist that yield solutions arbitrarily close to the optimal solution. For example, when one uses a converging infinite series, such as a Taylor series, to approximate a function, one can reduce the approximation error of the algorithm as much as desired by adding more terms.

Randomized algorithms use nondeterministic steps and have a known probability of yielding correct answers. Randomized algorithms that can sometimes return incorrect results are called Monte Carlo algorithms, whereas Las Vegas algorithms may return an indication that a solution was not found but never return incorrect results. In contrast, heuristic algorithms, often known simply as heuristics, specify sets of steps but yield solutions that do not have well-known properties. In other words, heuristic algorithms yield solutions that are not known to be correct (or even approximately correct) but are thought to be often useful in practice.

Turing Machines

The Turing machine is an abstract representation of a computer introduced by Turing in 1936 to give a precise definition to the concept of the algorithm. It is still widely used in computer science, primarily in proofs of computability and computational tractability. Turing imagined a mechanical device that moved along an infinite length of recording tape, reading and modifying symbols on that tape in accordance with a fixed internal table of actions. As a Turing machine moves along a tape, it uses its table, in combination with the current input symbol, and the contents of its internal state register to determine the next action. The table indicates to the machine whether to modify the current symbol and/or state, and also whether to move forward or backward along the tape.

Mathematically, a Turing machine is a tuple: $M = (K, \Sigma, \delta, s)$, where K is a finite set of states, $s \in k$ is the initial state, Σ is a finite alphabet of symbols, and δ is a transition function that represents the "program" for the machine:

$$\delta: K \times \Sigma \longrightarrow \left(K \cup \{halt, accept, reject\}\right) \times \Sigma \times \{left, right, stay\}.$$

A string of symbols σ from the alphabet Σ represents the input to the Turing machine. To "execute" the machine, one applies δ to the first symbol in σ: $\delta_o = \delta(s, S_0)$ and uses the output to update σ and to provide the input for the next iteration of δ.

The Church–Turing thesis, in its most common form, states that every physically possible form of computation can be carried out by a Turing machine. This thesis is generally assumed to be true, and it has some important and useful implications: all computer languages that are Turing complete, which includes all common programming language, are equivalent in what they can compute: any computation possible in FORTRAN, for example, is possible (if not necessarily equally convenient) in any other language. If one can construct a proof of the (non)-computability of a particular problem, or of the effectiveness of an algorithm, that proof applies to all other physically possible forms of computation (including quantum methods).

Computability and Computational Complexity

A problem is said to be computable (or decidable) if and only if there exists an algorithm that solves the problem. Turing, in his 1936 paper, first proved the halting problem to be undecidable. Informally, the halting problem can be stated as follows:

> *Given a description of an arbitrary algorithm and its input, decide whether the algorithm halts (yielding an answer) or runs infinitely.*

Turing demonstrated that a direct consequence of the halting problem being undecidable is that there cannot be an algorithm that, given any statement about the natural numbers, determines that statement's truth. Subsequently, many other undecidable problems have been described, and the typical method of proof has been to show that a new problem reduces to the halting problem. Remarkably, two decades later, Rice showed that given any nontrivial property of a computer program (or mathematically, a partial function), the problem of determining whether that property applies to an arbitrary computer program is generally undecidable.

It is important to note that Turing's and Rice's proofs apply to the set of algorithms as a whole, not to all individual instances. It is certainly possible, for example, to prove the correctness of some computer programs, although it is impossible for an algorithm to be able to determine the correctness of any program given to it. For individual instances of algorithms, the central roles of algorithmic analysis are to determine the correctness and efficiency of individual algorithms and to characterize the difficulty of different classes of problems.

Computer scientists use computational complexity classes to characterize the difficulty of computable problems. A complexity class comprises a model/mode of computation (e.g., the deterministic Turing machine described previously), a resource we wish to bound (e.g., execution time or storage space), and a bounding function. A problem is said to be a member of the class if some algorithm exists that, using the specified mode of computation, can solve any instance of that problem using amounts of resources limited by the given bound. Bounding functions for execution time are conventionally denoted using "big O notion," $O(f(n))$, where n is the size of the problem. Additive and multiplicative constants are omitted because these vary with the computing model used. For example, $O(2^n)$ denotes that the time it takes to execute an algorithm grows exponentially as input grows (for worst-case instances).

There is an infinite number of possible complexity classes. Two classes, P and NP, are of particular interest because they are widely used as measures of computational tractability. Both P and NP are measures of time complexity, which is proportional (by construction) to the number of the instructions that an algorithm must execute to reach a solution. The bounding function is expressed in terms of the size of the problem-instance, which is defined as the number of parameters or items (of fixed size) in the instance. (Technically, NP applies to decision problems that yield true or false as an answer. However, other types of problems can easily be converted to decision problems to determine the complexity class.)

The class P is the set of problems for which algorithms exist that can solve any instance in polynomial time. Formally, the class NP is defined as the set of problems solvable in polynomial time by a nondeterministic Turing machine, which would automatically choose the correct answer from among a finite set of possible logic branches. (This is a useful mathematical construct but not physically possible.) This class of problems is widely thought to require exponential time to compute by any real computer, for at least one instance of the problem: $O(c^n), c > 1$. NP-complete problems are thought to be the most difficult problems in NP. A problem is NP-complete if it is in NP and if every other problem in NP is reducible to it.

A problem is said to be computationally tractable if it is in P. A problem is said to be computationally intractable (also referred to as computationally complex or computationally hard) if it is at least as difficult as a problem in NP. No polynomial-time algorithm is known to exist, using conventional computers, for any problem in NP.

The most common way to show that a particular type of problem is NP-hard is to show that another problem already known to be NP-hard can be reduced to it. There are many types of reduction techniques, and one particularly straightforward type is called the Karp reduction, or the polynomial-time many-one reduction. To use this technique, one finds a known NP-hard and a polynomial-time algorithm that converts any instance of that problem to an instance of the new problem. Since any algorithm that solves the new problem would also solve the intractable problem, the new problem must be at least as difficult as the intractable problem. To show that the problem is NP-complete, one proves that a known NP-complete problem can be reduced to the new problem and vice versa.

The use of membership in P and NP to characterize a problem as tractable or intractable, respectively, has two advantages. First, it is independent of any particular computer hardware design. Intractable problems cannot be made tractable through improvements in conventional hardware technology. Second, it is independent of any particular algorithm since it is the problem itself, not a specific algorithm, that drives the requirement of exponential time. Intractable problems cannot be made tractable through advances in software or algorithmic design.

There are, however, some limitations to this characterization of tractability. First, the distinction between tractable and intractable problems is most important for instances of large size, where the exponential factors in the time requirements of these problems become dominant. If problem A is solvable in $O(1.1^n)$ time and problem B is solvable in $O(n^{2000})$ steps, B is formally more tractable than A but is more difficult to solve in practice. Second, NP-completeness is a worst-case measure of complexity: Some problems in NP may have instances that can be solved in polynomial time, and it may even be the case that the average instance is solvable in polynomial time. Third, NP applies strictly to deterministic exact algorithms. An "intractable" problem may still be "solved" by a randomized algorithm that gives a solution with high probability or an approximation algorithm that is close to the desired solution. Fourth, a small number of problems in NP (but not NP-complete) are thought to be solvable efficiently with quantum computers, should such computers ever be constructed on a large enough scale. It is currently believed, however, that no physically possible quantum computer can compute NP-complete problems efficiently.

Despite these theoretical limitations, relatively few NP-hard problems have been found to be easier than

expected in practice; few have yielded to approximations, randomization, or quantum algorithm techniques; and few have been found easy in the average case. NP-completeness remains a powerful and widely used gauge of computational tractability.

Application of Complexity Theory: How Difficult Is It to Manipulate an Election?

One key problem for voting systems is the potential for voters to manipulate the results through strategic voting. A voter is said to act strategically when he or she casts a vote that does not reflect his or her true ranking over the choices but is calculated instead to achieve a favorable outcome. For example, a voter in a presidential election might prefer the Libertarian candidate to the Republican and Democratic candidates but casts a vote for the Republican candidate because he or she believes the Libertarian has a negligible chance of winning. A voting system is said to be nonmanipulable if it is not possible for any voter to gain from strategic voting.

Strategic voting has been studied extensively in political science and economics. A powerful negative result, discovered by Gibbard and Satterthwaite independently in the early 1970s, is that any nondictatorial voting scheme is manipulable (for elections with at least three candidates). Like Arrow's theorem, on which Satterthwaite's proof drew, this impossibility result engendered some pessimism regarding the design of electoral systems.

In 1989, Bartholdi *et al*. used computational complexity theory to show that under some voting systems effective strategic voting is NP-hard. Thus, these elections systems are, if not manipulation-proof, at least manipulation-resistant. In using complexity theory to inform social choice theory, they initiated the study of the computational properties of electoral systems.

Bartholdi *et al*.'s proof is too long to present here, but another proof in the same vein is instructive. This proof, which comes from previous work by the author, shows that the problem of constructing "optimal" election districts is NP-hard. The following portion shows that constructing a district plan having the minimum possible population deviation among them from discrete nonuniform census blocs, as the law requires, is NP-hard:

1. Note that each of the n census blocs, c_i, must be assigned to one and only one of k election districts, d_j, and that the population of the district is simply the sum of all census blocs that comprise it:

$$Population = P(d_i) = \sum_{j \in d_i} c_j.$$

2. Define the measure of population deviation for a redistricting plan to be the difference in population between the most and least populous district:

$$\textit{Population deviation score} = \mathrm{PD}(\mathbf{c}) = \max_{i \in k}\left(\sum_{j \in d_i} c_j\right) - \min_{i \in k}\left(\sum_{j \in d_i} c_j\right).$$

3. The optimal districting plan is thus a division (strictly a partition) of the n census blocs into k districts such that PD is minimized.

4. Finally, we show that we can convert any instance of 3-partition,a known NP-complete problem, into the redistricting problem:

3-partition

Input: Set A of $3m$ elements, a bound $B \in Z^+$ and a size $s(a) \in Z^+$ for each $a \in A$ such that $B/4 < s(a) < B/2$ and such that $\sum_{a \in A} s(a) = mB$.

Solution: Determine whether A can be partitioned into m disjoint subsets such that for $1 \leq i \leq m$, $\sum_{a \in A_i} s(a) = \mathrm{B}$.

To convert an instance of 3-partition into an instance of optimal redistricting,

a. For each element $a_i \in A$, create an artificial census bloc with a population equivalent in size, $c_i = s(a_i)$.

b. Take the solution for the optimal redistricting problem, PD*, using the artificial census blocs created in step (a). If $\mathrm{PD}^* = 0$, the answer to the corresponding 3-partition is "true"; otherwise, the answer is false.

Thus, any algorithm that solves the optimal redistricting problem can also be used to solve 3-partition. Since the 3-partition problem is computational intractable, optimal redistricting is computationally intractable as well.

Implementation: Bugs, Verification, and Accuracy

Although algorithms are at the conceptual core of all software, computers execute not algorithms but programs—implementations of an algorithm written in some real programming language, and executing within a particular computing environment. The same algorithm may be expressed using various computer languages, use varying encoding schemes for variables and parameters, rely on arithmetic operators with varying levels of accuracy and precision in calculations, and run on computers with varying performance characteristics. Three problems can occur in the gap that arises between the formal algorithm and its actual implementation: bugs, inaccuracies, and performance bottlenecks.

Bugs and Verification

Any computer program of reasonable size is sure to have some programming errors or "bugs," and there is always a possibility that these errors will affect research results. In practice, software used in research will be tested but not proven correct. As Dahl *et al*. famously noted in 1972, program testing can be used to show the presence of bugs but never to show their absence. It has also been observed generally that even software that worked well when first written tends to encounter problems as changes occur to the computing environment within which it runs, such as the operating system, system libraries, and computing hardware. (This phenomenon is known colloquially as "software rot".)

Errors in mathematically-oriented programs are often particularly difficult to detect since the software may return plausible results rather than failing entirely. Well-replicated studies of experienced spreadsheet programmers performing standardized tasks have demonstrated that undetected bugs are the rule, not the exception. Although extensive testing will substantially reduce the rate of errors that remain in the final version of a piece of software, much caution is still warranted when creating one's own software.

In limited circumstances, it is possible to prove software correct, but it is exceedingly unlikely that any particular software package used by social scientists will have been subject to formal methods of verification. Until recently, in fact, such formal methods were widely viewed as completely impractical by practitioners, and despite increasing use in secure and safety critical environments, usage remains costly and restrictive.

Computer Arithmetic, Numerical Accuracy, and Stability

Mathematicians, social scientists, and other humans perform arithmetic symbolically: computers do not. The difference between symbolic and computer arithmetic can lead to inaccuracies, and to avoid these inaccuracies we need to understand how computers do math. All computer hardware, and practically all software, performs arithmetic by representing every number as a fixed-length sequence of 1s and 0s, or bits, b. Integers are often represented as a single sequence of bits, each representing a different power of two, with a single bit indicating the sign. Under this representation, arithmetic on integers operates according to the "normal" (symbolic) rules of arithmetic, as long as the integer operands nor the results are too large ($>2^{b-1}-1$), leading to an (possibly undetected) overflow error. For example, usually $b=32$, so the number 2147483648 ($1+2^{32-1}-1$) would overflow and may actually roll over to -1.

Real numbers are represented using floating point arithmetic. Floating point numbers are represented by two sequences of bits, with one sequence representing a mantissa (m) and the other representing an exponent (e): $\pm m \times 10^e$. An additional bit indicates the sign. The specific details of floating point arithmetic operations vary across different computing platforms. (The algorithms for performing floating point arithmetic encompass some subtle technical details, which are beyond the scope of this article.)

All floating point representations are subject to overflow, underflow (when the true number is smaller than the smallest value capable of being represented), and rounding errors. Rounding and other numerical problems can lead to inaccurate results, even when every step of an algorithm is correctly followed. (The accuracy of the solution is, roughly, the distance between the results that are actually produced and the correct answers when computed using infinite precision.) One source of rounding error arises directly from storing data in this representation: some numbers cannot be exactly represented using this scheme. An example is the number 0.1, which has an infinitely repeating binary representation using this technique. The infinitely repeating floating point transformation of "0.1" must be rounded to m bits, resulting in a slight loss of accuracy when performing subsequent calculations. A second source of rounding error occurs when a number is added to (or subtracted from) a very much smaller number. This type of rounding error can occur even when both operands are exactly represented. In the extreme case, the result simply rounds to the very large number.

Underflow, overflow, and rounding have many implications for accurate computing. One implication is that summations are more accurate when performed on a list of elements that is sorted in order of increasing magnitude. Therefore, the algorithm in would produce a more accurate result if we modified it as in Fig. 1. Standard proofs of the correctness of particular algorithms usually ignore the underlying arithmetic implementation and the effects of rounding.

The limits of computer arithmetic, and the variations in it across different platforms, have three implications for replicability and accuracy. First, a computer program can produce different answers when run on different computers, run on the same computer using a different operating system, or recompiled with different options.

```
function Standard_deviation_3 (X: vector ){
  variables X_sort: vector;
  X_sort = sort_least_to_greatest(X);
  return (Standard_deviation (X_sort));
}
```

Figure 3 A more accurate standard deviation.

Second, numeric errors can accumulate within an algorithm or can (rarely) cancel each other. Third, inaccuracies in floating point arithmetic can interfere with the formal mathematical properties of elementary and nonelementary functions. For example, the associative law of arithmetic does not hold universally for computer arithmetic: Where $\oplus$ is the floating point addition, $(a \oplus b) \oplus c \neq a \oplus (b \oplus c)$. Practically, floating point inaccuracies can cause a range of problems, from small inaccuracies in the results to results that are returned without error but are completely inaccurate or even failure of an otherwise correct algorithm to halt. Careful analysis of the accuracy of each numerical implementation, in its entirety, is necessary in order to ascertain the level of accuracy that can be associated with a particular solution.

Surprisingly, accuracy alone is not enough to ensure that implementations of algorithms produce usable results. Because of the rounding of data when stored initially, and because of the possibility of measurement error in much of social science, a reliable implementation must be numerically stable as well as accurate. An algorithm for computing a function is said to be numerically stable if small errors in input cause only small errors in output; that is, $\hat{y} + \Delta y = f(x + \Delta x)$, where x is the true input, $\hat{y}$ is the true output, and $\hat{y} + \Delta y$ is the computed value. Δx is error that enters into computations through, for example, converting a decimal number into a binary number with a finite degree of precision. Less formally, a stable algorithm gives "almost the right answer to almost the right problem."

Performance Tuning and Bottlenecks

Algorithms determine performance at the grand scale. For sufficiently large values of n, an $O(n)$ sort algorithm will finish before an $O(n^2)$ algorithm. Nevertheless, implementation is important: It is not uncommon for a well-tuned implementation of a particular algorithm to run an order of magnitude faster and use an order of magnitude less resources than a naive implementation of the same algorithm. This arises most commonly because of performance bottlenecks. In all computing architectures, executing a program involves accessing implicitly a variety of heterogeneous resources, such as floating point units for arithmetic calculations, memory chips and storage devices for access to data, and networks and busses for communication. These resources have different performances characteristics, and a bottleneck may occur when the calculations of the program are interrupted to wait for some slower (or temporarily unavailable) computer resource. It is rare that formal algorithmic analysis delves down to this level of detail.

Programmers and compilers can use profiling tools to analyze the empirical behavior of a particular computer program by monitoring its performance and the resources its uses as it runs. By rearranging the order of operations, changing the pattern of access to data, and substituting note equivalent (but more efficient) sets of computing instructions, the program can be made to run faster. Low-level performance tuning, however, is often tied closely to a particular hardware configuration, programming language, and operating environment, and is at odds with portability, clarity, and maintenance. Moreover, it is usually counterproductive to tune a program without an empirically generated profile of its performance. Thus, performance tuning is best done after the software is designed, written, and tested.

Application: Benchmarking a Statistical Package

Consider the two algorithms for computing the standard deviation discussed previously. If the vector $\mathbf{X}$ is very large, it may be expensive to read values from it. In this case, despite both algorithms having approximately equivalent time complexity, the program implementing the single-pass algorithm in Fig. 2 could be much faster than a program implementing the algorithm in Fig. 1, which requires that every element of $\mathbf{X}$ be read twice. However, the algorithm in Fig. 2 is, in practice, much more susceptible to rounding errors when $n\sum x^2$ and $(\sum x)^2$ are both large. (In this case, the tradeoff between performance and accuracy is avoidable; more accurate one-pass algorithms exist.)

In practice, programs are often so complex that numerical benchmarks, rather than formal analysis, are used to gauge their accuracy. Numerous benchmarks are available for testing simple statistical functions and models, such as univariate descriptive statistics, cumulative distribution functions, linear regression, analysis of variance, and nonlinear regression. One particularly popular and useful set, the Statistical Reference Datasets (StRD), is maintained by the National Institute of Standards and Technology (NIST).

Each StRD problem is composed of either data taken from published research or data specially generated to stress computational capabilities. For each problem, the data are accompanied by values certified by NIST to be correct. These values are obtained analytically where possible, or by using supercomputers to compute approximate results using two independent algorithms and exceptionally high-precision floating point arithmetic.

As an example of a benchmark, consider a simple univariate descriptive statistics problem. Compute the mean, standard deviation, and one-observation lag autocorrelation for the first n digits of π. The StRD provides both the input data and the result values. These have been calculated on a supercomputer using very high-precision arithmetic and the results rounded to 15 significant digits.

```
> options(digits=22)                                    # set number of digits to display
> x<-read.csv(file=''PiDigits.txt'' header=TRUE)        # read test data
> x[1:10,1]                                             # check data, digits of pi
[1] 3 1 4 1 5 9 2 6 5 3
> xm<-mean(x[[1]])                                      # calculate mean of data
> xm
[1] 4.534799999999720046
> xsd<-sd(x[[1]])                                       # calculate standard deviation
> xsd
[1] 2.867543699108215271565
> xacf<-acf (x[[1]], lag.max=1, type=c(''correlation''),plot=FALSE)
> xac<-xacf [[1]][2]                                    # calculate autocorrelation
> xac
[1] -0.003683261271785385603666
> -log(abs((xm-4.5348)/4.5348))                         # calculate LRE for mean, sd, ac
[1] Inf
> -log(abs( (xsd-2.86733906028871)/2.86733906028871))
[1] 35.0175962904394
> -log(abs( (xac+0.00355099287237972)/-0.00355099287237972))
[1] 34.8496905126905
```

Figure 4 Testing a statistics package for accuracy by using the digits of pi.

The resulting values are said to be certified by the benchmark.

To gauge the reliability of a particular statistical package using the StRD, one loads the data into the program, runs the analysis, and compares the results generated by the software to the certified values provided by NIST. Although no benchmarking method can prove that a piece of software is accurate, performing well on the StRD benchmark provides evidence that a software package is accurate for that domain of problems.

The transcript in Fig. 4 shows the results of running the NIST "Pi-digits" benchmark in a popular statistics package. In this example, we calculate the number of correct digits in the results produced by the statistical software using the log relative error (LRE). More formally, the LRE is:

$$-\log_{10}\left(\left|\frac{result-certified}{certified}\right|\right), \quad certified \neq 0.$$

The previously discussed statistics package agreed with the certified benchmark results to at least 34 digits. Since the accuracy of the benchmark is only certified to 15 digits, we can infer that the statistical package was accurate to at least 15 digits for these calculations.

Software Development

Developing software remains a complex and difficult activity. Many practitioners suggest that this complexity is unavoidable. The complexity of the problem domains to which software is applied, the inherent malleability of software, and the problems that characterize the behavior of discrete systems with large state-spaces all contribute to the overall difficulty of developing software. Regardless of its source, the difficulty of writing software has a number of important consequences, and much of the work in the field of software engineering is devoted to managing the complexity of software and the risks that result from such complexity.

Implications of Complexity for Programming

One well-known consequence of software's complexity is that there is wide variation in the quantity and quality of work produced by individual programmers: Early findings by Sackman *et al.* found differences of more than 20 to 1 in the time required by experienced programmers to solve the same problem. This result has been widely replicated, with findings of large differences in productivity and defect rate across programmers and programming teams.

A second consequence of the software's complexity is that as the desired functionality of a program increases, a monolithic program providing that functionality eventually becomes too complex to understand and manage. As a consequence, most programming techniques seek to manage the complexity of programs by decomposing them into smaller, simpler components. All

decompositions attempt to form abstractions to represent each of the components so that some details about the implementation can be encapsulated, or hidden from, the other components. For each component, a set of interfaces are created that define the way each component is used, so that components can be integrated to form the program. If the decomposition is successful, the implementation of each component can be changed over time and can later be adapted to different computing needs. Also, as long as the interface behavior is preserved, the program will continue to function correctly as a whole.

The first generation of programming languages, such as FORTRAN I, was designed to support decomposition of programs into mathematical expressions. It was quickly realized that this method of decomposition was too limiting. Modern programming languages and methods typically support one of five strategies for decomposing problems. Procedure-oriented methods aim to decompose programs directly into sets of algorithms. Object-oriented methods aim to decompose programs into classes, objects, and behaviors, the last of which encapsulates the specific problem-solving algorithms used. Logic-oriented, rule-oriented, and constraint-oriented methods aim to decompose programs into sets of goals, if–then rules, and constraints, respectively. These three methods use generalized algorithms to solve for or optimize against the specific sets of goals, rules, or constraints.

For example, consider the sort_least_to_greatest() routine in Fig. 3. This function is an example of a procedure-oriented decomposition of a problem. The decomposition of our program separates the sorting algorithm from the algorithm used to compute the standard deviation. The implementation of the sort procedure is unspecified, but it could be any one of a wide variety of sort algorithms, depending on the programmer's desire to save space, time, or effort. Whichever algorithm is used, the program as a whole remains correct as long as the same procedural interface is provided with each algorithm.

There is no method of decomposition that is universally better for all applications. For example, logic-oriented programming techniques and languages are considered to be particularly well suited for some applications in artificial intelligence. For general applications, however, the procedure and object-oriented methods are most commonly used, and modern best practices and programming languages emphasize the object-oriented approach. Moreover, research is active in the area of extending and augmenting the object-oriented paradigm: Techniques such as component-based programming and design patterns provide methods for grouping objects into larger abstractions, and new paradigms such as aspect-oriented programming aim to augment object-oriented approaches with alternative, concurrent decomposition strategies.

Software Development Life Cycle

Caution is warranted when a software program is large enough to involve more than one author. In 1975, Brooks discussed the widespread difficulties of software development and formulated his well-known, and well-studied, "law": "Adding manpower to a late software project makes it later." This results from the fact that adding additional programmers often increases the communication and coordination costs involved in a project faster than it decreases the remaining work.

Surveys of practice in industry continue to demonstrate the difficulties of software development. A significant minority of projects are never completed, and the vast majority of the remainder finish significantly over budget, long past the original deadlines, and often with reduced or impaired functionality. Although the exact percentages are debated, it is widely recognized that the majority of software projects of moderate size fall short in some serious way.

Projects falter for many reasons, but the two causes most commonly diagnosed are poor schedule estimation, which is nearly universal, and problems deriving from excessive, changing, unclear, or incomplete requirements. Models for development have been proposed to address these common problems. The first model for developing software, the "waterfall" model, was articulated (although not advocated in its pure form) by Royce in 1970 and quickly gained dominance. It advocated that software development proceed in five phases: (i) requirements specification, in which the functionality of the software is described in detail; (ii) design, in which the overall structure of the software is designed and categorized into subcomponents with well-defined interfaces; (iii) implementation, in which the code for each component is written and tested individually; (iv) integration, in which individual components are integrated into a complete system that is then tested together; and (v) operation and maintenance, in which the software is delivered to the customer, modified to meet changing requirements, and repaired as bugs are discovered.

Although the waterfall model can still be found in modern use, it is now regarded as somewhat naive. A decade after the model was developed, it was widely criticized as it became clear from experience that it did not adequately address either design risks or requirements risks. Risks that requirements were not properly anticipated, were misunderstood, or needed to change over the course of the project and risks that the design of the project was flawed, incomplete, or misunderstood in implementation. Recognition of these risks has led many to abandon the waterfall model in favor of incremental and iterative models of software development, in which multiple versions of a project are developed and delivered to users over the life cycle of the project. Rapid development, testing,

and delivery of smaller (and possibly incomplete) increments, prototypes, and/or versions of a software product allow for the ongoing incorporation of feedback from users into the requirements and design phases of future increments. Although there are ongoing and vigorous debates about which processes are best, it is widely recognized that some form of incremental approach is necessary to successfully complete a project.

Software Distribution

After software is created, it is most often distributed in one of two forms. Software can be distributed as source code, which provides the high-level, human-readable set of instructions comprising the software, or the source code can be compiled (converted) into low-level instructions, commonly known as object code, which can be distributed alone and executed directly by the computer.

Object code is difficult, although not impossible, for humans to inspect or modify, and it inherently obscures the design and algorithms used in the software. Distribution of software as object code is the norm for commercial software products because it helps to protect the intellectual property embodied in the software. In addition, this intellectual property is protected by copyright law and often by some combination of patent, trademark, and trade secret law. Under current law, large civil and/or criminal penalties can be levied against those who make illicit use of source code or even simply reverse engineer the object code.

On the other hand, source code distribution, when done properly, is conducive to software reuse and extension. Source code distribution is the method of choice in academic research and noncommercial projects because distribution of the source code enables others to learn from and potentially improve the software. Moreover, an innovative family of licenses, known as "open source" licenses, have been designed to provide an incentive for others to learn from and improve software by guaranteeing that the software may be freely used for any purpose (including commercial purposes) and that any future modifications or extensions of the software by anyone will also be freely available in source form. The open source license parallels the academic norm of openness, which requires that publicly recognized (published) research be replicable so that others may verify and extend it.

What Software to Write and What Software to Use?

In most research, especially that involving standard methodologies, it is usually more appropriate to use a standard software package than to write one's own. Since all software contains bugs and can produce inaccurate results in some circumstances, one should choose a package that is as open to inspection as possible. The software should document the algorithms used, especially those relevant to data processing and analysis. The documentation should also include information regarding the expected range of inputs for each algorithm and the accuracy of the results within this range, and it should explain the warnings or errors that the software will produce when it encounters problems. Software packages that provide source have an advantage in this area because users can inspect the code directly. However, the availability of source code is not a substitute for thorough documentation.

Choose code that is also well tested, particularly for the tasks for which you intend to use it. The developers of the software should have clearly explained the methodology used to test their software and provide a complete record of all changes to the software, including previously reported bugs and subsequent fixes. Mathematical programs should document the accuracy of any functions and routines available to the users and provide test results using standard benchmarks.

Sometimes, however, one may not be able to find well-documented and thoroughly tested software that uses algorithms appropriate for one's problem. When this occurs, one must weigh carefully the potential for inaccuracies or inefficiencies to arise from applying an algorithm to a problem for which it is not well suited against the considerable effort required to develop software and the prevalence of bugs and inaccuracies in newly written software.

Spatial Autocorrelation

Daniel A. Griffith
University of Miami, Coral Gables, Florida, USA

Glossary

auto-model A statistical model whose associated probability density/mass function contains a linear combination of the dependent variable values at nearby locations.
correlation A description of the nature and degree of a relationship between a pair of quantitative variables.
covariance matrix A square matrix whose diagonal entries are the variances of, and whose off-diagonal entries are the covariances between, the row/column labeling variables.
estimator A statistic calculated from data to estimate the value of a parameter.
geographic connectivity/weights matrix An n-by-n matrix with the same sequence of row and column location labels, whose entries indicate which pairs of locations are neighbors.
geostatistics A set of statistical tools used to exploit spatial autocorrelation contained in georeferenced data usually for spatial prediction purposes.
Moran scatterplot A scatterplot of standardized versus summed nearby standardized values whose associated bivariate regression slope coefficient is the unstandardized Moran coefficient.
semivariogram plot A scatterplot of second-order spatial dependence exhibited in georeferenced data.
spatial autoregression A set of statistical tools used to accommodate spatial dependency effects in conventional linear statistical models.
spatial statistics A recent addition to the statistics literature that includes geostatistics, spatial autoregression, point pattern analysis, centrographic measures, and image analysis.

Spatial autocorrelation is the correlation among values of a single variable strictly attributable to their relatively close locational positions on a two-dimensional surface, introducing a deviation from the independent observations assumption of classical statistics.

Introduction

Social scientists often study the form, direction, and strength of the relationship exhibited by two quantitative variables measured for a single set of n observations. A scatterplot visualizes this relationship, with a conventional correlation coefficient describing the direction and strength of a straight-line relationship of the overall pattern. A variant of conventional correlation is serial correlation, which pertains to the correlation between values for observations of a single variable according to some ordering of these values. Its geographic version is spatial autocorrelation (*auto* meaning self), the relationship between a value of some variable at one location in space and nearby values of the same variable. These neighboring values can be identified by an n-by-n binary geographic connectivity/weights matrix, such as $\mathbf{C}$: If two locations are neighbors, then $c_{ij} = 1$, and if not, then $c_{ij} = 0$ (see Fig. 1, in which two areal units are deemed neighbors if they share a common nonzero length boundary).

Positive spatial autocorrelation means that geographically nearby values of a variable tend to be similar on a map: high values tend to be located near high values, medium values near medium values, and low values near low values. Most social science variables tend to be moderately positively spatially autocorrelated because of the way phenomena are geographically organized. Demographic and socioeconomic characteristics such as population density and house prices are examples of variables exhibiting positive spatial autocorrelation. Neighborhoods tend to be clusters of households with similar preferences. Families tend to organize themselves in a way that concentrates similar household attributes on a map—creating positive spatial autocorrelation among many variables—with government policies and activities, such as city planning and zoning, reinforcing such patterns.

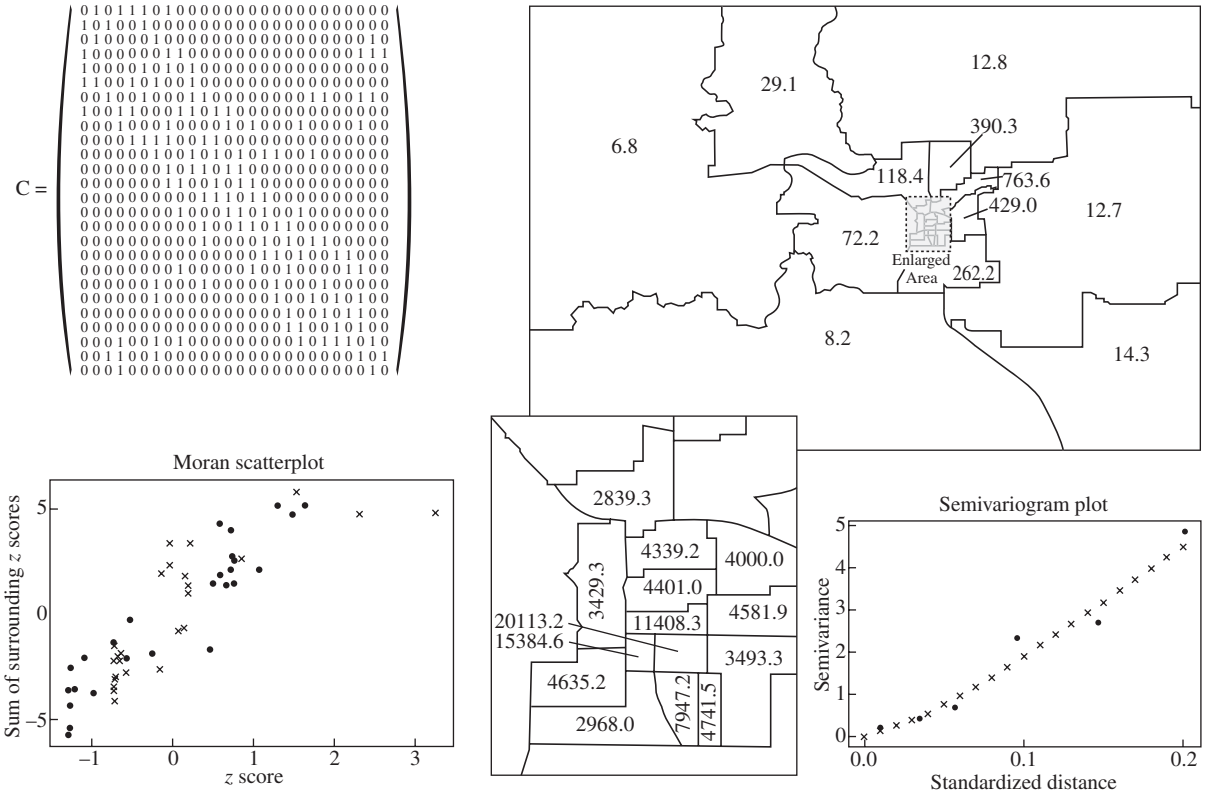

Figure 1 Adair County, Missouri, 1990 population density and census block areal units. (Top left) Binary geographic connectivity matrix C. (Top right) Geographic distribution of population density (with Kirkville as an inset). (Bottom left) Moran scatterplot for population density (x) and LN (population density + 164) (•). (Bottom right) Semivariogram plot for LN (population density + 164) (•) and its Bessel function predicted values (x).

Why Measure and Account for Spatial Autocorrelation?

Spatial analysis frequently employs model-based statistical inference, the dependability of which is based on the correctness of posited assumptions about a model's error term. One principal assumption states that individual error terms come from a population whose entries are thoroughly mixed through randomness. Moreover, the probability of a value taken on by one of a model's error term entries does not affect the probability of a value taken on by any of the remaining error term entries (i.e., the independent observations assumed in classical statistics). Nonzero spatial autocorrelation in georeferenced data violates this assumption and is partly responsible for geography existing as a discipline. Without it, few variables would exhibit a geographic expression when mapped; with it, most variables exhibit some type of spatial organization across space. Zero spatial autocorrelation means geographically random phenomena and chaotic landscapes.

Therefore, there are two primary reasons to measure spatial autocorrelation. First, it indexes the nature and degree to which a fundamental statistical assumption is violated and, in turn, indicates the extent to which conventional statistical inferences are compromised when nonzero spatial autocorrelation is overlooked. Autocorrelation complicates statistical analysis by altering the variance of variables, changing the probabilities that statisticians commonly attach to making incorrect statistical decisions (e.g., positive spatial autocorrelation results in an increased tendency to reject the null hypothesis when it is true). It signifies the presence of and quantifies the extent of redundant information in georeferenced data, which in turn affects the information contribution each georeferenced observation makes to statistics calculated with a database. Accordingly, more spatially autocorrelated than independent observations are needed in calculations to attain an equally informative statistic.

Second, the measurement of spatial autocorrelation describes the overall pattern across a geographic landscape, supporting spatial prediction and allowing detection of striking deviations. In many situations, spatial prediction is as important as temporal prediction/forecasting. Explicitly accounting for it tends to increase the percentage of variance explained for the dependent variable of a predictive model and does a surprisingly

good job of compensating for unknown variables missing from a model specification. Exploiting it tends to increase the R^2 value by approximately 5%, and obtaining 5% additional explanatory power in this way is much easier and more reliably available than getting it from collecting and cleaning additional data or from using different statistical methods.

Graphical Portrayals of Spatial Autocorrelation

By graphically portraying the relationship between two quantitative variables measured for the same observation, a scatterplot relates to the numerical value rendered by a correlation coefficient formula. Not surprisingly, specialized versions of this scatterplot are closely associated with measures of spatial autocorrelation.

The Moran scatterplot is one such specialized version. To construct it, first values of the georeferenced variable under study, Y, are converted to z scores, z_Y. Next, the adjacent or nearby z score values of Y are summed; this can be achieved with the matrix product $\mathbf{CZ}_Y$, where $\mathbf{Z}_Y$ is the vector concatenation of the individual z_Y values. Finally, the coordinate pairs $(z_{Y,i}, \sum_{j=1}^{n} c_{ij} z_{Y,1})$, $i = 1, 2, \ldots, n$, are plotted on the graph whose vertical axis is $\mathbf{CZ}_Y$ and whose horizontal axis is $\mathbf{Z}_Y$. This construction differs from that proposed by Anselin in 1995, who uses matrix $\mathbf{W}$, the row-standardized stochastic version of matrix $\mathbf{C}$, to define the vertical axis. An example of this graphic illustrates a case of positive spatial autocorrelation (Fig. 1).

Another specialized scatterplot is the semivariogram plot. To construct it, first, for each pair of georeferenced observations both the distance separating them and the squared difference between their respective attribute values are calculated. Next, distances are grouped into G compact ranges preferably having at least 30 paired differences, and then group averages of the distances and of the squared attribute differences are computed. Semivariance values equal these squared attribute differences divided by 2. Finally, on a graph whose vertical axis is average semivariance and whose horizontal axis is average distance, the following coordinate pairs are plotted:

$$\left(\frac{\sum_{i=1}^{n} \sum_{j=1}^{n} \delta_{ij} (y_i - y_j)^2}{2K_g}, \quad \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} \delta_{ij} d_{ij}}{K_g} \right),$$

where K_g is the number of i–j pairs in group g, $\sum_{g=1}^{G} K_g = n(n-1)$, d_{ij} is the distance separating locations i and j, and δ_{ij} is a binary 0/1 variable denoting whether or not both locations i and j belong to group g. The steep slope in Fig. 1 indicates very strong positive autocorrelation that is due, in part, to a geographic trend in the data.

Autoregressive and Geostatistical Perspectives on Spatial Autocorrelation

Treatments of georeferenced data focus on either spatial autocorrelation (addressed in geostatistics) or partial spatial autocorrelation (addressed in spatial autoregression). The two classic works reviewing and extending spatial statistical theory are by Cliff and Ord, who have motivated research involving spatial autoregression, and Cressie, who has summarized research involving geostatistics. These two subfields have been evolving autonomously and in parallel, but they are closely linked through issues of spatial interpolation (e.g., the missing data problem) and of spatial autocorrelation. They differ in that geostatistics operates on the variance–covariance matrix, whereas spatial autocorrelation operates on the inverse of this matrix. More superficial differences include foci on more or less continuously occurring attributes (geostatistics) versus aggregations of phenomena into discrete regions (i.e., areal units) (spatial autoregression) and on spatial prediction (geostatistics) versus enhancement of statistical description and improvement of the inferential basis for statistical decision making (i.e., increasing precision) (spatial autoregression). Griffith and Layne, among others, present graphical, numerical, and empirical findings that help to articulate links between geostatistics and spatial autoregression.

Definition of Notation

One convention employed here denotes matrices with bold letters; another denotes names by subscripts. Definitions of notation used throughout appear in Table I.

Conceptual Meanings of Spatial Autocorrelation

Spatial autocorrelation can be interpreted in different ways. As a nuisance parameter, spatial autocorrelation is inserted into a model specification because its presence is necessary for a good description, but it is not of interest and only "gets in the way" of estimating other model parameters. In fact, if the value of this parameter were known, resulting statistical analyses would be much simpler and more powerful. Nonspatial analysts especially view spatial autocorrelation as an interference. They study the relationship between two quantitative variables that happen to be georeferenced, with spatial autocorrelation lurking in the background. Mean response and standard errors improve when spatial autocorrelation is accounted for, whereas conventional statistical theory could be utilized if the value of this parameter were known or set to 0. Ignoring latent spatial autocorrelation

Table I Symbols Used

AR	Abbreviation for the autoregressive response model
BB, BW, WW	Join count statistics: respectively, the number of neighboring ones, ones with zeroes, and zeroes
CAR	Abbreviation for the conditional autoregressive model
d	Distance separating two locations
det	Determinant of a matrix
$E(X)$	Expectation of the random variable X
exp	Inverse of the natural logarithm
Γ	Semivariance
G	The number of location pair groups in a semivariogram plot
GR	Abbreviation for the Geary ratio index
K_g	Number of distance pairs in group g for a semivariance plot
LN	Natural logarithm
MC	Abbreviation for the Moran coefficient index
MCMC	Abbreviation for Markov chain Monte Carlo
n	Number of locations in a georeferenced sample
n^*	Equivalent number of independent locations in a georeferenced sample
OLS	Abbreviation for ordinary least squares
s^2	Conventional sample variance
SAR	Abbreviation for the simultaneous autoregressive model
σ^2	Population variance
VIF	Abbreviation for the variance inflation factor
α_i	Population mean response
c_{ij}	Row i and column j entry of matrix $\mathbf{C}$
δ_{ij}	Binary 0–1 variable indicating membership of distance between locations i and j in semivariance grouping
$\lambda_{\max}$	Maximum eigenvalue of a matrix
$\lambda_{\min}$	Minimum eigenvalue of a matrix
$MC_{\max}$	Maximum possible Moran coefficient value
μ_y	Population mean of variable Y
$n_k!$	Factorial calculation for the number of entries in the kth group
ρ_j	Spatial autoregressive parameter for model j
Y_i	Value of variable Y for the ith observation
$z_{Y,i}$	z score of variable Y for the ith observation
$\mathbf{1}$	N-by-1 vector of ones
$\mathbf{ß}$	P-by-1 vector of regression parameters
$\mathbf{b}$	P-by-1 vector of regression parameter estimates
$\mathbf{C}$	N-by-n geographic weights matrix
$\mathbf{CZ}_Y$	Matrix summation of neighboring z scores of variable Y
ε	N-by-1 vector of random error terms
$\mathbf{E}_j^*$	jth eigenvector of matrix $(\mathbf{I} - \mathbf{11}^T/n)\mathbf{C}(\mathbf{I} - \mathbf{11}^T/n)$
$\mathbf{I}$	N-by-n identity matrix
$\mathbf{V}\sigma^{-2}$	N-by-n inverse-covariance matrix
$\mathbf{W}$	Row-standardized version of the n-by-n geographic weights matrix
$\mathbf{X}$	N-by-p matrix of predictor variables
$\mathbf{Z}_Y$	N-by-1 vector of z scores for variable Y
$(y_i - \bar{y})/s_Y$	z score for the ith value of variable Y
$\langle \mathbf{1}^T\mathbf{C} \rangle_{\text{diagonal}}$	N-by-n diagonal matrix with diagonal entries of $\sum_{j=1}^{n} c_{ij}$
$TR(\mathbf{V}^{-1})/n$	Equation for the variance inflation factor
$n \times TR(\mathbf{V}^{-1})/\mathbf{1V}^{-1}\mathbf{1}$	Equation for the equivalent number of independent locations
$n^2/[\mathbf{1}^T\mathbf{V}^{-1}\mathbf{11}^T\mathbf{V1}]$	Equation for measuring the efficiency of OLS estimators in the presense of nonzero spatial autocorrelation
$(\mathbf{I} - \mathbf{11}^T/n)$	Projection matrix that centers vector $\mathbf{Y}$
$(\mathbf{I} - \mathbf{11}^T/n)\mathbf{C}(\mathbf{I} - \mathbf{11}^T/n)$	Modified connectivity matrix appearing in the Moran coefficient numerator

continues

Table I *continued*

$\sum_{j=1}^{n} c_{ij}$	Sum of the ith row entries of matrix **C**
$\sum_{j=1}^{n} c_{ij} z_{Y,j}$	Sum of neighboring z score values, $z_{Y,i}$
$\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})/n$	Conventional sample covariation between variables X and Y
$\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2/n}$	Conventional sample standard deviation of variable Y
$\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}$	Sum of the cell entries of matrix **C**
$\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}(y_i - \bar{y})(y_j - \bar{y})$	Covariation of neighboring Y values
$\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}(y_i - y_j)^2$	Sum of squared differences of neighboring Y values
$\sum_{i=1}^{n}\sum_{j=1}^{n} \delta_{ij} d_{ij}/K_g$	Average distance for a given semivariance distance grouping
$\sum_{i=1}^{n}\sum_{j=1}^{n} \delta_{ij}(y_i - y_j)^2/(2K_g)$	Semivariance estimate for a given distance grouping

results in increased uncertainty about whether findings are attributable to assuming zero spatial autocorrelation (i.e., misspecification).

As self-correlation, spatial autocorrelation is interpreted literally: Correlation arises from the geographic context within which attribute values occur. As such, it can be expressed in terms of the Pearson product moment correlation coefficient formula, but with neighboring values of variable Y replacing those of X:

$$\frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})/n}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2/n}\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2/n}}$$

becomes

$$\frac{\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}(y_i - \bar{y})(y_j - \bar{y})/\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}}{\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2/n}\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2/n}}. \qquad (1)$$

The first expression converts to Eq. (1) by substituting y's for x's in the right-hand side, by computing the numerator term only when a 1 appears in matrix **C**, and by averaging the numerator cross-product terms over the total number of pairs denoted by a 1 in matrix **C**. The denominator of the revised expression (Eq. 1) is the sample variance of Y, s_Y^2. Coupling this with part of the accompanying numerator term renders

$$\frac{(y_i - \bar{y})}{s_Y}\sum_{j=1}^{n} c_{ij}\frac{(y_j - \bar{y})}{s_Y},$$

where this summation term is the quantity measured along the vertical axis of the modified Moran scatterplot; Eq. (1) is known as the Moran coefficient (MC). Accordingly, positive spatial autocorrelation occurs when the scatter of points on the associated Moran scatterplot reflects a straight line sloping from the lower left-hand to the upper right-hand corner: high values on the vertical axis tend to correspond with high values on the horizontal axis, medium values with medium values, and low values with low values (Fig. 1). Negligible spatial autocorrelation occurs when the scatter of points suggests no pattern: high values on the vertical axis correspond with high, medium, and low values on the horizontal axis, as would medium and low values on the vertical axis. Negative spatial autocorrelation occurs when the scatter of points reflects a straight line sloping from the upper left-hand to the lower right-hand corner: high values on the vertical axis tend to correspond with low values on the horizontal axis, medium values with medium values, and low values with high values. These patterns are analogous to those for two different quantitative attribute variables—X and Y—rendering, respectively, a positive, zero, and negative Pearson product moment correlation coefficient value.

The semivariogram is based on squared paired comparisons of georeferenced data values. Emphasizing variation with distance rather than only with nearby values, the numerator of Eq. (1) may be replaced by

$$\frac{\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}(y_i - y_j)^2}{\left[2\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}\right]},$$

converting this measure to the Geary ratio (GR) when the unbiased sample variance is substituted in the denominator.

As map pattern, spatial autocorrelation is viewed in terms of trends, gradients, or mosaics across a map. This more general meaning can be obtained by studying the matrix form of the MC, specifically the term $\mathbf{Y}^{\mathrm{T}}(\mathbf{I} - \mathbf{1}\mathbf{1}^{\mathrm{T}}/n)\mathbf{C}(\mathbf{I} - \mathbf{1}\mathbf{1}^{\mathrm{T}}/n)\mathbf{Y}$ corresponding to the first summation in Eq. (1), where **I** is an n-by-n identity matrix, **1** is an n-by-1 vector of ones, T is the matrix transpose operation, and $(\mathbf{I} - \mathbf{1}\mathbf{1}^{\mathrm{T}}/n)$ is the projection matrix commonly found in conventional multivariate and regression analysis that centers the vector **Y**. The extreme eigenvalues of matrix expression $(\mathbf{I} - \mathbf{1}\mathbf{1}^{\mathrm{T}}/n)\mathbf{C}(\mathbf{I} - \mathbf{1}\mathbf{1}^{\mathrm{T}}/n)$ determine the range of the modified correlation coefficient, MC; therefore, MC is not restricted to the range $[-1, 1]$. Furthermore, the full set of n eigenvalues of this

expression establishes the set of distinct MC values associated with a map, regardless of attribute values. The accompanying n eigenvectors represent a kaleidoscope of orthogonal and uncorrelated map patterns of possible spatial autocorrelation.

The first eigenvector, $\mathbf{E}_1^*$, is the set of numerical values that has the largest MC achievable by any set, for the spatial arrangement defined by the geographic connectivity matrix $\mathbf{C}$. The second eigenvector is the set of values that has the largest achievable MC by any set that is uncorrelated with $\mathbf{E}_1^*$. This sequential construction of eigenvectors continues through $\mathbf{E}_n^*$, which is the set of values that has the largest negative MC achievable by any set that is uncorrelated with the preceding $(n-1)$ eigenvectors. As such, these eigenvectors furnish distinct map pattern descriptions of latent spatial autocorrelation in georeferenced variables.

As a diagnostic tool, spatial autocorrelation plays a crucial role in model-based inference, which is built on valid assumptions rather than on the outcome of a proper sampling design. Sometimes, spatial autocorrelation is used as a diagnostic tool for model misspecification, being viewed as an artifact of overlooked nonlinear relationships, nonconstant variance, or outliers. Cliff and Ord provide an excellent example with their empirical analysis of the relationship between percentage change in population and arterial road accessibility across the counties of Eire. MC = 0.1908 for residuals obtained from a bivariate regression using these two variables; MC = 0.1301 for residuals obtained from a bivariate regression applying a logarithmic transformation to each of these two variables. However, Griffith and Layne determine and then employ an optimal Box–Tidwell linearization transformation for these data, which renders MC = −0.0554 for the residuals, a value that suggests the absence of spatial autocorrelation. In other words, the weak positive spatial autocorrelation detected by Cliff and Ord is due solely to a nonlinear model misspecification.

As redundant information, spatial autocorrelation represents duplicate information contained in georeferenced data, linking it to missing values estimation as well as to notions of effective sample size and degrees of freedom. For normally distributed variables, these latter two quantities establish a correspondence between n spatially autocorrelated and n^* zero spatial autocorrelation (i.e., independent) observations. Richardson and Hémon promote this view for correlation coefficients computed for pairs of geographically distributed variables. Haining demonstrates an equivalency between their findings and the results obtained by removing spatial dependency effects with filters analogous to those used in constructing time series impulse-response functions.

Inference about a geographic variable mean when nonzero spatial autocorrelation is present is impacted by a variance inflation factor (VIF), and has $n^* \leq n$. The respective matrix formulae, where TR denotes the matrix trace operation and $\mathbf{V}\sigma^{-2}$ denotes the n-by-n inverse variance–covariance matrix capturing latent spatial autocorrelation effects, are $\text{VIF} = \text{TR}(\mathbf{V}^{-1})/n$ and $n^* = n \times \text{TR}(\mathbf{V}^{-1})/\mathbf{1}\mathbf{V}^{-1}\mathbf{1}$. Selected results for these two formulae appear in Table II, where $\hat{\rho}_{\text{SAR}}$ denotes estimated spatial autocorrelation using a simultaneous autoregressive (SAR) model specification, and suggest that on average approximately two-thirds of the information content is redundant; spatial autocorrelation is at least doubling the variance; and, for example, a cluster of approximately 10 additional census tracts needs to be acquired for Houston before as much new information is obtained as is contained in a single, completely isolated census tract in this metropolitan region.

As a missing variables indicator/surrogate, spatial autocorrelation accounts for variation otherwise unaccounted for because of variables missing from a regression equation. This perspective is particularly popular among spatial econometricians. In essence, autocorrelation effects latent in predictor variables match autocorrelation effects in Y. For instance, one well-known covariate of population density is distance from the central business district (CBD). For Adair (Table II), a bivariate regression analysis reveals that this variable accounts for approximately 91% of the variation in population density across the county, whereas $\hat{\rho}_{\text{SAR}}$ decreases to 0.33686 and the total percentage of variance accounted for increases slightly to approximately 92%. (The trend contributes considerably to the nature of the semivariogram plot curve in Fig. 1.) For Chicago, a bivariate

Table II Redundant Information Measures for Selected Georeferenced Population Density Datasets

Dataset	*MC*	*GR*	$\hat{\rho}_{\text{SAR}}$	n	*VIF*	$\hat{n}^*$	*% of variance accounted for*
Adair County, Missouri, block groups	0.62035	0.30765	0.95298	26	20.77	1.1	88.8
Syracuse census tracts	0.68869	0.28128	0.82722	208	3.08	17.9	71.9
Houston census tracts	0.55780	0.40129	0.77804	690	2.16	70.5	59.6
Chicago census tracts	0.68267	0.30973	0.87440	1754	3.24	85.5	68.6
Coterminous U.S. counties	0.62887	0.28247	0.84764	3111	2.68	186.6	68.7

regression analysis reveals that this variable accounts for approximately 42% of the variation in population density across the city, whereas $\hat{\rho}_{SAR}$ decreases to 0.76994 and the total percentage of variance accounted for remains at approximately 68%.

As a spatial spillover effect, spatial autocorrelation results from effects of some phenomenon at one location "spilling over" to nearby locations, much like a flooding river overflowing its banks. Pace and Barry provide an empirical example of house price spillover: the value of a house is a function of both its dwelling attributes and the value of surrounding houses. They studied 20,640 California block groups having houses and reported $\hat{\rho}_{SAR} = 0.8536$, indicating the presence of strong positive spatial autocorrelation, with inclusion of the autoregressive term increasing the percentage of variance explained by 25%.

As a spatial process mechanism, spatial autocorrelation is viewed as the outcome of some course of action operating over a geographic landscape. The contagious spread of disease, the dissemination of information or ideas, and spatial competition illustrate this viewpoint, and an autologistic model describes it: 1 denotes the presence and 0 denotes the absence of some phenomenon at different locations in a geographic landscape.

As an outcome of areal unit demarcation, spatial autocorrelation relates to the modifiable areal unit problem, whereby results from statistical analyses of georeferenced data can be varied at will simply by changing the surface partitioning to demarcate areal units. In an analysis of variance framework, devising areal units in a way that manipulates attribute differences within and between them impacts on the nature and degree of measured spatial autocorrelation. If this practice is executed in a gerrymandering fashion, a range of possible spatial autocorrelation, from positive to negative, materializes. In part, accounting for detected spatial autocorrelation in statistical analyses attempts to neutralize such outcomes.

Estimators of Spatial Autocorrelation

Spatial autocorrelation may be indexed, quantified by including an autoregressive parameter in a regression model, or filtered from variables. Spatial autocorrelation can be quantified with indices. Equation (1) provides the MC index, which can also be rewritten in terms of the regression coefficient affiliated with a Moran scatterplot. Its range is approximately ± 1; more precisely, it is

$$\left[\frac{n\lambda_{\min}}{\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}}, \quad \frac{n\lambda_{\max}}{\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}}\right],$$

where $\lambda_{\min}$ and $\lambda_{\max}$ are the extreme eigenvalues of matrix $(\mathbf{I} - \mathbf{1}\mathbf{1}^{T}/n)\mathbf{C}(\mathbf{I} - \mathbf{1}\mathbf{1}^{T}/n)$. As MC approaches the upper limit, the paired values $(\mathbf{Z}_Y, \mathbf{C}\mathbf{Z}_Y)$ in a Moran scatterplot increasingly align with a straight line having a positive slope. As MC approaches the lower limit, the alignment is with a straight line having a negative slope. As MC approaches $-1/(n-1)$ (its expected value indicating zero spatial autocorrelation), the paired values should resemble a random scatter of points. The standard error of this statistic is approximately $\sqrt{(2/\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij})}$; in terms of practical importance, modest levels of positive spatial autocorrelation begin at $0.5\text{MC}/\text{MC}_{\max}$, whereas moderate levels begin at $0.7\text{MC}/\text{MC}_{\max}$ and substantial levels begin at $0.9\text{MC}/\text{MC}_{\max}$.

One variation of this index is the GR, which replaces the numerator of Eq. (1) with a squared paired comparison and the denominator with the unbiased sample variance estimate. This index roughly ranges from 0 (i.e., $y_i = y_j$), indicating perfect positive spatial autocorrelation, to 2, indicating strong negative spatial autocorrelation; 1 indicates zero spatial autocorrelation. GR is inversely related to MC. The extreme values are more precisely given by

$$\left[\frac{(n-1)\lambda_{n-1}}{\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}}, \quad \frac{(n-1)\lambda_{\max}}{\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}}\right],$$

where λ_{n-1} and $\lambda_{\max}$ are the second smallest and the largest eigenvalues of matrix $(\langle \mathbf{1}^{T}\mathbf{C}\rangle_{\text{diagonal}} - \mathbf{C})$, where $\langle \mathbf{1}^{T}\mathbf{C}\rangle_{\text{diagonal}}$ is a diagonal matrix whose diagonal entries are the row sums of $\mathbf{C}$. This feature indicates that GR emphasizes edges and numbers of neighbors far more than does MC.

Another variation is the triplet of join count statistics used to analyze 0/1 binary georeferenced data, conveniently coded as 1 denoting black (B) and 0 denoting white (W). The number of neighboring pairs of 1's on a map equals 2BB, the number of neighboring pairs of 0's equals 2WW, and the number of 1's with neighboring 0's equals 2BW:

$$\text{BB} + \text{BW} + \text{WW} = \sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}/2,$$

where n_1 is the number of 1's. These quantities can be interpreted in terms of binomial random variables. The numerator of the MC reduces to

$$n_1^2 \sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}/n^2 + 2(1 - n_1/n)\text{BB} - 2(n_1/n)\text{BW}.$$

Spatial autocorrelation can be quantified by including an autoregressive parameter in a model specification. Regression becomes autoregression, with the most

common specifications being the SAR ($\mathbf{Y} = \rho_{SAR}\mathbf{WY} + (\mathbf{I} - \rho_{SAR}\mathbf{WY})\mathbf{X}\beta + \boldsymbol{\varepsilon}$), the autoregressive response (AR) ($\mathbf{Y} = \rho_{AR}\mathbf{WY} + \mathbf{X}\beta + \boldsymbol{\varepsilon}$), and the conditional autoregressive (CAR) ($\mathbf{Y} = \mathbf{X}\beta + (\mathbf{I} - \hat{\rho}_{CAR}\mathbf{C})^{-1/2}\boldsymbol{\varepsilon}$) models, where β is a vector of regression coefficients and $\boldsymbol{\varepsilon}$ is a vector of independent and identically distributed random error terms. These are popular among spatial statisticians, spatial econometricians, and image analysts, respectively. The SAR model specifies spatial autocorrelation as being in the error term, with the attribute error at location i being a function of the average of nearby error values: $E(\mathbf{Y}) = \mathbf{X}\beta$, $\mathrm{VAR}(\mathbf{Y}) = \sigma^2[(\mathbf{I} - \rho_{SAR}\mathbf{W}^T)\times(\mathbf{I} - \rho_{SAR}\mathbf{W})]^{-1}$, where E denotes the calculus of expectation operator. The AR model specifies spatial autocorrelation as being a direct dependency among the Y values: $E(\mathbf{Y}) = (\mathbf{I} - \rho_{AR}\mathbf{W})^{-1}\mathbf{X}\beta$,$\mathrm{VAR}(\mathbf{Y}) = \sigma^2[(\mathbf{I} - \rho_{AR}\mathbf{W}^T)(\mathbf{I} - \rho_{AR}\mathbf{W})]^{-1}$. The CAR model specifies spatial autocorrelation as being in the error term, with a weaker degree and smaller spatial field than the SAR model, and with the attribute error at location i being a function of the sum of nearby error values: $E(\mathbf{Y}) = \mathbf{X}\beta$, $\mathrm{VAR}(\mathbf{Y}) = \sigma^2(\mathbf{I} - \rho_{CAR}\mathbf{C})^{-1}$. Parameters of these models must be estimated using maximum likelihood techniques.

Parameterizing spatial autocorrelation through the semivariogram plot involves modeling the relationship between semivariance, γ, and distance, d. Dozens of specifications may be employed, all describing spatial autocorrelation as a nonlinear decreasing function of distance. The most popular ones are the spherical, the exponential, and the Gaussian; one that should increase in popularity is the Bessel function. The empirical semivariogram in Fig. 1 is best described by a Bessel function, K_1, both before and after adjusting for the underlying distance decay trend. Each semivariogram model describes the decline in spatial autocorrelation with increasing distance in terms of an intercept (nugget), a slope, and an implicit/explicit range of spatial dependency. For Adair County population density (Fig. 1), $\hat{\gamma} = 0.13 + 14.07[1 - (d/0.25)K_1(d/0.25)]$. Summarizing the variance–covariance matrix with this type of equation allows new variance–covariance matrices to be constructed for locations whose attribute values are unknown, permitting sensible predictions of their values.

Spatial filters remove spatial autocorrelation from variables by casting it as redundant information or as an outcome of map pattern. The former interpretation is employed by Haining and renders a spatial linear operator filter ($\mathbf{I} - \hat{\rho}_{SAR}\mathbf{W}$). The latter interpretation renders predictor variables, such as the battery of eigenvectors $\mathbf{E}_j^*$, that capture locational information summarized by a spatial autocorrelation parameter such as $\hat{\rho}_{SAR}$. For Adair County, the correlation between log-distance and log-density is −0.936; the spatial linear operator filter result based on an SAR model ($\hat{\rho}_{SAR} = 0.95298$; Table II) is −0.985. Eigenfunction filtering identifies two eigenvectors (MC = 0.76 and 0.47) that account for the residual spatial autocorrelation and increase the variance accounted for in log-population density by approximately 4%.

Theoretical Statistical Properties of Spatial Autocorrelation

Classical statistics establishes the quality of parameter estimators with specific properties that discriminate between useful and useless ones. Four of these properties are described here.

An unbiased estimator's sampling distribution arithmetic mean equals its corresponding population parameter value. This property is evaluated with the calculus of expectations. In general, in the presence of nonzero spatial autocorrelation, conventional estimators for first-order moments are unbiased, whereas those for second-order moments are biased. For example, for linear regression, $E(\mathbf{Y}) = E(\mathbf{X}\beta + \mathbf{V}^{-1/2}\boldsymbol{\varepsilon}\sigma) = \mathbf{X}\beta$. Similarly, $E(\mathbf{b}) = E[(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{XY}] = \beta$, where $\mathbf{b}$ is the ordinary least squares (OLS) regression coefficients estimator. However, $E[(\mathbf{Y} - \mathbf{X}\beta)^T(\mathbf{Y} - \mathbf{X}\beta)/n] = \sigma^2\mathrm{TR}(\mathbf{V})/n$, which reduces to σ^2 only when $\mathbf{V} = \mathbf{I}$. Griffith and Lagona report that misspecifying matrix $\mathbf{C}$, of which matrix $\mathbf{V}$ is a function, results in $\mathbf{b}$ remaining unbiased and s^2 remaining biased when autocorrelation is accounted for.

An efficient estimator is an unbiased estimator whose sampling distribution has the smallest possible variance, maximizing its reliability. Cordy and Griffith find that in the presence of nonzero spatial autocorrelation, the biased OLS variance estimator negates much of its computational simplicity advantage. Consequently, the OLS standard error estimator tends to underestimate the true standard error when positive spatial autocorrelation prevails. By accounting for latent spatial autocorrelation, gains in efficiency increase as both its magnitude and n increase. With regard to the aforementioned VIF and n^*, $E[(\bar{y} - \mu_Y)^2] = (\mathbf{1}^T\mathbf{V}^{-1}\mathbf{1}/n)(\sigma^2/n)$, and $E[(\mathbf{Y} - \mu_Y\mathbf{1})^T\times(\mathbf{Y} - \mu_Y\mathbf{1})/n] = [\mathrm{TR}(\mathbf{V}^{-1})](\sigma^2/n)$. These results reduce to their respective standard results of σ^2/n and σ^2 only when $\mathbf{V} = \mathbf{I}$. A measure of OLS efficiency when spatial autocorrelation is nonzero is given by $n^2/[\mathbf{1}^T\mathbf{V}^{-1}\mathbf{1}\mathbf{1}^T\mathbf{V}\mathbf{1}]$; when spatial autocorrelation is zero, this quantity equals 1, whereas when perfect positive spatial autocorrelation exists, it is 0. Griffith and Lagona report that misspecifying matrix $\mathbf{C}$ results in $\mathbf{b}$ being asymptotically efficient and s^2 remaining inefficient when autocorrelation is accounted for.

A consistent estimator's sampling distribution concentrates at the corresponding parameter value as n increases. Considering situations in which the maximum number of neighbors for any given location is finite, when sample size increases by increasing the size of a region to

an unbounded surface (i.e., increasing domain asymptotics), consistency of the mean and variance estimators is attained. When sample size increases by partitioning a region into an increasingly finer tessellation (i.e., infill asymptotics), consistency is lost. Griffith and Lagona report that misspecifying matrix **C** in a typical situation results in **b** and s^2 being consistent, with the autocorrelation parameter failing to converge to its true value.

A sufficient estimator utilizes all of the pertinent information content of a sample needed to estimate a particular parameter. This property is established using the factorization criterion for a likelihood function. A likelihood can be rewritten as the product of a term that depends on the sample only through the value of the parameter estimator and of a term independent of the corresponding parameter. The importance of this property is twofold: (i) Estimating missing georeferenced data requires imputation of the complete-data sufficient statistics, which in the case of an auto-normal probability model involves a spatial autocorrelation term, and (ii) the Markov chain Monte Carlo (MCMC) procedure used to estimate the auto-logistic and auto-binomial models requires the sufficient statistics, again one being a spatial autocorrelation term.

Common Auto-Probability Model Specifications

The normal distribution is the base of much statistical analysis of continuous data. The binomial distribution plays the same role for binary variables and percentages, whereas the Poisson distribution plays the same role for counts. Auto-specifications of these models almost always have pairwise-only spatial dependence.

The auto-Gaussian model specification yields the likelihood function

$$L = \text{constant} - (n/2)\text{LN}(\sigma^2) + (1/2)\text{LN}[\det(\mathbf{V}^{-1})] - (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})^{\text{T}}\mathbf{V}(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})/(2\sigma^2),$$

where LN denotes the natural logarithm, and det denotes the matrix determinant operation. The normalizing constant, $(1/2)\text{LN}[\det(\mathbf{V}^{-1})]$, complicates calculation of the maximum likelihood estimates of parameters because it involves an n-by-n matrix. For the CAR model, $\mathbf{V}^{-1} = (\mathbf{I} - \rho_{\text{CAR}}\mathbf{C})$, whereas for the SAR model $\mathbf{V}^{-1} = (\mathbf{I} - \rho_{\text{CAR}}\mathbf{W})^{\text{T}}(\mathbf{I} - \rho_{\text{SAR}}\mathbf{W})$.

The auto-logistic model for a pure spatial autoregressive situation involves estimating the parameters of the following probability function:

$$E[Y_i = 1 \,|\, \mathbf{C}_i\mathbf{Y}] = \frac{\exp(\alpha_i + \rho \sum_{j=1}^{n} c_{ij}y_j)}{1 + \exp(\alpha_i + \rho \sum_{j=1}^{n} c_{ij}y_j)},$$

where α_i is the parameter capturing large-scale variation (and hence could be specified in terms of vector $\mathbf{X}_i$), ρ is the spatial autocorrelation parameter, and $\mathbf{C}_i$ is the ith row vector of matrix **C**. Spatial autocorrelation may be measured with the join count statistics. Parameters can be estimated with MCMC techniques: $\sum_{i=1}^{n} y_i \sum_{j=1}^{n} c_{ij}y_j/2 = \text{BB}$ (the join count statistic) is the sufficient statistic for spatial autocorrelation. The model for percentages is very similar.

The auto-Poisson model for a pure spatial autoregressive situation involves evaluating the following log-probability mass function term:

$$\sum_{i=1}^{n} \alpha_i n_i - \sum_{i=1}^{n} \text{LN}(n_i!) + \rho \sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}n_i n_j,$$

where n_i are the counts for areal unit i. Parameters, which in this specification restrict ρ to being negative, can be estimated with MCMC techniques here, too. Also, the estimate of ρ could be driven to zero by introducing judiciously selected spatial autocorrelation filtering variables, such as the aforementioned eigenvectors.

What Should an Applied Spatial Scientist Do?

To ignore spatial autocorrelation effects when analyzing georeferenced data may be tempting, but it is ill-advised. Assuming independent observations—the atypical in a geographic world—is merely for the convenience of mathematical statistical theory. Introducing a spatial autocorrelation parameter into a model specification, which indeed results in more complicated statistical analyses, produces better statistical practice and results: Auto-models provide clearer data descriptions, parameter estimators exhibit better statistical properties and behavior, and data analysis results can be more easily interpreted. Modern statistics supplies the necessary estimation tools, and standard commercial statistical software packages supply the capability for executing this estimation.

When studying a georeferenced dataset, the applied spatial scientist should (i) compute a spatial autocorrelation index, (ii) estimate an auto-model keeping conventional regression analysis in mind, and (iii) inspect local spatial autocorrelation statistics as part of the battery of model diagnostics. Conventional regression model analysis protocol offers a guide because both the Moran scatterplot and the MC link directly to regression analysis. During this pursuit, computations such as effective sample size may help determine whether collecting supplemental data is worthwhile, more precise standard errors may help determine whether two variables are significantly correlated, and a sizeable quantity of variance explained by spatial autocorrelation may help determine

whether variables are missing from a model specification. Also, marked levels of spatial autocorrelation may be exploited for spatial interpolations and small geographic area estimations, providing the scientist with a window into the unknown. Moreover, accounting for spatial autocorrelation latent in georeferenced data has the capacity to increase our understanding of the social world.

Spatial Cognition and Perception

Marina Vasilyeva
University of Chicago, Chicago, Illinois, USA

Glossary

allocentric coding Coding location in relation to external features of the environment.
egocentric coding Coding location in relation to self.
landmarks Elements of the environment that stand out from their surroundings.
large-scale space Space that cannot be seen from a single viewpoint and thus requires movement in order to be perceived in its entirety.
small-scale space Space that can be seen in its entirety from a single viewpoint.

Spatial cognition refers to a diverse set of abilities, all of which require perceiving and reasoning about spatial properties, such as size, shape, and location. These abilities are critically important for the functioning of all mobile organisms. Animals rely on spatial skills to find food, return to shelter and avoid danger. Likewise, humans are constantly confronted with a variety of problems that require reasoning about space. Some of these problems involve judging and transforming spatial relations among objects, as in assembling an item of furniture from its component parts. Other problems concern navigating through and locating objects in familiar or unfamiliar environments, such as finding the best route through a neighborhood or locating a car in a large parking lot. Spatial thinking is thus crucial to everyday life. Furthermore, it provides a foundation for successful performance in the sciences, in technological fields, and in engineering.

Regardless of the complexity of the task, spatial understanding depends on the basic ability to code metric information, namely distance and directional cues. This information can be used to determine the size and shape of objects and to specify object locations. Researchers distinguish two fundamental ways in which spatial cues can be used to determine location. The first is known as *egocentric coding*, that is, coding location with respect to oneself. The second is known as *allocentric (or geocentric) coding*, that is, coding location with respect to external features of the environment. Since the egocentric strategy specifies a target location relative to the observer, it can be used either when the observer remains stationary or when the observer moves but is able to keep track of the movement and update the changing relation between him or herself and the target location. In some situations, however, the observer may become sufficiently disoriented so that it is impossible to reconstruct the changes that led to the new position. In this case, one must rely on the allocentric strategy that provides information about the target location relative to the environment itself, independent of the observer. Research in the spatial domain indicates that both egocentric and allocentric types of coding are available to humans as well as nonhuman animals.

Spatial Cognition in Animals

Most animals must travel away from their shelters to get food and then find their way back. The path traversed in search of food may be quite long and unpredictable, and finding one's way home often involves navigating through unfamiliar environments. Yet animals ranging from mollusks to primates are impressively accurate in solving such spatial tasks. In doing so, they rely on a number of spatial strategies, the most common of which is dead reckoning that involves keeping track of changes in one's position. This tracking mechanism allows for constant updating of the egocentrically encoded location. To measure the animal's reliance on dead reckoning, researchers use a displacement technique in which they remove the animal from its natural path connecting the nest and the food source and examine how the animal attempts to return to the nest. A set of studies with desert ants conducted

by Wehner illustrates this technique. A desert ant travels along a circuitous path searching for food; once the food is found, the ant returns home following the most efficient straight path. If the ant is displaced by the experimenter right before it is about to start its journey back to the nest, it moves the same distance and in the same direction as if it were not displaced (thereby failing to arrive back at the nest). Thus, the desert ant seems to rely on the representation of the egocentric relation between itself and the location of the nest, rather than on the external features of the environment. Similar behavior has been observed in a variety of other animal species, including bees, spiders, gerbils, and hamsters.

An important question is how animals manage to keep track of continuous changes in their position. It has been proposed that an animal may represent its position as a vector that indicates distance and direction from the nest to the current position. As the animal moves to a new position, a vector specifying the distance and direction traveled during the move is added to the vector specifying the previous position, thereby updating the relation between the animal and the nest. A critical aspect of this mechanism is the ability to code distance and directional cues. Experimental evidence indicates that animals use the patterns of visual flow to obtain information about changes in distance traveled and rely on their vestibular system to represent changes in directions.

In addition to relying on dead reckoning, animals use landmarks to find locations of important objects and places. Although landmarks are features of the external environment, they can be integrated into an egocentric strategy. For example, the work of Collett and Rees shows that bees tend to approach landmarks (e.g., trees) marking the location of a goal (e.g., a hive) from the same direction in which they originally saw those landmarks. It has been argued that they match the image of landmarks as seen from their current viewpoint with the original view. However, many animals can approach landmarks from different directions and still locate the goal, leading researchers to posit that these animals store multiple images representing landmarks from different viewpoints. It should be pointed out, though, that the use of landmarks can also be integrated into an allocentric strategy in which location is coded independently of the viewer's perspective. To measure the ability to code location independent of one's own perspective, investigators use disorientation tasks in which the relation between the viewer's original position and the goal is disrupted completely. Performance on these tasks shows that many animal species use landmarks to locate a goal after being disoriented.

Studies of animal behavior following disorientation reveal another impressive spatial skill, namely the ability to use information about the shape of enclosed spaces in locating a goal. In one of the earliest studies by Cheng, rats were placed in a rectangular box with food hidden in a particular location. The rats searched for the food after they had been disoriented. On most trials, they looked for the food at either the correct location or at a geometrically equivalent location diagonally opposite from it. Since disorientation prevents the animals from tracking the change in their relation to the hiding corner, their search behavior must have been based on the use of features of the space itself. The observed behavior can be explained by positing that the animals coded the relative lengths of the walls and represented the target location as the corner with a particular relation between adjacent walls (e.g., the longer wall to the right and the shorter wall to the left or vice versa). Thus, when animals can use tracking during their movement, they rely on viewer-centered egocentric spatial strategies, but when tracking becomes unavailable they use environment-centered allocentric spatial strategies.

Development of Spatial Cognition in Humans

The systematic study of spatial development in human beings began in the 1940s with the work of Jean Piaget. He believed that children initially have a very impoverished understanding of space and that they progress through several developmental stages gradually acquiring a more advanced understanding of spatial relations. During the first, Topological stage, children are able to encode only a limited set of spatial relations, such as proximity (adjacent vs nonadjacent), order (in front vs behind), and enclosure (inside vs outside). Distances and lengths are not coded as features of stimuli themselves, but rather are specified in terms of action, e.g., as the amount of reach or movement. A major limitation of this stage is the egocentric nature of spatial coding—information about location is only preserved from an initial viewing position.

The topological stage is followed by the Projective and Euclidean stages, which have been described sometimes as sequential and sometimes as concurrent. The main line of development during the Projective stage is from egocentric to allocentric coding. Piaget demonstrated this development with a series of perspective-taking tasks, in which children had to indicate how a spatial array would look to a person who viewed it from a different position. The predominant response in children younger than 9 years of age was to choose the representation of the array that showed it from their own point of view, but older children were able to select the correct representation. Piaget concluded that around the age of 9 children start using actual spatial relations between objects in the layout rather than relying on egocentric information. Another major line of development, associated with

the Euclidean stage, is from nonmetric to metric spatial coding. Piaget argued that around 9–10 years of age children become accurate in coding locations of objects that are not immediately adjacent to landmarks, which requires using information about distance.

More recent findings, however, indicate that children represent metric properties of space at earlier ages than previously thought. For example, toddlers can find an object hidden in an enclosed space by remembering the distance between that object and the edge of the space. Even infants show sensitivity to distance information, which was demonstrated in a series of habituation studies. In the habituation paradigm, infants are repeatedly shown the same display until their looking time decreases substantially, after which they are shown a novel display. An increase in looking time indicates that children have noticed the difference between the two displays. Five-month-olds who have seen a toy being repeatedly hidden and then retrieved at a particular location within a space, look longer if a toy hidden in that location emerges from a new location.

An accumulating body of evidence also indicates that spatial coding in young children is not necessarily tied to their initial viewing position. As discussed above, one way to identify a location from a new position is by keeping track of changes in the relation between oneself and the location. Toddlers demonstrate this ability in tasks where they observe an object being hidden in a particular location and are then required to locate the object after walking to a new position. When the task is administered in a homogeneous environment where no landmarks are visible, children must rely on dead reckoning to perform successfully. Another way to locate an object after movement is by using the relation between the object's location and landmark(s). In the first two years of life, children mostly use landmarks to locate a target object when the landmarks are immediately adjacent to the object. Starting around the age of two, however, children also begin to benefit from the presence of distal landmarks. While these findings indicate that the ability to code object location relative to distal landmarks emerges earlier than proposed by Piaget, other evidence suggests that landmark use nonetheless undergoes substantial development through the elementary school age. During that period children become progressively more accurate and flexible in the use of landmark information; they begin integrating their knowledge of individual landmarks to represent relations among multiple locations and to form routes that connect ordered sequences of landmarks.

In addition to landmark use, children demonstrate the ability to rely on geometric properties of space (shape) to code object location. Adopting Cheng's paradigm, Hermer and Spelke showed toddlers an object being hidden in a corner of a rectangular room and then asked them to find the object following disorientation. Similar to the results of animal studies, children searched for the object either in the correct corner or in the geometrically equivalent corner. It has been shown that under certain conditions, namely in small enclosed spaces, children use geometric cues to the exclusion of landmark cues. For example, when a rectangular room contains a landmark that distinguishes the two geometrically equivalent corners (e.g., a wall of a particular color), children seem to ignore that landmark and search solely on the basis of geometry. These findings have led Hermer and Spelke to propose that toddlers' ability to locate an object following disorientation is modular, restricted to the use of geometric information. However, in larger spaces, children successfully combine landmark and geometric cues, suggesting that space size may be critical in determining the types of cues used to reason about space.

The research on spatial development reveals impressive abilities in young children, indicating that the skills they possess at the starting points of development are stronger than those posited by Piaget. At the same time, this research shows certain limitations of early spatial behaviors, suggesting a long developmental progression between the starting points and a mature spatial competence. Many of the spatial abilities revealed by children can be observed only in limited contexts. While a number of studies have shown that children code metric information to identify object location, other studies reveal that children do not always realize the need to consider distance and direction and may revert to a more primitive strategy of coding location only in terms of adjacent landmarks. Moreover, while children clearly have an ability to solve spatial tasks by using the relations between spatial features of the environment, they still have difficulty with Piagetian perspective-taking tasks (until about the age of 9 years), which require the use of allocentric rather than egocentric strategies.

Spatial Perception and Reasoning in Adults

When researchers discuss a mature form of spatial cognition, they often imply by the term "mature form" the ability to encode metric relations and to represent these relations independently of one's own viewpoint. Adults, indeed, are more precise in metric coding than children and more flexible in the ability to take different perspectives. Nevertheless, a closer examination of strategies underlying performance of adults on some spatial tasks reveals the influence of nonmetric information on their judgments of distance as well as viewpoint specificity in reasoning about space. Thus, the mental representation of space constructed by adults is not the exact replica of the actual physical space.

One factor underlying this phenomenon is the influence of categorical information. For example, when people are asked about the positions of two cities relative to each other, they rely on their knowledge of geographic categories. As a result, Seattle (USA) is often thought to be to the south of Montreal (Canada) because USA lies largely to the south of Canada even though for these particular cities the relation is reversed. In addition to geographic categories, people use other kinds of categorical information in reasoning about spatial relations. To examine the use of categories in spatial reasoning, researchers present people with sets of stimuli that vary in terms of size or location. For example, people are shown lines on the computer screen that vary in length. The lines are presented one at a time; after the line disappears, the subject is asked to reproduce it by pressing designated keys on the keyboard. In another type of reproduction task, people are shown a rectangular enclosure with a dot inside it. The location of the dot varies from trial to trial and the task is to reproduce the dot's location as accurately as possible.

The examination of performance on such reproduction tasks has led to a proposal that people combine fine-grained information about location or size of a particular stimulus with category information. In remembering the location of an object within an enclosed space, people seem to subdivide that space into categories (e.g., quadrants); their estimates are misplaced toward the prototypes (centers) of these imposed spatial categories. In remembering the size of an object, people combine the information about that particular object with the categorical information about objects of that kind; their estimates are biased toward a prototypical size of objects belonging to this category. The use of categorical information introduces some degree of bias in estimating individual stimuli, however, on average, it yields more accurate judgments.

Another important factor that affects spatial reasoning in adults is viewpoint dependence. While adults are capable of coding spatial relations in terms of external features of the environment (i.e., independent of their own perspective), they do not necessarily rely on this type of coding in solving spatial tasks. This phenomenon has been documented, for example, in object recognition studies. In identifying individual objects, people often rely on their spatial characteristics. To investigate factors affecting object recognition, researchers have used matching tasks, in which participants are shown a pair of objects, one after another, and are asked to determine whether the objects are the same. On some trials the objects are identical whereas on other trials they differ. The critical manipulation is whether the pair of objects is presented from the same or different perspectives. Using this design, Hayward, Tarr, and colleagues demonstrated an *alignment effect*—people find it easier to match the objects if they are aligned (i.e., presented from the same viewpoint) than if they are rotated relative to each other. At the same time, Biederman and colleagues argued that the perception of certain features of objects is virtually unaffected by rotation and that matching objects that contain these features is equally easy whether the objects are aligned or not. Some examples of spatial features that can uniquely specify the structural description of an object include whether a particular contour is straight or curved or whether pairs of contours are parallel or not. Biederman proposed that based on this kind of information, people represent objects in terms of relations between simple parts (called *geons*) that have a uniquely identifiable shape.

A parallel set of findings concerning viewpoint dependence versus viewpoint independence of spatial coding is reported in studies of how people represent object locations. These studies commonly use a perspective-change paradigm, in which people learn the positions of objects in a spatial layout from a particular perspective and then are asked to imagine themselves facing the layout from the same or different perspective; in either case the task is to point to various objects in the layout. Most studies report alignment effects—performance suffers, both in terms of pointing error and reaction time, when the viewing perspective at the time of testing is not the same as at the time of learning. Furthermore, the results show a roughly linear increase in reaction time as a function of angular difference between the two perspectives. These findings suggest that people may solve the task by transforming the view of the layout at testing into the view of the layout formed during learning, possibly by mental rotation. Larger transformations take longer and result in greater errors.

It should be noted that under certain conditions, particularly in tasks involving larger spatial layouts, people show a lack of alignment effects in reasoning about spatial relations. The finding that spatial behavior varies depending on the size of the space thus appears to be common to children and adults. Researchers distinguish between small-scale space that can be seen from a single viewpoint and large-scale space that requires movement to be perceived in its entirety. It has been proposed that by navigating in a large-scale space people construct a survey-like mental representation that includes landmarks as well as routes through the space. This type of representation is often referred to as a *cognitive map*, a term introduced by Tolman in his 1948 paper, "Cognitive maps in rats and men." Cognitive maps can be used to reason about relations among different locations, to create a shortcut or a detour through a familiar space. The degree to which such mental representations are complete or accurate depends on the amount of experience with the represented space. It is often argued that cognitive maps have no particular perspective, allowing people to analyze relations between

objects from different viewpoints. Thus, the research on cognitive maps combined with perspective-taking studies that demonstrate alignment effects suggests that human adults can form both viewpoint-dependent and viewpoint-independent representations of layouts, and that the nature of spatial representations seems to depend at least to some extent on the size of the layout.

The Use of Symbolic Spatial Tools

While the concept of cognitive map refers to the mental representation of space constructed by an individual, spatial behavior may also involve the use of maps that are external symbolic representations of space. In fact, the uniquely human ability to use symbolic representations significantly augments spatial capabilities by allowing humans to acquire and communicate information about space beyond that available from direct experience. Maps commonly provide a bird's-eye view of the space covering a large area and making explicit the relations among multiple locations that cannot be seen all at once (or may never have been seen at all). While maps and models provide important tools for spatial reasoning, using these tools requires additional skills that can be acquired though implicit or explicit learning.

In order to be able to use a map, one must establish the correspondence between symbols on the map and objects in the real world (representational correspondence) and also between the spatial relations on the map and those in the real world (geometric correspondence). The work of DeLoache has shown that the ability to establish correspondence between individual symbols and their real-world spatial referents is acquired early in life, around 3 years of age. Dealing with the correspondence of spatial relations that involve distances and angles is a more complicated task. Interpreting metric information presented on the map requires translating distances between spaces of different sizes (i.e., scaling). Recent studies indicate that the ability to carry out a scaling transformation of distance develops during the preschool years. However, this ability is initially quite limited and in many map tasks children ignore the difference in scale between the two spaces. Using a map to find locations in the actual space is especially challenging when the map is not aligned with that space. Children often fail to correct for the lack of the alignment, which leads them to particular patterns of errors in map-reading tasks. When adults are presented with a small-size map that is not aligned with the environment, they often rotate the map until it is oriented in the same way. If they are not allowed to reorient the map, they attempt to correct mentally for differences in orientation, which takes more time and often results in greater errors compared to dealing with aligned maps.

Experience with maps may have important implications for spatial reasoning, particularly in thinking about large-scale spaces that are typically represented on geographic maps. As argued by Uttal, the influence of maps on spatial cognition is both specific and general. Using a map provides people with an opportunity to think about a particular space in terms of multiple relations between different locations, as they are represented on the map. However, maps may also transform our understanding of the environment in a more general sense, by providing a structure that can be mentally imposed on a space in thinking about its overall shape, its constituent elements and the relations among them.

Individual Differences in Spatial Cognition

It is commonly known that individuals differ substantially in the level of their spatial skills. This is true both for tasks involving navigating a large-scale space and for tasks involving manipulating objects and small-scale spatial arrays. Some people get lost easily, even after some degree of familiarization with the space, whereas others learn about spatial environments rapidly. People also vary in the ability to assemble objects, such as items of furniture or equipment, out of the component parts. These individual differences in everyday functioning parallel scientific findings that show a wide variation in performance on tasks that require spatial reasoning. The experimental paradigms used to compare levels of performance across individuals range from psychometric paper-and-pencil tasks (e.g., solving mazes, completing patterns, and matching shapes) to tasks that require problem solving in real-world large-scale spaces (e.g., map reading and wayfinding). It has turned out to be rather difficult to identify a small number of basic underlying spatial factors that could account for performance on such diverse tasks. Whereas some individuals are successful in a wide range of spatial tests, others show more within-subject variability. For example, a person who is good at solving mazes may not be as good at object assembly or map reading.

Individual differences in spatial processing are often discussed under the rubric of sex differences. Indeed, research indicates that males and females differ on both measures of accuracy and reaction time on many spatial tasks. Before addressing these differences, however, it is important to emphasize that there is also large variation within each gender group and that, in fact, there is a substantial overlap between the two groups. That is, particular women may outperform particular men on tasks where males, on average, have an advantage.

One type of sex difference reported in the literature concerns the kinds of cues (e.g., landmarks versus metric information) that are used in representing a spatial environment. This difference is revealed, for example, in direction-giving tasks in which subjects are asked to provide directions specifying how to get from one place to another. Males are more likely to use cardinal directions (e.g., North) and to indicate the distance between points (e.g., number of miles), whereas females are more likely to use landmark information (e.g., buildings). Note though that females increase the use of metric and cardinal information when explicitly asked to do so. Other tasks show that females and males may actually differ in how accurate they are in using different kinds of spatial cues obtained in a large-scale environment. For example, when people are walked through a particular area and then are asked to draw a map of their route, males tend to make smaller errors for distance and direction, whereas females tend to make fewer errors in reporting landmarks that lie along the route. If people are familiarized with the area not by walking through it but rather by studying a picture of that area, gender differences in sensitivity to particular cues disappear. Namely, when the picture is taken away and people are asked to draw a map of a route that they have studied, females and males show comparable levels of accuracy in reporting distances, directions, and landmarks. Thus, the differential sensitivity to landmark versus metric cues may only apply to acquiring information in the large-scale environments.

Another ability that has been associated with sex-related differences is mental rotation. Some mental rotation tasks use a matching paradigm similar to the object recognition studies—participants judge which one of the choice figures represents the target form in a different orientation and which one represents a totally different form. In other tasks, participants are required to rotate mentally and/or fit together component pieces to form a target shape. The results across studies show that males outperform females, as measured by accuracy and reaction time. It has been suggested that the observed differences in performance can be partly due to the difference in strategies used to solve mental rotation tasks. In particular, on matching task, males may favor the strategy of mentally rotating the whole object and comparing the result of this rotation to the target while females may approach the task by comparing the individual parts comprising the target and choice figures. Both strategies can lead one to the right solution, but the latter appears to be less efficient.

It has long been believed that sex-related differences in spatial cognition emerge around the age of puberty. However, more recent evidence indicates the existence of such differences even in preschool children. A number of factors have been proposed as a possible explanation for the observed variation in performance. Biological theories emphasize the relation between hormone levels and spatial ability. It has been shown that males who have androgen deficiency early in life have low spatial ability compared to males with normal hormonal levels. At the same time, females with high androgen levels early in life have higher spatial ability compared to normal controls. Furthermore, hormonal changes within subjects also appear to influence spatial abilities. Thus, females perform best on spatially demanding tasks when their estrogen levels are lowest (in contrast to verbal skills that correlate positively with estrogen levels). The evidence of biological effects does not exclude, however, a possibility that spatial skills are affected by environmental factors. It has been proposed that early play experience, for example playing with construction sets and other spatially relevant toys, may be an important factor in the growth of spatial abilities. Convincing evidence concerning the malleability of spatial skills comes from studies showing that training can significantly enhance performance on tasks involving mental manipulation of spatial stimuli. Thus, both biological and environmental factors appear to be integral to the development of differentiation in spatial skills. It remains to be determined how these factors interact to produce particular skill levels and particular patterns of performance.

Cultural Differences in Spatial Cognition

Culture may influence spatial thinking and behavior in a variety of ways. Symbolic spatial representations, such as maps and models, provide one example of a culturally mediated spatial cognition. The use of measurement tools exemplifies another way in which human cognition is aided by cultural devices. Recent evidence shows that the growth of spatial skills is greater during periods when children are in school compared to vacation periods. This effect of schooling may be carried by a number of factors—engaging children in activities (for example, in math and science classes) that require mental transformation, object assembly, and other spatial skills; teaching them how to use symbolic tools in spatial tasks; and providing them with spatial terminology.

The way in which language codes spatial relations may be related to the way people think about space. There is large variation across languages in how features of space are captured. As a result, what counts as the same spatial relation in one language can be counted as different relations in another language. For example, English uses the preposition "in" to represent the relation of containment, such as "putting an apple in a bowl" or "putting a videotape in its case." In Korean, however, these two examples would be expressed with different prepositions

because the Korean language makes a critical distinction between the relation of a loose fit (apple in a bowl) and a tight fit (videotape in a case). Cross-linguistic studies suggest that people speaking different languages have different criteria for carving up space and for forming spatial categories. The work of Bowerman and colleagues shows that even very young children are sensitive to particular spatial distinctions made in their language.

Some researchers (e.g., Levinson) raise the possibility that people from different cultures may vary not only in how they speak about space, but also in how they reason about space in nonverbal tasks. Levinson and colleagues compared the spatial performance of people whose languages vary quite radically in their approach to coding spatial relations. In particular, when coding the positions of objects in small arrays, speakers of Dutch as well as speakers of English rely on relative terms, such as left/right/front/back (e.g., the fork is on the left side of the plate). In contrast, speakers of the Mayan language Tzeltal lack relative terms and, instead rely on absolute coding by using terms equivalent to the English cardinal directions (e.g., the fork is to the North of the plate).

In a series of studies in which participants were shown an array of objects and were asked to reconstruct the array after been rotated 180°, the speakers of Tzeltal performed differently than their Western counterparts. That is, the Dutch participants preserved the egocentric relations so that the object originally shown in the leftmost position was also placed in the leftmost position following the viewer rotation. In contrast, the Mayan participants preserved the fixed bearings of the array which meant reversing the egocentric relations; e.g., the object originally shown in the leftmost position relative to the viewer was placed in the rightmost position relative to the viewer after rotation. Parallel findings have been obtained on a wide range of tasks involving spatial perception, memory, and inference. To be sure, it is possible that the observed differences in spatial cognition may not be due to language per se, they may reflect cultural differences more generally. However, these findings highlight the importance of considering the mechanisms underlying variation in spatial skills.

Summary

In sum, spatial cognition covers a wide range of skills that enable organisms to navigate their environment and to transform spatial relations among objects or their constituent parts. Some aspects of spatial cognition are shared by humans and animals. Others are uniquely human, such as the use of spatial symbols. Across species, the development of spatial skills is shaped, to a large extent, by characteristics of the physical environment. In humans, spatial cognition is also influenced by cultural tools that augment spatial abilities by providing a way to represent and think about space beyond that which is available through direct experience.

Glossary

database management system (DBMS) A collection of computer programs designed to enable creation and maintenance of a large database.
geographic information system (GIS) A popular family of software designed to enable visualization, manipulation, and analysis of small spatial data sets.
object-relational database management system (OR-DBMS) A modern database management system that allows the effective modeling of spatial data using user-defined data types and operations.
query A question posed to a database.
query language A medium to express interesting questions within a computer program; a structured query language (SQL) is used for commercial database management systems.
spatial data model A type of data abstraction that hides the details of data storage.
spatial database A collection of large, interrelated spatial data items stored within a computer environment.
spatial database management system (SDBMS) A software module that manages the database structure and controls access to a large spatial database.
spatial query A question involving spatial concepts.

Spatial databases address the growing data management and analysis needs of spatial applications such as geographic information systems, remote sensing, urban planning, and natural resource management. Spatial database systems have been the focus of an active area of data management research and application for more than two decades. The research has produced major accomplishments including a taxonomy of models for space, spatial query languages, spatial storage and indexing, and query-processing and optimization strategies.

Introduction

Spatial Database and Spatial Database Management Systems

The world is undergoing an information revolution. The raw material powering this controlled upheaval—data—is being gathered constantly via sensors and other data-gathering devices. For example, the Earth Observing System developed by the United States National Aeronautics and Space Administration generates approximately 1 terabyte of data every day. Spatial data (with the term "spatial" referring to any type of space, not only the space on and above Earth's surface) are abundant in many application domains. Satellite images are one prominent example of spatial data. Information extracted from a satellite image must be processed with respect to a spatial frame of reference, possibly Earth's surface. But satellites are not the only source of spatial data, and Earth's surface is not the only frame of reference. A silicon chip can be, and often is, a frame of reference. In medical imaging, the human body acts as a spatial

frame of reference. In fact, even a supermarket transaction is an example of spatial data, if, for example, a zip code is included. A collection of interrelated spatial data is called a spatial database. Examples of publicly accessible spatial databases include the U.S. Census 2000 database created by the U.S. Census Bureau, the United States Crimes Database of the Federal Bureau of Investigation, and the County Boundary Database of the U.S. Geological Survey.

Data are housed in and managed via a database management system (DBMS). Databases and the software (computer programs and documentation) that manage them are the silent success story of the information age. They have slowly permeated all aspects of daily living, and modern society would come to a halt without them. Despite their spectacular success, the prevalent view is that a majority of the DBMSs in existence today are either incapable of managing spatial data or are not user friendly when doing so. Why is that true? The traditional role of a DBMS has been that of a simple but effective warehouse of business and accounting data. Information about employees, suppliers, customers, and products can be safely stored and efficiently retrieved through a DBMS. The set of likely queries is limited, and the database is organized to answer these queries efficiently.

Compared to the data in traditional DBMSs, spatial data are more complex because they include extended objects, such as points, lines, and polygons. The relationships among spatial objects are often implicit, i.e., relationships such as "overlap," "intersect," and "behind" are not explicitly modeled in a DBMS. A traditional database management system must be specialized to meet the requirements of spatial data. By doing so, spatial domain knowledge can be extrapolated to improve the overall efficiency of the system. Thus, simply speaking, a spatial database management systems (SDBMS) may be defined as a software module that manages the database structure and controls access to data stored in a spatial database. More specifically, a spatial database management system is a software module that can work with an underlying database management system, e.g., an object-relational database management system (OR-DBMS). It supports multiple spatial data models, commensurate with spatial data types and operations. It also supports spatial indexing, efficient algorithms for spatial operations, and domain-specific rules for query optimization.

Commercial examples of spatial databases management include IBM/Informix's DataBlade module (e.g., 2D, 3D, and Geodetic); Oracle's Universal server, with either the Spatial Data Option or the Spatial Data Cartridge; and ESRI's Spatial Data Engine. PostGIS/PostgreSQL is a research prototype example of spatial database management systems. The functionalities provided by these systems include a set of spatial data types, such as point, line segment, and polygon, and a set of spatial operations, such as inside, intersection, and distance. The spatial types and operations may be made part of an extensible query language such as structured query language (SQL), which allows spatial querying when combined with an OR-DBMS. The performance enhancement provided by these systems includes a multidimensional spatial index and algorithms for spatial access methods, spatial range query, and spatial joins.

Geographic Information Systems and Spatial Database Management Systems

A geographic information system (GIS) provides a rich set of operations over few objects and layers, whereas an SDBMS provides simpler operations on sets of objects and sets of layers. For example, a GIS can list neighboring countries of a given country (e.g., France), given the political boundaries of all countries. However, it will be fairly tedious for a GIS to answer set queries (e.g., "list the countries with the highest number of neighboring countries" or "list countries that are completely surrounded by another country"). Set-based queries can be answered easily in an SDBMS. SDBMSs are also designed to handle very large amounts of spatial data stored on secondary devices (magnetic disks, compact disk—read-only memory, jukeboxes, etc.) using specialized indices and query-processing techniques. SDBMSs inherit the traditional DBMS functionality of providing a concurrency-control mechanism to allow multiple users to access shared spatial data simultaneously, while preserving the consistency of that data. A GIS can be built as the front end of an SDBMS. Before a GIS can carry out any analysis of spatial data, it accesses that data from an SDBMS. Thus, an efficient SDBMS can greatly improve the efficiency and productivity of a GIS.

Space Taxonomy and Data Models

Space Taxonomy

"Space" is indeed the final frontier, not only in terms of travel on and beyond Earth's surface, but also in the difficulty of capturing the meaning of the word and the concept with a simple, concise description. Consider the following refrain echoed by hapless drivers all over the world: "I don't remember how far Mike's house is: once I am nearby, I might recall on which side of the street it lies, but I am certain that it is adjacent to a park." This sentence gives a glimpse of how the human brain (mind) structures geographic space. We perform poorly in estimating distances, maybe only slightly better in retaining direction and orientation, but fairly capably when it comes to remembering topological relationships such as "adjacent," "connected," and "inside." Topology,

a branch of mathematics, is exclusively devoted to the study of relationships that do not change due to elastic deformation of underlying space. For example, if there are two rectangles, one inside the other, or both adjacent to each other, drawn on a rubber sheet, and if the sheet is stretched, twisted, or shrunk, the named relationships between the two rectangles will not change!

Another clue about how the human mind organizes space is revealed by examining how languages communicate concepts. For example, the shapes of objects are major determinants in how objects are described. Is that the reason why we have trouble accepting a whale as a mammal and a sea horse as a fish? Objects are described by nouns, and languages have as many nouns as there are different shapes. On the other hand, the spatial relationships among objects are described by prepositions, which encode very weak descriptions of shapes. For example, in saying that "Coffman Student Union is to the southeast of Vincent Hall," the shapes of the buildings play almost no role in the relationship "southeast." We could easily replace the buildings with coarse rectangles without affecting their relationship.

Space taxonomy refers to the multitude of descriptions that are available to organize space: topological, network, directional, and Euclidean. Depending on why we are interested in modeling space in the first place, we can choose an appropriate spatial description. Table I provides an example of a spatial operation associated with a different model of space. It is important to realize that no universal description (model) of space can answer all queries.

Spatial Data Model

A data model is a type of data abstraction that hides the details of data storage. For example, Minnesota is the "land of ten thousand lakes." How can these lakes be represented? An intuitive, direct way is to represent each lake as a two-dimensional region. Similarly, a stream, depending on the scale, can be represented as a one-dimensional curved line, and a well site can be represented by a zero-dimensional point. This is the object model. The object model is ideal for representing discrete spatial entities such as lakes, road networks, and cities. The object model is conceptual; it is mapped into the computer using a vector data structure. A vector data structure maps regions into polygons, curves into polylines, and points into points.

Table I Different Types of Space Descriptions

Family of descriptions	*Example concept*
Topological	Adjacent
Network	Shortest path
Directional	North of
Euclidean	Distance

The field model is often used to represent amorphous or continuous entities (e.g., clouds or temperature maps). A field is a function, which maps the underlying spatial reference frame into an attribute domain. For temperature, popular attribute domains are Celsius and Fahrenheit. The raster data structure implements the field model on computers. A raster data structure is a uniform grid imposed on the underlying space. Because field values are spatially autocorrelated, i.e., smoothly varying over space, the value of each cell is typically the average of all of the field points that lie within the cell. Other popular data structures for fields are the triangulated irregular network (TIN), contour lines, and point grids.

Spatial Query Languages

Spatial Query

Once the design of a database is complete and a DBMS is chosen to implement the database, we can carry out queries to the database. It is worthwhile to view a query as a question posed to a database. A query is expressed in a high-level declarative manner, and the algorithms needed to answer the query are not specified in the query. For example, typing a keyword in a search engine (e.g., Google or Yahoo Search) forms a query corresponding to the question "Which documents on the web contain the given keyword?" Queries involving spatial concepts are called spatial queries. For example, the query "List the counties with populations over 500,000 in the United States" is an example of a nonspatial query. On the other hand, the query "List crime hot spots within 10 miles of downtown Minneapolis" is an example of a spatial query because it uses the spatial concept of distance.

Spatial Query Languages

A query language is a medium used to express interesting questions about data, and queries expressed in query languages retrieve answers from databases. Query languages include natural languages, such as English, which can express almost all queries, and computer languages, such as Java, which can express computable queries. Many query languages often restrict the set of possible queries. For example, an interactive map may allow users to drag a mouse pointer over or to point and click on locations to ask questions about different spatial properties of those locations. Although drag and point-and-click methods are user-friendly features, users are limited in the kinds of queries they can make. Structured query

language (SQL) was thus designed to express set-oriented queries.

SQL is now the standard query language for commercial relational databases. SQL is a comprehensive database language, and it has statements for data definitions, manipulations, and controls. Queries are expressed using SQL constructs for data manipulations. The queries are expressed in a high-level declarative manner, so users specify only what the results are to be, leaving how to execute the queries to the DBMS. SQL is text based and is mostly geared toward set-based operations. For example, the query "List the counties with populations over 500,000 in the United States" finds a set of counties with populations of more than 500,000.

In 1999, the Open GIS Consortium (OGC), led by major GIS and database vendors, established a specification for incorporating spatial data types (e.g., polygons) and operations (e.g., distance) in SQL. The OGC extensions are based on the object model and support multiple spatial data types, such as the point, curve, line string, polygon, and surface. The operations supported in the OGC extensions fall into three categories:

1. Basic operations applicable to all geometry data types. For example, a spatial reference returns the underlying coordinate system where the geometry of the object was defined. Examples of common reference systems include the well-known latitude and longitude system and the Universal Traversal Mercator.
2. Operations that test for topological relationship among spatial objects. For example, an intersect operation tests whether the interior of two objects has a nonempty set intersection.
3. General operations for spatial analysis. For example, a distance operation returns the shortest distance between two spatial objects.

Others efforts to standardize spatial extensions to SQL include SQL/MM and ISO/TC 211 Geographic Information/Geomatics.

Examples can be used to illustrate query operations. Say there are three data sets in a spatial database, Country, City, and River. The Country data include the name, continent, population, and spatial footprint for each country in the world. The City data consist of the name, country, population, and spatial footprint for each city in the world. The River data are made up of the name, origin, length, and spatial footprint for each river in the world. The following example queries can be expressed easily in SQL using the OGC spatial data types and operations:

Query 1: List the name, population, and area of each country.
Query 2: Find the names of all countries that are neighbors of the United States.
Query 3: For each river, find the countries through which they pass.
Query 4: For each river, identify the closest city.
Query 5: Find the shortest path from Minneapolis to Duluth.

Spatial Storage and Indexing

Database management systems have been designed to handle very large amounts of data. This translates into a fundamental difference in how algorithms are designed in a GIS data analysis vs. a database environment. In the former, the main focus is to minimize the computation time of an algorithm, assuming that the entire data set resides in the main memory of a computer. In the latter, emphasis is placed on minimizing the sum of the computations using data in the main memory and the input/output (I/O) to fetch data from secondary storage data. This is because, despite falling prices, the main memory is not large enough to accommodate all of the data for many applications.

It is worthwhile to view the secondary storage device as a book. The smallest unit of transfer between the secondary storage and main memory is a page, and the records of tables are like structured lines of text on the page. A query issued by a user essentially causes a search within a few selected lines embedded in pages throughout the book. Some pages can reside in the main memory, and pages can be fetched only one at a time. To accelerate the search, the database uses an index. Thus, in order to search for a line on a page, the DBMS can fetch all of the pages spanned by a table and can scan them line by line until the desired record is found. The other option is to search in the index for a desired keyword and then go directly to the page specified in the index. The index entries in a book are sorted in alphabetical order. Similarly, if the index is built on numbers, such as social security numbers, the numbers can be numerically ordered.

The R-tree data structure was one of the first indexes specifically designed to handle multidimensional spatial objects on secondary storages, such as disks. The R-tree groups together objects in spatial proximity on the same leaf nodes of a tree-structure index. Figure 1 shows an example of how the R-tree organizes extended objects. Because a leaf node can point only to a certain number of objects, minimum bounding rectangles are applied to divide the space. The internal nodes of R-trees are associated with rectangles, the areas of which cover all of the rectangles in the subtree. Hence, R-trees can easily answer queries; they can find all objects in a given area by limiting the tree search to those subtrees with rectangles that intersect with the given query area. Note that the minimum bounding boxes may have

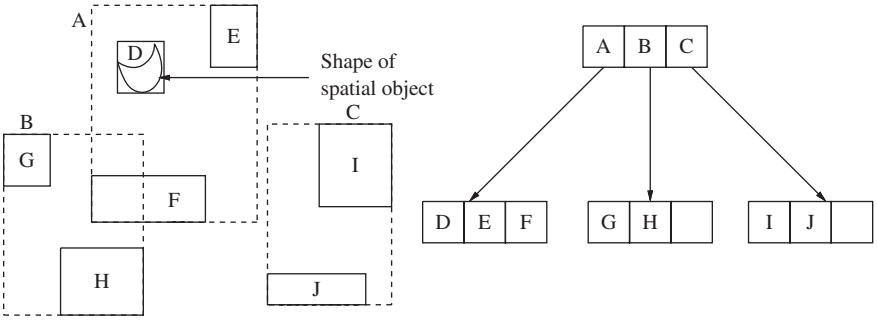

Figure 1 Use of an R-tree to organize spatial objects.

overlapping spatial areas (e.g., rectangles A and B in Fig. 1); this type of problem is handled in different ways by the many different variations of R-trees. Other spatial storage structures include the grid file, quad-trees, and their variations.

Query Processing

As noted earlier, a database user interacts with the database using a declarative query language such as SQL. The user specifies only the result desired, and not the algorithm to retrieve the result. The DBMS must automatically implement a plan to execute the query efficiently. Query processing refers to the sequence of steps that the DBMS will initiate to process the query.

Queries can be broadly divided into two categories: single-scan queries and multiscan queries. In a single-scan query, a record (tuple) in the table (relation) being queried has to be accessed at most once. Thus, the worst-case scenario, in terms of time, is that each record in the table will be accessed and processed to verify whether it meets the query criterion. The spatial query introduced earlier, "List crime hot spots within 10 miles of downtown Minneapolis," is an example of a single-scan query. The result of this query will be all crime hot spots that intersect a circle of 10 miles from downtown Minneapolis. This query is also an example of a spatial range query, whereby the "range" refers to the query region. Here the query region is the circle of radius 10 miles. If the query region is a rectangle, the spatial range query is often referred to as a window query.

A join query is a prototype example of a multiscan query. To answer a join query, the DBMS has to retrieve and combine two tables in the databases. If more than two tables are required to process the query, then the tables may be processed in pairs. The two tables are combined, or "joined", on a common attribute. Because a record in one table can be associated with more than one record in the second table, records may have to access more than once to complete the join. In the context of spatial databases, when the joining attributes are spatial in nature, the query is referred to as a spatial-join query.

The SDBMS processes range queries using the filter–refine paradigm. This is a two-step process. In the first step, the objects to be queried are represented by their minimum bounding rectangles. The rationale is that it is easier (computationally cheaper) to compute the intersection between a query region and a rectangle rather than between the query region and an arbitrary, irregularly shaped spatial object. If the query region is a rectangle, at most four computations are needed to determine whether the two rectangles intersect. This is called the filter step, because many candidates are eliminated by this step. The result of the filter step contains the candidates that satisfy the original query. The second step is to process the result of the filter step using exact geometries. This is a computationally expensive process, but the input set for this step, thanks to the filter step, often has low cardinality, i.e., few candidates are to be checked in the second step.

Summary

A SDBMS manages the database structure and controls access to data stored in a spatial database. The SDBMS plays a prominent role in the management of query of spatial data. Spatial data management is of use in many disciplines, including geography, remote sensing, urban planning, and natural resource management. The Open GIS Consortium has established a specification for incorporating two-dimensional spatial data types (e.g., point, curve, and polygon) and operations. Using the OGC specification, common spatial queries can be posed in structured query language. The spatial indexes (e.g., R-trees) were designed to facilitate efficient accesses to spatial databases, and the filter–refine strategy can be applied to process spatial queries efficiently.

Spatial Discounting

Bruce Hannon
University of Illinois, Champaign-Urbana, Champaign, Illinois, USA

Glossary

biomagnification The increased concentration of a chemical found in species as one moves up the food chain.
discounting To reduce value (positive or negative) in proportion to a given metric.
intragenerational Between members of the present generation.
space In this article, restricted to the surface of the earth.
utility A general measure of usefulness or desirability as used in economics.

Spatial discounting is a parallel process to time discounting. Just as people devalue actions in their future, they devalue present actions at a distance. People are both socially myopic and parochial.

Introduction

There exists in people a desire to be near things that they consider "good" and to be far from things they consider "bad." People prefer to live near schools, churches, and grocery stores and far from sewage treatment and power plants, landfills, and prisons; they prefer to live near the ocean and far from harsh climates. In the workplace, people prefer higher offices and shun basement offices. At home, people prefer living on top of a hill to the bottom, upstream to downstream. People prefer to live away from a national boundary rather than close to it. People tend to discount their fear of (desire for) an object the further they are away from it—a negative (positive) geographic discounting. Animals and plants exhibit spatial discounting as well. Spatial discounting is one of five distinguishable forms of discounting; the others are the discounting of time, uncertainty, the insensible, and the interpersonal.

Basic Requirements for the Concept

For simplicity, assume that the geographic discount rate is constant with respect to time and distance, and that the geographic discounting function is one of exponential decline with respect to distance. The exponential function is mathematically convenient, but its use implies a rather specific kind of feedback relationship with the quantity being discounted.

This is not as constraining a requirement as it might first seem. Consider the temporal accumulation process in finance. The amount of interest money that accrues this year on an amount of invested money depends directly on the amount of invested money itself; at the end of the first year, the base amount has grown by the amount of interest, so the second year's interest money is larger than it was in the first year, and so on. The initial investment grows at an accelerated rate as interest accumulates. The investment amount provides a feedback signal that controls the size of the next period's accumulation. The reverse of this process is called time discounting: a stream of future payments to a person is said to have a unique value at this moment because that person is assumed to have a known discount rate. Therefore, he or she values a promised payment in the future in proportion to its size and how far into the future the payment is supposed to be. The farther a particular payment is seen in the future, the less he or she values it now; that is, the more the person discounts it. The interesting part of the devaluation of future payments into today's value is that the devaluation is proportional to time.

When a separate factor is developed to represent spatial discounting, it is an admission that it is convenient to do so, it is appropriate to do so, or both. It can be argued

that any function that represents the benefits and costs (the utility) of a living organism should contain all geographical discounting effects. But this may not be possible or practical, even though the benefits and costs are functions of distance. The geographical discounting function being proposed should multiply the net benefits to represent the psychological state of the organism and any of its distance-related perceived risks. In such a use, the geographical discounting function exactly parallels the time discounting function so common in economic optimization applications.

The basic question then becomes, "Exactly what is being discounted with respect to distance and why should that discounting process be exponential?" As examples of geographic discounting in humans, animals and plants were evaluated and no units were found that were commensurate with those economists use. That is, not everything that is geographically discounted in living systems can be cast into the same units of measure. In humans, that which is discounted with distance seems to be fear or desire: the fear of something dangerous, or the desire to be in some place or to have some desired sensory input from some particular place. The further the object of threat or desire is from the individual, the more that object is discounted. Clearly, in this sort of discounting, one can find positive and negative expressions, both of which decline in importance as the distance from the object of attention grows.

This sort of positive and negative expression of desire and fear is also demonstrable over time. Such thoughts as "I can't wait until I see her again" or "I dread the thought of tomorrow's dental appointment" are good examples. People usually do not quantify any aspect of time value except the positive financial one, but these alternatives are possible.

Finally, the difference between geographical discounting by an individual and by a group must be clarified. The rate of geographical discounting will vary for an individual over time, with increasing information and with changes in personal outlook. While such changes may be useful to individuals and help them better understand their perceptions of the landscape, the policy implications of geographical discounting are most interesting. Consequently, the focus is on the rates as they might be revealed by typical groups of people. These rates should represent a meaningful average for such groups, and they are likely to change more slowly and be more comparable between different groups in similar situations.

The Nature of Spatial Discounting

Early studies of willingness to pay for the avoidance of aesthetic or environmental threat did not include distance between the observer and the object of concern in the criteria. More recent literature must be consulted for references to the quantified connection between valuation and distance.

People who object to the proposed nearness of generally objectionable activity are seen as being fixed to geographic location and wishing to force the activity away from them. This is one view of a sense of place, from the home place. But suppose that someone is aware of a desired home place but is presently located away from it. That person then has a desire to be nearer the home place, and his or her desire varies with the separation distance. It seems reasonable to assume that those who move frequently will not develop a sense of place, and consequently, that their distance discounting is very significant. Without a sense of place, residents tend to allow deterioration of that place without resistance. Sense of place and its attribute, geographical discounting, appears to be a necessary condition for environmental concern, at least in the novice environmentalist. Genuinely nomadic peoples, however, have a low rate of geographical discounting. Although they move frequently, they repeatedly circulate through a series of spaces, the whole of which can be seen as their territory or home.

Part of the reason people discount distance may be derived from their perception of risk: the closer an undesirable object is, the greater the risk of exposure to its undesirable aspects. If this were the case, then, would it be easier to locate an undesirable object in an area where the perceived risks are already high than in an area where risks are seen as low? The percentage increase in risk is less in the first instance. This view of risk perception is confounded by the possibility that the areas where general risk of personal harm is higher are urban areas, in contrast with rural areas. While the percentage increase in risk individually perceived from the proposed location of a certain object is lower in the city than in the rural areas, the collective perception of risk in the urban area may be higher. The higher the collective perceived risk, the greater the likelihood of the emergence of an opposition leader.

Early interest in geographical discounting comes from the often-indicted "not in my backyard" (NIMBY) behavior on the part of those who publicly object to the proposed location of a generally undesirable object near them. The condemnation of geographic selfishness is reminiscent of the biblical excoriation of usury. But who would not object to the proposed location of a hazardous waste incinerator near their home? Aren't most people likely to exhibit NIMBY behavior under the right circumstances? Aren't most, if not all, zoning regulations just a formalization of this distancing desire of the local population? If people have sufficient income, they will not live near factories, landfills, sewage treatment

plants, etc. Conversely, commercial and industrial firms will often pay premiums for property near facilities similar to their own rather than locate in a cheaper, perhaps more remote, but allowable location.

The NIMBY response is an expression of territoriality and has been noted since the beginning of the human record. In China in the 6th century BC, the Imperial Palace was situated at the city center, with declining social prestige assigned to those living farther from the palace. Those at the very edge of the city were judged the most uncivilized, the least human, living in the "zone of cultureless savagery." The round city of Mansur, in the 8th century, placed the palace and the mosque at its center and the prison in the outer wall. The Yurok Indians of northern California lived at "the center of the world" with the unknowable land and ocean "beyond the world." In the late Middle Ages, the city was viewed as a sacred place, and the surrounding wilderness was seen as "profane." By the 19th century, the landscape of the yeoman was perched between the "profane" city and the "profane" wilderness. Today, the wilderness is considered a place of innocence and purity, while the city is still profane and the suburb is the hoped-for combination of utility and sacredness.

NIMBY behavior is a natural reflection of people's insistence to be near objects of desire and far from objects of fear. It is no more a dispensable part of human behavior than is eating when hungry or sleeping when tired. It is a behavior very much like the tendency to devalue useful items when that use is delayed.

Evidence from Opinion Surveys

One of the first studies that attempted to measure the discounting of distance was reported by Mitchell and Carson in 1986. They surveyed the degree of acceptance of nuclear and electric power plants, a hazardous waste disposal facility, a large office building, and a factory within various distances from home. The data on power plants was translated into the fraction of the rejecting population (i.e., a measure of the level of concern) and its variation with distance from home (see Fig. 1). About 9% of the population indicated that they did not want any coal plants built anywhere; the comparable figure for nuclear plants was 29%. Of the remaining population, about 60% did not want either type of plant within a mile of their home. By statistically fitting the response data, it can be shown that the rate at which rejection declined with distance was about 4.3% per mile for the coal plant and about 2% per mile for the nuclear plant. The goodness of fit was very high: $r^2 = 0.97$ and 0.98.

These geographic discount rates clearly reflect the declining level of concern as distance from the proposed object of concern increases. They are not the same number, however, and neither would the time discount rates regarding these proposals be the same. For a given distance, the time discount rate would probably reveal a greater level of time discounting of a coal plant compared to a nuclear plant. Individuals with similar incomes do not necessarily express the same level of time discounting about potential financial gain even when they

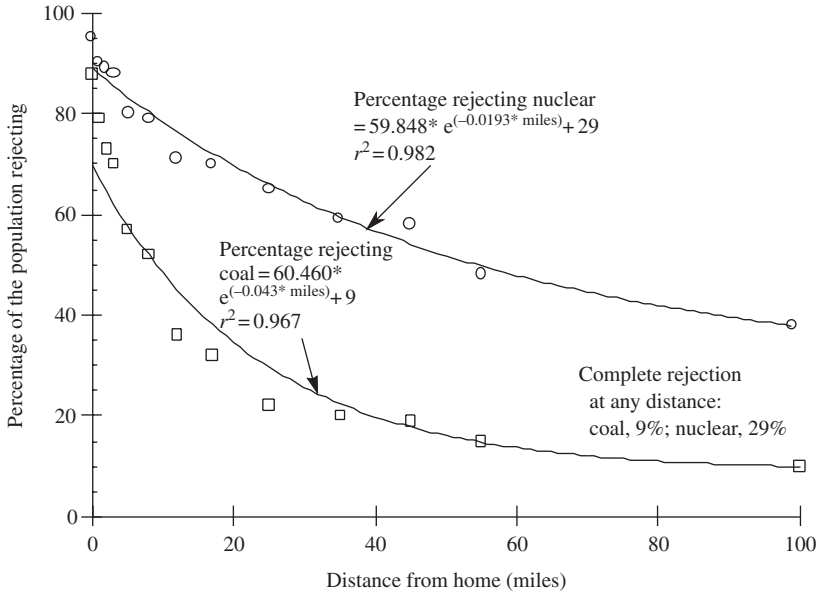

Figure 1 Percentage of the population rejecting a hypothetically proposed electrical generating plant with various distances from home. Data adapted from Mitchell and Carson (1986).

see the same risk of investment. People discount the delay of food consumption much more highly than they do delay in financial return. Therefore, the appearance of two different geographic discount rates regarding different facilities with the same output does not seem unreasonable.

The geographic discount rate has use in economic analysis. For example, the utility of the individual electricity user contains functions of time, price, and distance from the generator. To properly assess the social welfare of electricity, an analyst must therefore include a geographical discounting factor, such that the utility decreases as the distance to the generator decreases.

Mitchell and Carson also found that people discounted distance from a proposed hypothetical hazardous waste plant at about the same rate as they did a nuclear power plant. They geographically discounted a large factory at about the same rate as they did a coal plant. They also discounted a 10-story office building less than any of these facilities. The authors did not elaborate on these sorts of differences, but they did distinguish between the hazardous waste plant and the other facilities, in that the waste plant siters do not have the complete freedom to locate where they wish. Although the authors saw this problem as a lack of property rights, it is possible to view the issue somewhat differently.

Waste facilities are difficult to site for psychological reasons as well: people do not want to be reminded regularly that their consumption activities generate a socially negative signal. They conform to the old maxim "out of sight, out of mind." This is an aspect of what is called sensual discounting: "If I can't see or smell the facility, I tend to sensually discount it." But the change in the rejection rate as distance increases between home and a waste plant, for example, is pure spatial discounting.

The survey data in Fig. 1 are hypothetical. If levels of concern about such facilities after they are installed are measured, a slightly different picture emerges. Those living 1.4 km from a nuclear plant expressed nearly the same level of concern as those living 10 km from the plant. In another study of toxic waste sites, the perceived rather than the actual distance was inversely correlated with level of concern.

People who want to be away from such facilities as power plants can also be seen as expressing territorial behavior, in much the way that it can be imagined some animals do. If such territorial behavior is manifest, it should be found that the value of private property can be influenced by the geographic distance from certain objects, with values rising with increasing proximity to objects of desire (e.g., elementary schools, shopping centers) and falling with increasing proximity to objects of negative concern (e.g., high voltage transmission lines, noisy business districts). In fact, the actual distribution of property value changes may reflect the combination of negative and positive geographic discounting.

Evidence from Real Estate Markets

If people strongly dislike or prefer certain objects located at specific places, then variations in their property values should reflect this dislike or preference. All other real estate variables being unchanged, the property values should increase with distance away from the object of popular scorn, or decrease with distance away from an object of popular desire. Some objects have both positive and negative values to residential property owners. People may like living near a shopping center, for example, but not next to it. Certain attributes of these sorts of objects are positive (e.g., minimal travel time and distance) and some are negative (e.g., noise, nighttime lighting, lack of trees). So, variations in property values should reveal an optimal distance between home and certain objects. Other objects, such as nuclear power plants, seem to have no apparent positive features regarding the nearness to people. In the complex urban environment, it may be the nearest neighbors to generally undesirable objects who are selected for their unique indifference to the object. For example, people who live near busy shopping centers may seldom use their yards or may seldom open their windows, i.e., they may be focused on the interior of their place, disregarding the physical environment outside their home or office. Such people reveal very high geographic discount rates. Thus, people's geographic discount rates, on average, may vary with time (i.e., people may be able to adapt to nearly anything, given enough time).

Furthermore, the complex urban environment could present such an array of positive and negative objects that it could be nearly impossible to sort out the geographical discount rate because of the overlapping effects. Some financial experts believe this problem is best approached by mapping the unexplained residual of the hedonic equation (object price = function of the attributes) and looking for geographic and other patterns. In this way, the explanatory power of the equation can be improved, perhaps reducing the number of variables required in the equation.

Consider the impact of a recently completed shopping center on housing values. The statistical model indicates that there is an apparent negative effect up to about 1500 feet from the shopping center. Beyond that distance, up to about 4000 feet, housing sale prices were higher than historical values. This result indicates that people negatively discount the increased noise of autos and trucks and the nighttime lighting at the shopping center. But people also positively discount the convenience of the shopping center. These effects are difficult to separate in a statistical model, although one might be able to base the negative effects on straight-line distances and the positive effects on street-based distances. These discount effects and their net impact on the property values are illustrated in Figs. 2 and 3.

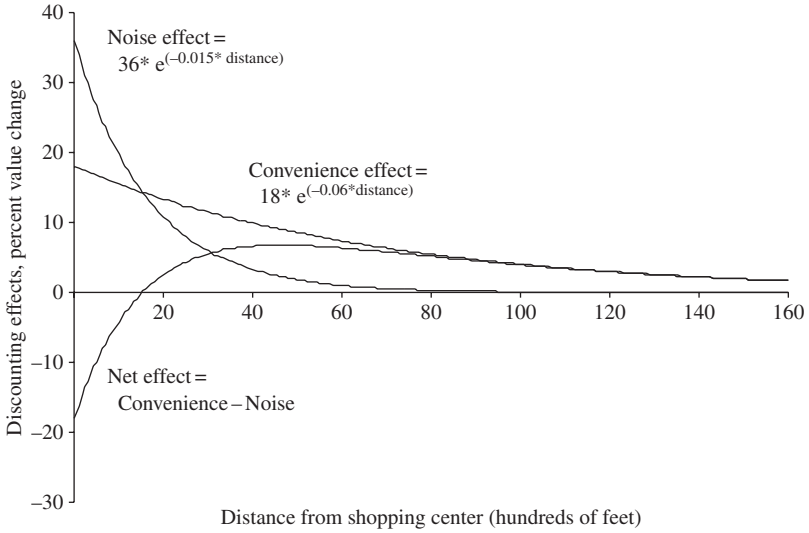

Figure 2 The effects of positive and negative geographical discounting on the real value of housing prices. An approximate fit to the results of Colwell *et al.* (1985).

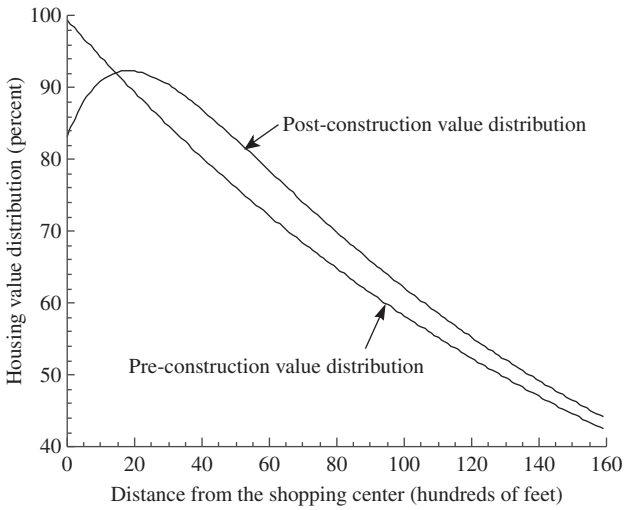

Figure 3 The combined effects of positive and negative geographical discounting on the real value of housing prices, comparing the values before and after the construction of a shopping center. An approximate fit to the results of Colwell *et al.* (1985).

Figure 2 shows a rough estimate of the discounting functions and their net effects on property values for the shopping center issue. Noise is discounted at a rate of 6% per 100 feet and convenience is discounted at a rate of 1.5% per 100 feet, approximately. The array of net value change should be added to the distribution of property values that existed before the shopping center proposal was announced to get an estimate of the percentage change in the post-shopping center property values (see Fig. 3). The agreement with Colwell's results is only approximate, but these graphs are intended to show a possible decomposition into two controlling effects. The curves in both Figs. 2 and 3 show that the neutral distance is about 1500 feet from the shopping center. At this distance, the negative effects of the shopping center on housing valuation are just offset by its positive effects.

In another study, the change in residential property values with distance from the central business district of a community (CBD) is enumerated. Here, the distance effect was $\exp(-0.044 \times \text{distance from the CBD})$, a straightforward exponential decline in value at the rate of 4.4% per mile (lot area and appreciation held constant).

The use of property value variation with distance forms the basis of some novel arguments. If people feel so strongly about nearness to elementary schools that their residential property values rise as one nears the school, then desegregating busing programs may result in an uncompensated property loss.

It is possible to generate a theory for the optimal size of a group's territory with the concept of spatial discounting. Suppose that the target population has no time preference and that the territory is to be established within a circular field of uniform resources, desired by the people in the group. What is the optimal territory size? Let $B(D)$ be the known benefit (e.g., food, shelter, reproductive potential) derived from this territory; D is distance from the center of the circular territory to the edge. The benefit is a known composite measure of food, shelter, or other desired property of the territory. Let $C(D)$ be the known cost of harvesting and defending the territory. Assume that the

distance preference is $e^{-\delta D}$, where δ is the known spatial discount rate. Then the optimality problem becomes:

$$\max \int_0^D [B(D) - C(D)]e^{-\delta D} dD$$

the solution of which will yield the optimum (circular) territory size. $B(D)$ is a monotonically rising function of D, in the same units as $C(D)$, whose derivative is positive but declining with distance. This means simply that the benefit for the animal grows as D increases, but gains in benefit per unit D decrease as D increases. The net gain must be spatially discounted ($e^{-\delta D}$) because the animals act as though they fear their boundaries, an effect not included in the benefit or cost functions. Given B, C, and δ, the optimal territorial size can be found. This procedure is a relatively simple example of the way in which the concept of geographic or spatial discounting might be used. Certainly, if the resource is not uniform and a set of physical barriers block the travel in particular directions, the shape of the potential territory becomes very complex, and the optimal problem would have to be cast in two dimensions and numerically solved.

An Economic Basis for Spatial Discounting

The debates of the early part of the last century on the ethics of time discounting focused on the problem of utility discounting and its moral implications. In particular, they concerned the notion that preferences over time reflect not only individual or collective impatience to consume, but also a judgment about the responsibility that today's decision-makers have for the future consequences of their actions. Positive rates of time preference were taken to imply that members of the current generation choose to bear strictly limited responsibility for any harm they might inflict on future generations. This is certainly a motivation for ethical objections to discounting. By analogy, positive rates of spatial preference, the spatial equivalent of time preference, reflect not only a preference for consumption at home, but also a judgment about the responsibility that local decision-makers have for the distant consequences of their actions. Because positive rates of spatial preference imply a preference for local consumption relative to distant consumption, they indicate that the relative deprivation of distant members of the present generation may be a locally desirable outcome. The reference point for evaluating consumption flows that are separated in space and time is consumption "here and now."

The utility rate of time discount defines the rate at which present consumption is preferred to future consumption. By analogy, the utility spatial discount rate should capture people's preferences for consumption at a given location relative to consumption at some distance from that location. This may refer either to their own consumption or to consumption by other members of the present generation. As is the case for time discounting, positive rates of spatial preference imply an ethical judgment about the responsibility of the decision-maker for the welfare of others. More particularly, positive rates of spatial preference imply that people care more about actions that are close to them than about those that are distant. The picture is obviously complicated by familial, tribal, ethnic, linguistic, or political affiliation (as it is with time discounting). People tend to care more about their kith and kin than about others. They may also be very tightly constrained in their ability to implement the concern they have for the well-being of those outside of their own location. A positive rate of spatial preference implies that consumers place greater weight on home interests than on outside interests. Home in this case may be the household, village, city, region, or nation.

In 2001, Perrings and Hannon gave a detailed technical explanation of the warranted or socially desirable rate of spatial discounting. It is the spatial decay rate of the effects of local actions, and it is also the spatial rate at which consumption recovers from the effects of local actions. They also pointed out that the effects of spatial discounting are not necessarily reflected in local market prices.

A rate of time or spatial preference will be said to be warranted if distant effects discounted at that rate may be fully compensated, i.e., those effects are valued at their marginal social cost. Utility rates of time discount have been argued to be ethically neutral or sustainable only if they do not exceed the net growth rate of the capital. The warranted rate of spatial preference is analogous to that time-based discount rate. Positive utility rates of spatial preference may be said to be ethically neutral only if they do not exceed the rate at which the spatially dispersed effects of local activity decay with distance. In the case of environmental effects, this can be thought of as the rate at which they are diffused or filtered out by the environment.

It is assumed for simplicity in technical analysis that spatial effects decay smoothly, continuously, and monotonically. This is a strong assumption, though no stronger than the analogous assumptions made about time-based rates of growth or regeneration, depreciation, or decay. In reality, many spatial and temporal effects are far from smooth. There are certainly cases where the effects of current activities are not diffused over time or space. Biomagnification, for example, can lead to the concentration of effects at points distant in both time and space. Emissions to rivers can lead to the concentration of pollutants in downstream sinks. Mixing can mean that emissions to air can affect all locations equally. But for

the most part, the adverse effects of local activity tend to be a decreasing function of distance from the source. Environmental effects are transmitted through the flows of mass and energy in biogeochemical cycles. All such flows involve some energy or material cost; that is, they involve losses in transmission. Not all of the SO_2 that is emitted from Ohio, for example, lands in New York and Boston. Some drops out over the Great Lakes. Not all the toxins entering a food chain are consumed by species at the top of the chain; some are transformed and excreted by those at an intermediate point in the chain. There are various determinants of the filtering effect of ecosystems on flows of mass and energy through the system, and not all effects are filtered at the same rate. In reality, the decay of effects is neither smooth and continuous nor monotonic. Nonetheless, it is useful to think in terms of a diffusion rate that is uniform at least within the boundaries of a given ecosystem.

Economists are interested in the warranted spatial rate of discount associated with this form of diffusion. The higher the actual rate of discount, the more the distant costs of local emissions will be ignored. Intuitively, effects that are discounted at the rate at which the pollutant diffuses will be neutral in their effect. Discount rates that exceed the rate of diffusion imply that the distant costs of local emissions will not be fully taken into account.

Summary and Conclusions

Spatial discounting derives from a sense of place. How large that place is and how well it is occupied depends on the relative strength of the individuals involved and the harshness of their environment. Spatial discounting can be seen as a reaction to threats to those in the home place. The manifestation of the discounting process is seen in opinion polls and property value distribution.

There is physical evidence of both positive and negative spatial discounting. The paucity of such data is an indication that the spatial discounting process is still thought of as a character defect rather than a basic attribute of human nature. The rates of discounting are assumed to be constant, and the discounting functions are assumed to be declining exponentials. These assumptions were made to retain simple displays of the idea, but the fit to actual data of such functions is remarkably good. The net effect of the geographical discounting process is the interplay of both negative (e.g., noise) and positive (e.g., convenience) effects.

It should not be surprising that high spatial discount rates have the potential to prejudice the well-being of distant members of the present generation in the same way that high time discount rates prejudice the well-being of members of future generations. Time discount rates above the warranted rate of regeneration/assimilation imply a myopic approach to the management of environmental resources that is potentially dangerous and is certainly inequitable (in intergenerational terms). In the same way, spatial discount rates above the natural rate of diffusion imply a parochial approach to the management of environmental resources that is equally inequitable (in intragenerational terms). Nevertheless, high spatial discount rates may be warranted by high rates of diffusion (or decay) of environmental effects. Where the environmental consequences of emissions are localized and decay quickly, high discount rates may still be ethically neutral in the sense that they appropriately weight the damage to distant members of the present generation resulting from local decisions.

Glossary

generalized moments estimation A method of estimation that determines parameter estimates by matching moments of the observed sample data to the data-generating process.
limited dependent variable models Models involving a dependent variable that takes on discrete values rather than the typical continuous values.
Markov Chain Monte Carlo estimation A method of estimation that samples sequentially from the complete sequence of conditional distributions for all parameters in the model.
maximum likelihood estimation A method for determining parameter estimates that maximize the likelihood of the observed sample data.
non-parametric locally linear models Models that construct estimates of complicated phenomena from a series of many linear models fitted to sub-samples of observations.
spatial dependence When observations collected from points or regions in space at one location are a function of the value of observations from nearby locations.
tobit models Models in which the dependent variable is subject to censoring for values greater than or less than a particular magnitude.

Spatial econometrics provides models for situations in which sample data observations are taken with reference to points or regions on a map. These sample data often exhibit spatial dependence, ruling out use of conventional econometric estimation methods.

Regression Analysis with Spatial Data

Spatial data samples involve observations collected with reference to points or regions in space, for example, a sample of observations based on all counties in a state, or a sample of census tracts in a particular city. Each observation reflects values of the observed variable associated with a particular geographical area such as a country, state, county, or census division. Another example is a sample of sales prices for real estate parcels, where the location (perhaps in the form of map coordinates such as latitude–longitude coordinates) of each parcel is known. Cross-sectional observations collected with reference to spatial locations often exhibit spatial dependence, violating the independence assumption of traditional least-squares regression.

Spatial Dependence

Spatial dependence in a collection of sample data implies that observations at location i depend on other observations at locations $j \neq i$. This can be stated formally as

$$y_i = f(y_j), \quad i = 1, \ldots, n \quad j \neq i. \tag{1}$$

Note that the dependence can be among several observations, as the index i can take on any value from 1 to n.

Spatial dependence can arise from theoretical as well as statistical considerations. From a theoretical viewpoint, for example, maintenance of a neighbor's house may directly impact the value of one's property. Local governments might engage in competition that leads to local uniformity in taxes and services. Pollution can create systematic patterns over space; clusters of consumers who travel to a more distant store to avoid a nearby store located in a high-crime zone would also generate these patterns. In addition, spatial dependence can arise from unobservable latent variables that are spatially correlated. Consumer expenditures collected at spatial locations such as census tracts exhibit spatial dependence, as do other variables such as housing prices. It seems plausible that difficult-to-quantify or unobservable characteristics

such as the quality of life may also exhibit spatial dependence.

Estimation Consequences of Spatial Dependence

In some applications, the spatial structure of the dependence may be a subject of interest or provide a key insight. In other cases, it may be a nuisance similar to serial correlation in time-series regression. In either case, inappropriate treatment of sample data with spatial dependence can lead to inefficient and/or biased and inconsistent estimates.

For models of the type $y_i = f(y_j) + X_i\beta + \varepsilon_i$, least-squares estimates for β are biased and inconsistent, similar to the simultaneity problem in econometrics. The right-hand-side function of variables y_j (where j indexes spatially dependent observations) cannot be treated as fixed in repeated sampling. This leads to a situation similar to that encountered with relationships involving simultaneously determined variables.

For a model of the type $y_i = X_i\beta + u_i$, $u_i = f(u_j) + \varepsilon_i$, least-squares estimates for β are inefficient but consistent, similar to the serial correlation problem. As in serial correlation, variance-covariance estimates for the vector of parameter β constructed using least-squares formulas are biased.

A Family of Spatial Econometric Models

A family of regression-based models that incorporate spatial dependence was introduced by Ord in 1975 and popularized by Anselin in 1988. Two members of this model family are most frequently employed in applied practice, the spatial autoregressive model (SAR) shown in Eq. (2) and the spatial error model (SEM) in Eq. (3). The model in Eq. (2) is sometimes referred to as a "mixed regressive spatial autoregressive model" to distinguish it from the model $y = \rho Wy + \varepsilon$, which is labeled a spatial autoregressive model. This simpler model is referred to as a first-order spatial autoregressive (FAR) model in this article, so the less awkward acronym SAR can be used for the model in Eq. (2).

$$y = \rho Wy + X\beta + \varepsilon \tag{2}$$

$$y = X\beta + u, \quad u = \lambda W + \varepsilon. \tag{3}$$

In Eqs. (2) and (3), y represents an $n \times 1$ vector of cross-sectional observations associated with points in space, X represents an $n \times k$ matrix of explanatory variables, ε is an $n \times 1$ vector of normally distributed disturbances, u is a vector of disturbances that follows a spatial autoregressive process, and W denotes an $n \times n$ spatial weight matrix, which is discussed later. The parameters to be estimated in the SAR and SEM models are the usual vector β and noise variance σ_ε^2, along with the scalar parameters ρ in the case of the SAR model and λ in the SEM model. The SAR and SEM models subsume least-squares as a special case that arises when $\rho = 0$ in the SAR model and $\lambda = 0$ in the SEM model.

The spatial weight matrix defines the connectivity structure between spatial observations, and various approaches to specifying W have appeared in the literature. Most specifications set $w_{ij} > 0$ for observations $j = 1, \ldots, n$ sufficiently close (as measured by some metric) to observation i, where w_{ij} denotes the (i, j)th element of the matrix W. Two of the more popular definitions used to construct W are first-order contiguity relationships and nearest neighbors. A matrix W based on first-order contiguity relationships would set $w_{ij} = 1$ for observations j that have borders touching region i, and $w_{ij} = 0$ for observations j that do not border on i. The nearest neighbors approach to specifying W would involve finding the m nearest neighbors to each observation i and using these to set $w_{ij} = 1, j = 1, \ldots, m$.

Two other points concerning the matrix W are that diagonal elements $w_{ij} = 0$, $i = j$, and the matrix W is usually row-standardized to have row-sums of unity. This is motivated by the use of the matrix W in the SAR and SEM models to create $n \times 1$ variable vectors called "spatial lags" formed by the products W_y and W_u. Given row-standardization of W, these vectors represent an average of spatially neighboring values. For example, if observations 1 and 3 represent the only regions with borders touching region 2, the second row of the SAR model will take the form

$$y_2 = \rho(0.5y_1 + 0.5y_3) + \sum_{j=1}^{k} x_{2j}\beta_j + \varepsilon_2 \tag{4}$$

This should make it clear why $w_{ii} = 0$, as this precludes an observation y_i from directly predicting itself. It also motivates row-standardization of W, which makes each observation y_i a function of the spatial lag Wy, an explanatory variable representing an average of spatially neighboring values to each observation i. Similarly, the spatial autoregressive disturbance process in the SEM model allows dependence between the disturbance from observation i and an average of disturbances from nearby observations specified by the spatial lag Wu.

A relatively simple extension of the SAR model called the spatial Durbin model (SDM) adds spatial lags of the explanatory variables in the matrix X, created by WX^* as

shown in Eq. (5), where the matrix X^* equals X with the constant term excluded.

$$y = \rho Wy + X\beta + WX*\gamma + \varepsilon. \quad (5)$$

The $(k-1)x_1$ parameter vector γ measures the marginal impact of the explanatory variables from neighboring observations on the dependent variable y.

Maximum Likelihood Estimation

Maximum likelihood estimation of the SAR, SDM, and SEM models involves maximizing a concentrated log likelihood function with respect to the parameter ρ or λ.

For the case of the SAR model

$$\begin{aligned} \ln L &= C + \ln |I_n - \rho W| - (n/2)\ln(e'e) \\ e &= e_o - \rho e_d \\ e_o &= y - X\beta_o \\ e_d &= W_y - X\beta_d \\ \beta_o &= (X'X)^{-1}X'y \\ \beta_d &= (X'X)^{-1}X'Wy, \end{aligned} \quad (6)$$

where C represents a constant not involving the parameters. The computationally troublesome aspect of this is the need to compute the log-determinant of the $n \times n$ matrix $(I_n - \rho W)$. The operation counts for computing this determinant grow with the cube of n for dense matrices. This same approach can be applied to the SDM model by simply defining $X = [X\ WX^*]$ in Eq. (6). A concentrated log-likelihood can also be devised for the SEM model.

Computational Issues

One of the earlier computationally efficient approaches to solving for estimates in a model involving a sample of 3107 observations was proposed by Pace and Barry. They suggested using direct sparse matrix algorithms such as the Cholesky or LU decompositions to compute the log-determinant. A sparse matrix is one that contains a large proportion of zeros. As a concrete example, consider the spatial weight matrix for the sample of 3107 U.S. counties used by Pace and Barry. This matrix is sparse because the largest number of neighbors to any county is 8 and the average number of neighbors is 4. To understand how sparse matrix algorithms conserve on storage space and computer memory, consider that only the non-zero elements need be recorded along with an indication of their row and column position. This requires a 1×3 vector for each non-zero element consisting of a row index, a column index, and the element value. Because non-zero elements represent a small fraction of the total $3107 \times 3107 = 9{,}653{,}449$ elements in the weight matrix, computer memory is saved. For the example of the 3107 U.S. counties, only 12,429 non-zero elements were found in the weight matrix, representing a very small amount (about 0.4%) of the total elements. Storing the matrix in sparse form requires only $3 \times 12{,}429$ elements, or more that 250 times less computer memory than would be needed to store 9,653,449 elements.

In addition to storage savings, sparse matrices result in lower operation counts, which speeds computations. In the case of non-sparse (dense) matrices, matrix multiplication and common matrix decompositions such as the Cholesky require $O(n^3)$ operations, whereas for sparse W these operation counts can fall as low as $O(n_{\neq 0})$, where $n_{\neq 0}$ denotes the number of non-zero elements.

In addition to proposing the use of sparse matrix algorithms, Pace and Barry proposed a vector evaluation of the SAR or SDM log-likelihood functions over a grid of q values of ρ to find maximum likelihood estimates. It is well known that for row-stochastic W, $\lambda_{\min} < 0$, $\lambda_{\max} > 0$, where $\lambda_{\min}$, $\lambda_{\max}$ represent the minimum and maximum eigenvalues of the spatial weight matrix. In this case, ρ must lie in the interval $[\lambda_{\min}^{-1}, \lambda_{\max}^{-1}]$, but typical applied work simply relies on a restriction of ρ to the $(-1, 1)$ or $[0, 1)$ interval to avoid the need to compute eigenvalues. The computationally intense part of this approach still is calculating the log-determinant, which takes approximately 201 s for a sample of 57,647 U.S. census tracts. This is based on a grid of 100 values from $\rho = 0$ to 1 using sparse matrix algorithms in MATLAB Version 6.0 on a 600 Mhz Pentium III computer. The SEM model log-likelihood is not as amenable to the vectorized form, but can be solved using more conventional optimization, such as a simplex algorithm. Nonetheless, a grid of values for the log-determinant over the feasible range for λ can be used to speed evaluation of the log-likelihood function during optimization with respect to λ.

Recent Advances in Computation

An improvement based on a Monte Carlo estimator for the log determinant suggested by Barry and Pace allows larger problems to be tackled without the memory requirements or sensitivity to orderings associated with the direct sparse matrix approach. Their method not only provides an approximation to the log-determinant term but also produces an asymptotic confidence interval around the approximation. As an illustration of these computational advantages, the time required to compute a grid of log-determinant values for $\rho = 0, \ldots, 1$, based on 0.001 increments for the sample of 57,647 census tracts, was 3.6 s, which compares quite favorably to 201 s for the direct sparse matrix computations cited earlier. LeSage and Pace reported experimental results indicating that the Monte Carlo log-determinant estimator produces nearly the same estimates as the direct method.

Estimates of Dispersion

An implementation issue is constructing estimates of dispersion for the maximum likelihood parameter estimates for the purpose of inference. In problems involving a small number of observations, an asymptotic variance matrix based on the Fisher information matrix shown below for the parameters $\theta = (\rho, \beta, \sigma^2)$ can be used to provide measures of dispersion for the estimates of ρ, β, and σ^2. Anselin provided the analytical expressions needed to construct this information matrix.

$$[I(\theta)]^{-1} = -E\left[\frac{\partial^2 L}{\partial\theta\partial\theta'}\right]^{-1} \tag{7}$$

This approach is computationally impossible when dealing with large scale problems involving thousands of observations. The expressions used to calculate terms in the information matrix involve operations on very large matrices that would take a great deal of computer memory and computing time. In these cases, the numerical Hessian matrix can be evaluated using the maximum likelihood estimates of ρ, β, and σ^2 and the sparse matrix representation of the likelihood. Given the ability to evaluate the likelihood function rapidly, numerical methods can be used to compute approximations to the gradients shown in Eq. (7).

Alternatives to Maximum Likelihood Estimation

A number of alternative approaches to dealing with spatial samples that exhibit spatial dependence have been proposed in the literature.

Generalized Moments Estimation

Kelejian and Prucha suggested a generalized moments estimation approach for the family of spatial models that they labeled generalized two-stage least squares (G2SLS). This is purported to be computationally simpler than maximum likelihood estimation but is unlikely to be efficient relative to maximum likelihood. Note that the asymptotic distribution of the G2SLS estimator is not established, but Bell and Bockstael provided Monte Carlo evidence that these estimates are only slightly inefficient relative to maximum likelihood estimates. The G2SLS procedure involves three steps. The first step generates residuals using 2SLS with an $n \times m$ instrumental variables (IV) matrix $Q = (X, WX, W^2X, \ldots)$ formed using functions of X and W. Residuals based on these estimates are used to construct a consistent generalized moments estimate of ρ or λ in the second step. The third step involves generalized 2SLS estimation on a set of quasi-differenced variables constructed using the consistent estimates of ρ or λ, from step two. It should be noted that the Kelejian-Prucha GMM approach does not impose a restriction on the parameter ρ or λ, so that estimates having values greater than unity may arise in practice.

Bayesian Methods

LeSage proposed the use of Bayesian estimation methods for the SAR, SDM, and SEM models based on Markov Chain Monte Carlo (MCMC) estimation methods described in Gelfand and Smith. This approach allows an extended version of the SAR, SDM, and SEM models that introduces nonconstant variance scalars as parameters to accommodate spatial heterogeneity and outliers that often arise in applied practice. Maximum likelihood estimation methods rely on the assumption $\varepsilon \sim N(0, \sigma^2)$, where the noise variance is assumed constant over space. The Bayesian method introduces a set of variance scalars $(v_1, v_2, \ldots, v_n)$, as unknown parameters that need to be estimated. This allows the constant variance assumption to be replaced with $\varepsilon \sim N(0, \sigma^2 V)$, where $V = \text{diag}(v_1, v_2, \ldots, v_n)$.

Application of Bayesian estimation methods to SAR, SDM, and SEM spatial regression models should result in estimates nearly identical to those from maximum likelihood methods when the number of observations is large. This is a typical result when prior information is dominated by a large amount of sample information. However, the heteroscedastic Bayesian variants of the SAR and SDM models represent a situation in which prior information regarding the variance scalars exerts an impact even in very large samples. The sparse matrix approaches to computing the log-determinant term discussed in the context of maximum likelihood estimation can be applied to MCMC estimation of the Bayesian variant of these models, making them relatively fast.

Nonparametric Locally Linear Models

One branch of spatial econometrics uses distance-weighted subsamples of the data in conjunction with ordinary least-squares to produce parameter estimates at various points in space. McMillen introduced this form of nonparametric locally linear weighted regression (LWR), which Brunsdon, Fotheringham, and Charlton termed geographically weighted regressions (GWR). By estimating separate models using data near each observation, these intuitively appealing methods attempt to overcome the problem of spatial heterogeneity. If spatial dependence arises due to inadequately modeled spatial heterogeneity, LWR can potentially eliminate this problem. These models often rely on the estimated parameters to detect systematic patterns over space.

Using the previously introduced notation and letting $W(i)$ represent an $n \times n$ diagonal matrix containing distance-based weights for observation i that reflect the distance between observation i and all other observations, the LWR model can be written as

$$W(i)^{1/2}y = W(i)^{1/2}X\beta_i + W(i)^{1/2}\varepsilon_i. \tag{8}$$

The subscript i on β_i indicates that this $k \times 1$ parameter vector is associated with observation i. The LWR model produces n such vectors of parameter estimates, one for each observation. These estimates are calculated using

$$\hat{\beta}_i = [X'W(i)X]^{-1}[X'W(i)y]. \tag{9}$$

A number of alternative approaches have been proposed for constructing the distance-based weights for each observation i contained in the vector on the diagonal of $W(i)$. As an example, McMillen suggested a tri-cube weighting function,

$$\text{diag}[W(i)] = \left[1 - \left(\frac{d_i^j}{d_i^m}\right)^3\right]^3 \quad \text{I}\left(d_i^j < d_i^m\right), \tag{10}$$

where d_i^j represents the distance between observation j and observation i, d_i^m represents the distance between the mth nearest neighbor and observation i, and I( ) is an indicator function that equals one when the condition is true, and zero otherwise. In practice, the number of nearest neighbors used (often referred to as the bandwidth) is determined with a cross-validation procedure, typically a prediction criterion based on excluding a single observation for each i.

LeSage pointed out that aberrant observations or outliers arising from spatial enclave effects or shifts in regime can exert a large impact on the locally linear estimates. Because LWR estimates are based on a small number of observations, and the sample data observations are re-used when estimates are produced for each point in space, a single outlier can contaminate estimates covering large regions of the spatial sample. LeSage proposed a Bayesian variant of the locally linear models that overcomes sensitivity to outliers by introducing explicit stochastic spatial parameter transition relationships as prior information in the model. Because prior uncertainty regarding parameter variability is under the control of the user, a continuum of estimates ranging from highly volatile to relatively constant over space can be produced.

Pace and LeSage argued that traditional LWR methods exhibit a trade-off: increasing the sample size produces less volatile estimates that contain increasing spatial dependence. Selecting a smaller sample size reduces the spatial dependence, but at the cost of increased parameter variability that impedes detection of systematic patterns of parameter variation over space. They introduced a spatial autoregressive locally linear estimation method that extends the LWR approach to include a spatial lag of the dependent variable, which they labeled spatial autoregressive local estimation (SALE). They accomplished this using a recursive approach for maximum likelihood estimation of spatial autoregressive models. This allows consideration of a series of estimates based on sub-samples of varying size in the spirit of the LWR methods. They argued that inclusion of the spatial autoregressive term in the model results in improves prediction and stability of the parameter estimates, decreasing the sensitivity of performance to the bandwidth that is typically observed.

Matrix Exponential Spatial Models

Pace and LeSage introduced a spatial model specification based on the matrix exponential. Use of the matrix exponential spatial specification (MESS) eliminates the log-determinant term from the log-likelihood function, and a closed-form solution exists for this model. The MESS is shown in Eq. (11), where W represents a spatial weight matrix, and the scalar parameter α plays the role of the spatial dependence parameter ρ in the SAR model.

$$\begin{aligned} Sy &= X\beta + \varepsilon \\ S &= e^{\alpha W} = \sum_{i=0}^{\infty} \frac{\alpha^i W^i}{i!}. \end{aligned} \tag{11}$$

If $W_{ij} > 0$ for the nearest neighbors of observation i, $W_{ij}^2 > 0$ contains neighbors to these nearest neighbors for observation i. Similar relations hold for higher powers of W, which identify higher order neighbors. Thus, the matrix exponential S, associated with matrix W, can be interpreted as assigning rapidly declining weights for observations involving higher order neighboring relationships. That is, observations reflecting higher order neighbors (neighbors of neighbors) receive less weight than lower order neighbors.

Maximizing the log-likelihood is equivalent to minimizing $y'S'MSy$ with respect to S, where $M = I - H$ and $H = X(X'X)^{-1}X'$ are idempotent matrices. This is essentially a closed-form problem in that it involves solving a constrained non-linear (polynomial) least-squares problem.

LeSage and Pace provided a Bayesian variant of this approach, estimated using MCMC methods. This approach involves a more flexible spatial weight matrix specification that allows posterior inferences regarding the magnitude and extent of spatial influence. In an economic context, where the spatial structure can arise from externalities or spillovers, the magnitude and extent of influence from one observation or spatial location on other observations at nearby locations may be a subject of interest.

The flexible specification for the spatial weights that allows hyperparameters to control the number of

neighboring entities as well as decay of influence over space is shown in Eq. (12), where m denotes the maximum number of neighbors considered.

$$W = \sum_{i=1}^{m} \left(\frac{\gamma^i N_i}{\sum_{i=1}^{m} \gamma^i} \right) \tag{12}$$

In Eq. (12), γ^i weights the relative effect of the ith individual neighbor matrix N_i, so that S depends on the parameters γ as well as m in both its construction and the metric used. By construction, each row in N sums to 1 and has zeros on the diagonal. To see the role of the spatial decay hyperparameter γ, consider that a value of $\gamma = 0.87$ implies a decay profile where the 6th nearest neighbor exerts less than half the influence of the nearest neighbor. This value of γ can be thought of as having a "half-life" of six neighbors. On the other hand, a value of $\gamma = 0.95$ implies a half-life between 14 and 15 neighbors.

Censored and Limited Dependent Variables

As in the case of non-spatial data samples, spatial data often involve binary or censored dependent variables. Binary data might arise when the sample indicates the presence or absence of some phenomena at various points in space. Censored samples often arise from census reporting methods. As in the case of continuous dependent variables, the presence of spatial dependence requires special estimation approaches for modelling these problems.

Autologistic Model

Besag introduced the autologistic estimator for binary dependent variable data problems exhibiting spatial dependence. In this case, the log-likelihood no longer has a closed form solution, but Besag proposed an approximate or pseudo-likelihood technique. He showed that one can use the typical logistic regression estimation algorithms with an additional explanatory variable constructed from the spatial average of the binary dependent variable, i.e., W_y. The pseudo-likelihood estimates that arise from proceeding in this fashion are consistent and asymptotically normal.

Spatial Tobit Models

These models accommodate situations in which the dependent variable y can be partitioned into one group of observations that are censored and a second set of observations that are continuous. This situation might arise because government agencies suppress information for confidentiality reasons. For example, the census might report housing values greater than a particular level, say C dollars using the value C. These observations are said to be censored. A partitioning of the data can be used, where y_u stands for the uncensored, or continuous, sample data and y_c, denotes observations that are subject to censoring.

For the case of independent data as in ordinary tobit regression, Chib introduced a latent variable z for the censored observations. He showed that the conditional distribution of z simplifies into a product of independent distributions, taking the form of a truncated univariate normal distribution. For the case of spatial dependence in y, a sequence of univariate conditional distributions is arrived at that embody the multivariate spatial dependence between observations. The censored observations can be sampled using a sequence of univariate conditional truncated normals arising from the multivariate normal distribution, taking the form

$$p(z_i \mid i \in y_c, \beta, \sigma^2, \rho) \sim TN_{(-\infty, C]}\{E(y_i \mid y_j, \forall i \neq j), \mathrm{var}(y_i \mid y_j)\}. \tag{13}$$

Spatial Probit Models

The difference between the expression for the likelihood function of the SAR or SEM model involving a continuous dependent variable and the likelihood for a binary probit model in the presence of a spatial dependence covariance structure is tremendous. McMillen noted that for the family of spatial models, the likelihood involves an n-dimensional integral, where n is the number of observations.

In contrast, for the Bayesian SAR/SEM models, a vector z of latent continuous dependent variables can be introduced, as in the case of the tobit model from the previous section. With binary dependent variables, the latent vector can be interpreted formally as utility differences associated with individuals making decisions at various points in space, or more generally as the expected value of the explanatory variables in a standard linear model. In either case, this continuous vector becomes part of an MCMC sampling scheme, so that depending on these continuous values, all remaining parameters of the model can be sampled, as in the case of a continuous dependent variable model. In the case of a spatially dependent covariance structure, this approach requires modification similar to that described for the case of spatial tobit models in the previous section.

McMillen made the point that heteroskedasticity in spatial probit models will lead to inconsistent estimates if ignored during estimation. This makes the Bayesian heteroskedastic variant of the SAR and SEM models quite useful here. The use of the variance scalars (v_1, $v_2, \ldots, v_n$) with the sequence of independent, identically distributed $\chi^2(r)$ priors produces a model that

is equivalent to one based on an assumed student t-distribution for the disturbances of the model. Albert and Chib pointed out that in the case of the probit regression model, use of these variance scalars can be viewed as a probability rule based on a family of t-distributions that represent a mixture of the underlying normal distribution used in the probit regression, since the normal distribution can be modeled as a mixture of t-distributions.

The most popular choice of probability rule to relate fitted probabilities with binary data is the logit function corresponding to a logistic distribution for the cumulative density function. The quantiles of the logistic distribution correspond to a t-distribution with 7 or 8 degrees of freedom, and the normal probability density is similar to a t-distribution when the degrees of freedom are large. Setting the prior hyperparameter for the $\chi^2(r)$ prior to a value of $r=7$ or $r=8$ will approximate a spatial logit model, whereas setting this parameter to a large value such as $r=50$ approximates a probit model.

An alternative approach to spatial probit was set forth by Beron and Vijverberg, who used maximum likelihood methods to estimate a spatial probit model. As already noted, maximum likelihood requires evaluating an n-dimensional normal probability integral, similar to the case that arises in non-spatial multinomial probit (MNP). The n-dimensional normal probability integration is implemented using a method known as GHK simulation.

Summary

Econometric methods exist for regression modeling of spatial data samples that exhibit spatial dependence. These estimation methods model spatial dependence using spatial weight matrices to construct spatial lags of the dependent variable or the disturbances. Methods have been devised for continuous and dichotomous as well as censored dependent variables. Maximum likelihood, Bayesian, and method of moments estimators are available, as well as nonparametric locally linear approaches.

Areas for future work are simultaneous equation systems and the case of multinomial probit estimation for relationships involving spatial dependence. Also, estimation methods that could be applied to space-time data samples would be of use.

Spatial Externalities

Dean M. Hanink
University of Connecticut, Storrs, Connecticut, USA

Glossary

distancing The imposition of a negative externality at some distance from the source of its generating action.
externality The difference between the marginal social cost of an action and its marginal private cost.
geographical externality An externality that exists without variation across an entire geographical unit, such as a country or metropolitan area.
increasing returns A rate of increase in output that exceeds the rate of increase in tangible inputs.
net externality The difference between the negative and positive externalities imposed by a single source.
Pigouvian tax A tax that exacts the cost of a negative externality from its source agency.
spatial externality An externality that varies continuously with distance from its source.

Externalities exist when the marginal social cost of an action is different than its marginal private cost. Spatial externalities are differences in marginal private costs and marginal social costs that co-vary with distance from the place where the action occurs. A negative externality, or marginal social cost, occurs when marginal total cost is greater than marginal private cost. The externality is that part of an action's total marginal cost that is imposed on society. Negative spatial externalities exist when the difference between a higher marginal total cost and a lower marginal private cost changes with distance from the source of the action. A positive externality exists when social costs are negative, meaning that a social benefit is provided completely at private cost. Positive spatial externalities exist when the difference between lower marginal total cost and higher marginal private cost changes with distance from the source of the action.

Externality Effects

Externalities can be positive or negative, and they can result from production or consumption. Negative production externalities include, for example, costs of pollution abatement that are borne by the public at large rather than individual producers. Positive production externalities may result from an individual company's labor training that spills over to an industry at large. Roadside littering is an example of a negative consumption externality, while becoming educated (consuming education) often yields positive externalities in the broadest social sense. In their effects, externalities can often be compared to subsidies when they are positive—they increase consumption and production beyond expected levels. Negative externalities, on the other hand, can be treated like taxes or transaction costs that can decrease consumption and production below otherwise expected levels.

Externalities cause changes in behavior because they either reduce the cost of an action (positive externalities) or increase it (negative externalities). Such a change in behavior is illustrated in Fig. 1, which illustrates an externality's impact on consumption of a hypothetical product from the supply side. In that figure, S represents the typical upward sloping supply function of conventional economic analysis. Assuming a competitive market, S represents price of output as well. The line D represents the typical downward sloping demand function. In a typical example of this sort, S should represent marginal production costs in full, but that is not the case in Fig. 1. In this case, E represents production costs that are externalized by producers, which for purposes of illustration are indicated as marginally increasing with levels of production. If the external costs were internalized by producers, then the relevant supply function would be traced by S'—the total of S and E. The effect of externalized cost on consumption is readily apparent. When S traces costs, then

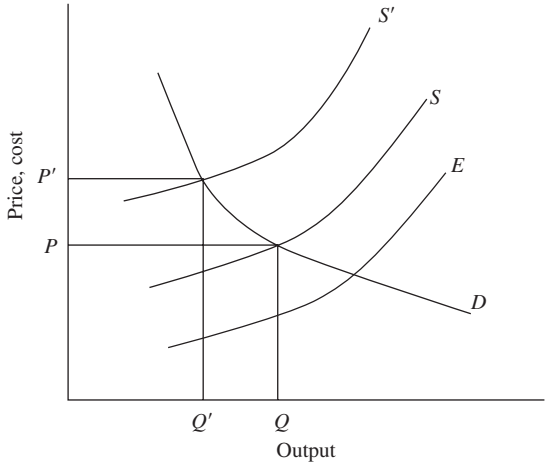

Figure 1 Externalities in production.

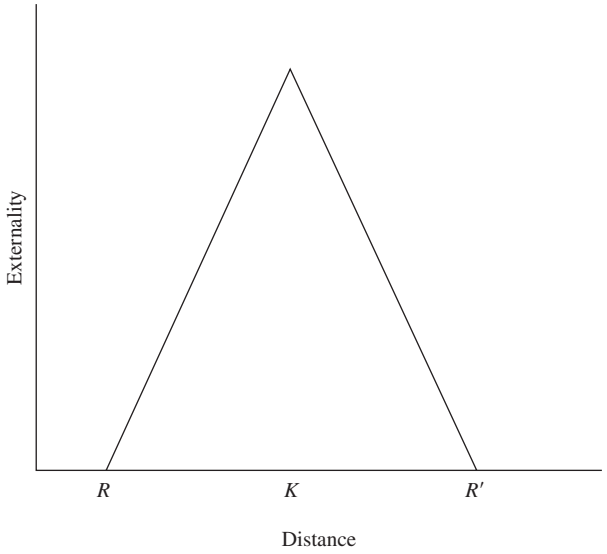

Figure 2 Spatial externality.

the equilibrium price is P with supply and demand at Q. If, however, external costs are internalized, there is a supply shift to the left (S'), and the equilibrium price rises to P' and supply and demand equilibrium shrinks to Q'.

Is the externality described in Fig. 1 positive or negative? In this case, the quality of the externality is relative. From the viewpoint of the producers, the external cost (E) is positive, because their internal marginal cost of production is lower than the full marginal cost of production. The externality is also indirectly positive to consumers, who are able to consume more of the product. On the other hand, E is negative from a social perspective because it represents costs that must be paid by parties beyond the set of producers and consumers represented in the stylized example. Again using Fig. 1, say that the externality arises due to consumption rather than as part of the production process. That makes the externality directly beneficial to consumers because they can consume without paying the full cost themselves, and indirectly beneficial to producers, who are able to sell more output. If the externality is internalized to consumers, it is effectively added to the cost of the product, and again there is a shift from S to S', a price increase from P to P', and a decrease in consumption from Q to Q'.

Spatial and Geographical Externalities

Externalities can have a temporal characteristic. For example, the motive for conservation of natural resources is often the reduction of externalities of current consumption being imposed on future generations. Such externalities could take the form of species extinction or exhaustion of a particular natural resource. Externalities also often have areal extents, meaning their incidence can be mapped. Typically, externalities that are mappable are broadly described as "spatial," but it is worthwhile to classify mappable externalities into two groups: spatial externalities *per se* and geographical externalities.

Spatial externalities often vary continuously with distance and/or direction from their sources. That means that a spatial externality effect often can be modeled as a diffusion process or as an autocorrelation function, either of which typically incorporates distance (d) decay (for example, d^{-k} or $\exp^{-d}$) as a characteristic. A simple spatial externality is graphed in Fig. 2. Its source is at K, and it decreases with distance until it vanishes at R and R'; the externality's spatial extent, or range, is defined as KR. Extended to a plane, KR would be the radius of a circle that defines the externality's field.

The illustration in Fig. 2 represents only a simple case. It does not indicate any directional bias to the externality field. Such a directional bias would lead to a non-circular externality field, for example, in the case of pollution that is carried by either prevailing water or air currents. Further, the continuity of externality fields may be broken or diverted in direction by barriers.

Spatial externalities are fairly common. Almost any point-sourced pollution provides an example. Water effluents, air effluents, and noise usually dissipate along with their externality effects as distance from their origin increases. Alternatively, the positive externality of convenience associated with public transport stations decreases with their distance from residences.

Geographical externalities have effects that are spatially trivial in that they do not vary across an entire geographical unit such as a country or metropolitan area. Such an externality is illustrated in Fig. 3. While the

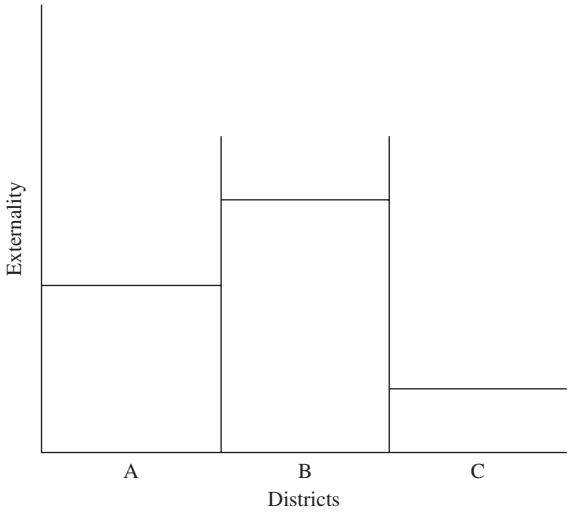

Figure 3 Geographical externality.

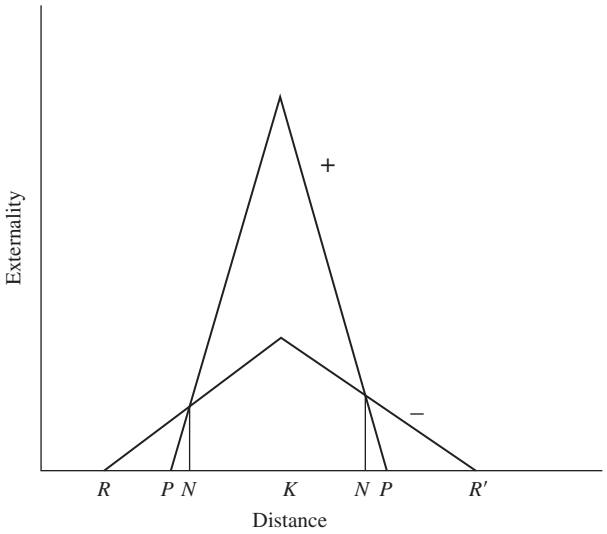

Figure 4 Net spatial externalities.

externality effect does vary in that figure from district to district, it is uniform within districts and does not vary with distance or direction from a particular source. Figure 3 could be describing the externality effects of variations in the quality of public education across school districts, for example, or different minimum regulation standards for water quality. Such geographical externalities may also have spatial properties. For example, the positive externality associated with higher air quality standards in one government jurisdiction can spill over into neighboring jurisdictions, with neighboring ones gaining more benefit than more distant ones.

A single place can be the origin of both negative and positive externalities. On a temporal basis, for example, a public park can provide positive externalities associated with recreation during the day but impose negative ones associated with criminal activity at night. On a spatial basis, airports may provide positive externalities associated with improved accessibility over an entire region but may considerably increase local costs associated with congestion and noise pollution.

Athletic stadiums are frequent sources of spatial externalities, which can be both positive and negative. For example, people who live near major college or professional football stadiums in the United States are affected periodically by the negative externalities of congestion before and after games. At the same time, some of those residents may be able to earn income from renting parking places on their own driveways and in their yards. Such income is a positive externality because it is obtained due to the action of the game. On days when games are not played, the parking places are worthless. Some local businesses may lose income on game days because regular customers may not want to incur traffic congestion costs, while other local businesses may experience a surge in income associated with the crowds attracted by the game.

Such a net spatial externality effect can be illustrated as in Fig. 4. An activity at *K* generates both positive and negative externalities. The positive externality field has range *KP*, while the negative externality field has range *KR*. Given that the maximum positive externality is greater in effect than the negative externality, but that the positive externality is subject to much greater distance decay than the negative externality, regions of net positive and net negative externality are defined by *KN* and *NR*, respectively.

Positive Externalities and Increasing Returns

Economies of scale are a decrease in the average cost of production with an increase in output. That is, increasing size leads to increasing efficiency, at least to a point. At an extreme, if economies of scale did not exist, then everyone would produce everything for her- or himself. Without economies of scale, there would be no need for firms. In a spatial sense, without externalities, there would be no need for cities; the landscape could consist of uniformly distributed households instead of the various levels of concentrated settlements that actually occur.

Economies of scale are often called increasing returns. Conventional economic analysis often characterizes production in a constant returns model that indicates that there are no economies of scale (and in relation, perfect competition). The Cobb-Douglas production function is a constant returns model that takes the following form:

$$Q = (K^{\beta}, L^{\alpha}), \qquad \alpha + \beta = 1, \tag{1}$$

where Q is output and K and L are capital and labor inputs, respectively. Increasing returns can be similarly modeled:

$$Q = (K^{\beta}, L^{\alpha}), \quad \alpha + \beta > 1, \tag{2}$$

so that output increases in observed, internal factors of production.

Externalities that contribute to output are often associated with concentrations of people and producers. For analytical purposes, whether the externalities are spatial or geographical is largely a matter of scale of interest (although that is not the case with respect to policy). Given that externality effects seem to vary with concentration, however, most of them that arise without policy inducement can be considered spatial in the sense that they will spill over from place of origin to neighboring places.

Concentrations of producers may generate so-called localization externalities that result, for example, from the ability to share a trained labor force. Costs of training are externalized, either to competitors or perhaps to public educational institutions. Other externality benefits arise from the availability of specialized suppliers (input–output relationships) that develop in industrial concentrations. Adam Smith noted that the division of labor "is limited by the extent of the market." The division of labor is efficiency-inducing specialization, which increases with the size of the localized market.

Other positive localization externalities arise from formal and informal producer networks. Formal networks with political goals are often strengthened when they represent geographical concentrations rather than dispersed ones, especially when it comes to guiding the development and implementation of local industrial regulations and policies. Other local networks facilitate knowledge spillovers so that production technology and managerial expertise are effectively reduced in cost for producers found within concentrations.

Agglomeration externalities are associated simply with concentrations of people as opposed to a specific set of producers. High levels of market potential, concentrations of general infrastructure, and a dynamic, knowledge-generating milieu have all been cited as sources of agglomeration-based efficiencies.

Linear regression analysis is often used to detect the externality effects in concentrations or agglomerations. For example, a cross-sectional production function could be estimated that takes the general operational form

$$\ln(Q_j) = \alpha + \beta \ln(K_j) + \gamma \ln(L_j) + \delta \ln(E_j) + \varepsilon, \tag{3}$$

where Q is output at the jth place, K and L are capital and labor quantities, and E is a measure of externality-inducing characteristics.

Negative Environmental Externalities

There are both positive and negative environmental externalities, but more attention has been given to the latter. Ironically, the concentrations of people or industries that yield positive externalities with respect to output may also yield negative externalities, such as those associated with traffic congestion. In fact, important negative environmental externalities often result from such concentrations. Air and water pollution, and the negative externalities they entail, can certainly arise from single sources, but certainly both are exacerbated by density of producers. Such negative externality effects of increased density or congestion are illustrated in the "tragedy of the commons." In that story, a village common sustainably supports pastoralists without constraint until a critical population is reached. Once that population is reached, however, each pastoralist's consumption of the common resource limits its supply for the others, and self-interest works against any individual effort at conservation.

So-called environmental distancing can reduce the problem of negative externalities by spatially separating them from their real source. Examples include international trade agreements that allow polluting components of a production process to be placed in one country while the benefits of that process are employed in another. Another example is the consumption of electricity from a nuclear power plant in one place, with storage of the power plant's waste in another. The effects of such distancing can be described in a cost–benefit framework, such as

$$NPV_i = \sum_{t=0}^{t} \frac{\left[B_{ti} - \left(C_t / d_{ij}\right)\right]}{(1+r)^t}, \tag{4}$$

in which the net present value at the ith place, NPV_i, of a project is the time discounted $(1+r)^t$ stream of benefits, B, minus the costs that accrue as a function of distance from the jth place, C_t/d_{ij}. Such distancing allows an alternative distribution of net spatial externality, as illustrated in Fig. 5. The maximum externality benefit of an action occurs at O; it is less but still positive at distance OK and negative at OM, and the negative externality is maximized at Z.

Environmental distancing often raises questions of environmental racism and environmental justice. In the United States, for example, waste disposal sites are often located in low-income or minority neighborhoods, far removed from the wealthier and whiter places in which the waste is generated. Negative externalities, including health effects, are therefore imposed on marginalized populations in their locations, while the positive externality of consumption below its social cost is enjoyed elsewhere.

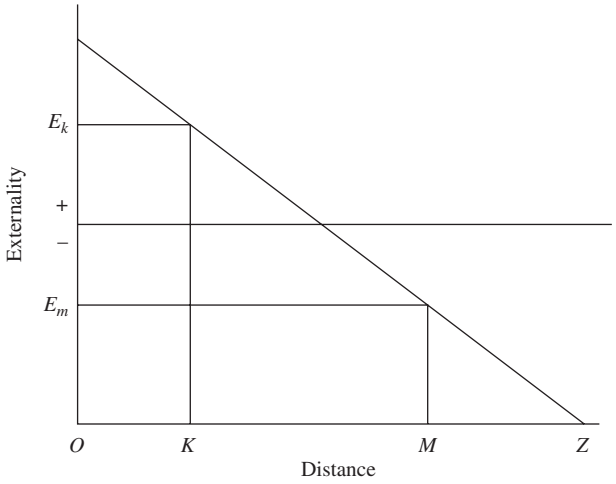

Figure 5 Distancing and spatial externality.

Externality Policy

Government policy toward externalities typically is focused upon the facilitation of positive externalities and the removal of negative externalities. The former typically requires some type of subsidy and the latter some form of tax or physical restriction on the activity that generates external costs. Much of government activity is involved with directly providing positive externalities. In the traditional sense, a public good was just that—something that could be used by the public with no direct charge or a charge lower than the actual value. Non-toll highways and other forms of infrastructure, for example, provide widespread benefits to many. Their cost is borne by the public at large, but individual users are not charged their marginal costs while their marginal benefits are significant.

Governments also have tried to specifically target externalities to particular areas. Enterprise zones (also called empowerment zones) are one example. They provide special tax benefits or labor subsidies to companies operating within specifically bounded districts, thereby directly providing geographical externalities, with little or no spatial effect. Recently, proponents of industrial policy have used the results of analyses incorporating increasing returns to argue for more active geographical policy toward inducing positive production externalities. Policies that facilitate locational clustering of firms within a broad industry are developed with the intent of nurturing such positive externalities as knowledge spillovers among firms and the development of a targeted labor force culture. Tax incentives for particular types of research and development activities or promotion of public university–private industry research or labor training consortiums are typically promoted as methods of inducing positive spatial externalities.

Much of land use planning is applied government policy toward externalities. Zoning, for example, is used to alleviate the negative spillover effects that certain land uses have on others, and green space requirements are designed to promote positive externalities associated with environmental amenities. Governments restrict certain production processes to certain places because of problems associated with water pollution or noise, and sometimes production processes are simply outlawed because of especially dangerous externality effects. The use of DDT as an agricultural insecticide is one example.

Taxation is another method of controlling negative externalities—the so-called "polluter pays" principle. Pigouvian taxes, named for their originator A. C. Pigou, are charged so as to ensure that a polluting firm pays its social cost of production rather than its marginal private cost. Returning to Fig. 1, a Pigouvian tax in the amount of $P'-P$ would reduce polluting activity to a "socially efficient" level as production is decreased from Q to Q'.

An argument against Pigouvian taxation specifically and government policy toward externalities in general is derived from the Coase theorem, which states that the initial distribution of property rights has no bearing on the use of the property because its use will ultimately be acquired by the person who values it the most. Given Coase's theorem, if the costs imposed by a negative externality become extreme, a market will be established so that the externality, as an unpaid cost or unpriced benefit, will be eliminated. Government intervention is unnecessary. For example, if water pollution becomes too severe, the polluter will be paid not to pollute. In effect, the right to pollute will be purchased from the polluter. Under Coase's theorem, negative externalities will be bought off and the benefits associated with positive externalities will be purchased outright. Land use zoning, for example, is unnecessary because private property markets will, theoretically, provide any compensation required for costs to one property owner raised by the actions of another property owner.

The only drag on the process is transaction cost. If transaction costs are high, externalities remain because the total purchase price (including the transaction cost) of an externality's source can exceed the social cost or benefit of the externality. If transaction costs are high, government intervention may indeed be necessary, even under Coase's theorem, to prevent a loss to one property owner from the actions of another.

Spatial Pattern Analysis

Arthur Getis
San Diego State University, San Diego, California, USA

Glossary

georeferenced data Data for which each element of the data set can be identified by its exact geographic location by means of a coordinate system.
geographical information system A technology comprising a set of computer-based tools designed to store, process, manipulate, explore, analyze, and present spatially identified information.
modifiable areal units A set of measurements on georeferenced zones that can be subdivided or aggregated into smaller or larger zones, respectively. Any results of an analysis of these subdivisions or aggregations may be conditional upon the chosen set of zones.
spatial autocorrelation The correlation between values of the same variable at different spatial locations.
spatial heterogeneity The condition when the mean and/or variance of a spatial distribution of a georeferenced variable differs over the study region.
variogram A function that describes the differences in values between all pairs of georeferenced data over a range of distances.

Spatial pattern analysis includes procedures for (1) the identification of the characteristics of georeferenced data, especially as they are portrayed on maps, (2) tests on hypotheses about mapped patterns, and (3) construction of models that give meaning to relationships among georeferenced variables. Georeferenced variables are the set of observations (data) about a variable for which each observation can be located exactly on a map by means of the use of a specified coordinate system, such as the latitude-longitude system. The data can be represented on a map as points, lines, and areas. This article devotes attention to maps of points, either where each point represents the exact location of the occurrence of a particular phenomenon (a single event), or where a point is weighted to represent a realization of a random variable for a particular bounded region (multiple events).

Introduction

The identification of the characteristics of mapped data can use a wide variety of procedures, many of which can be carried out within a geographical information systems (GIS) environment. For example, GIS provides tools that make it possible to measure distances between mapped objects, find summary measures of the density of mapped data, and identify similarities and differences between spatial patterns. Identification procedures are often exploratory in nature. Practical examples of exploratory procedures are to find the area of a region that is covered by a particular type of land cover and to provide a measure of the spatial distribution of a georeferenced variable.

Those who theorize about the spatial configuration of georeferenced variables often create hypotheses in order to verify or reject notions about spatial patterns. For example, suppose it is assumed that a georeferenced variable will display a spatial trend over a particular region. Suppose that this assumption is based on a relationship between the variable in question and another georeferenced variable (e.g., rainfall affected by elevation). Special spatial analytic techniques are required to verify or reject hypotheses about the spatial relationship between the variables. These techniques are part of the tool kit of the spatial pattern analyst.

The construction of models usually requires that assumptions about relationships among variables hold to a specific degree. For example, suppose a model predicts that a number of georeferenced variables interact in specified ways. These variables can be studied in a mathematical model that expresses the relationships

between them. The spatial pattern analysis procedures must take into account the nature of the spatial patterns of the variables in question.

An important special concern of the analyst is the error that may arise in model development that cannot be explained by any variable. Appropriate spatial analytic techniques can be used to ensure that the error has no systematic manifestation on the map. Otherwise, the model may be deemed misspecified.

The Nature of Spatial Pattern Analysis

A Brief History

Knowing that the spatial perspective is an important aspect of knowledge, analysts have always sought to better ways to depict data on maps and test notions based on some expected pattern form or structure. In the academic field of geography, there is a long history of the development of cartographic devices that allow for particularly insightful views of spatial data. From the wind rose of Leon Lalanne in the 19th century to the map transformations of Waldo Tobler in the 1960s, the literature is filled with interesting ideas designed to allow the spatial data to "speak for themselves." With the widespread arrival of powerful computers in the 1970s and 1980s, it was just a short step from relatively uncomplicated explorations and tests to powerful research tools that have the ability to manipulate large amounts of georeferenced data on many variables.

Spatial pattern analysis was a field given little attention until the 1950s and 1960s, when biologists such as Clark and Evans, Pielou, and Skellam sought to test hypotheses about the spatial distribution of certain plants. Of note is the work of the geographer Michael Dacey, who, taking the lead from plant ecologists, tested various statistical distribution theories by using sets of georeferenced data that represented the location of towns in a settlement system. Geographers Garrison, Berry, Dacey, and King, among others, set out to test the ideas of the great German settlement theorists, Christaller and Lösch. The antecedents for the modern statistical analysis of spatial pattern data include this work on settlement theory and also a wide variety of work in other areas, especially in spatial interaction and spatial correlation theory.

Also, in the mid-20th century, the statisticians Moran and Geary developed distribution theories for spatial autocorrelation, the association of elements of a georeferenced variable to each other. Building on their work, Dacey addressed the issue of the possible association among contiguous spatial units. This led to the work of Cliff and Ord, whose monograph *Spatial Autocorrelation*, published in 1973, opened the door to new, more analytically sophisticated approaches to spatial pattern analysis.

Part of the spatial pattern analysis movement, concomitant with these developments but totally separate from them, has been the development of the field of geostatistics. Geostatistics was largely a response by geologists to the problem of predicting the location of yet-undiscovered valuable minerals such as gold and petroleum. The pioneer in this field, Matheron, in the 1960s used the term regional variable as this article uses the term georeferenced variable. The statistician Cressie has done much to organize the extensive literature on the subject and to show how specialized techniques such as variogram analysis and kriging can be used to study map patterns.

All of this work has been greatly affected by computers. In fact, the resurgence of interest in spatial pattern analysis in the 1980s and 1990s is directly associated with the ability of computers to process large amounts of spatial data and to map data and outcomes of experiments very quickly and cheaply. Today, most spatial pattern analysis techniques are parts of different, and sometimes competing, software routines.

Current Uses of Spatial Pattern Analysis

In recent years, concerns about the physical and cultural environment have stimulated the rapid development of spatial pattern analysis. There are a variety of spatial pattern analysis research topics that not only are of considerable concern to societies around the world, but also are the kinds of problems to which the latest technologies lend themselves. These include such issues as the study of

- the occurrence and transmission of disease,
- the location and abatement of crime,
- the development and testing of models concerning environmental variables,
- traffic management,
- the data and models related to social, cultural, and economic trends.

Limitations of Spatial Pattern Analysis

The value of spatial pattern analysis comes from its ability to yield insights about processes that occur in the real world. The spatial patterns observed by analysts, however, are only abstract depictions of the real world. What is learned from spatial pattern analysis is only as valid as the assumptions that are made about the depictions.

Problems Associated with Spatial Pattern Analysis

The following six problems faced by the spatial pattern analyst help to define this field of study. By taking each of

these problems into account, the analyst gives more meaning and authenticity to the subject.

The Modifiable Areal Unit Problem

The modifiable areal unit problem consists of two related parts; the scale problem and the zoning problem. The scale problem is the challenge of choosing an appropriate geographical scale for analysis: should it be state, county, town, neighborhood, household, or individual? Oftentimes, the answer to the question is not necessarily obvious. Sometimes available data provide the only option, but if the level of analysis is inappropriate for the subject being studied, the conclusions reached after study will be of little use. If data must be aggregated into larger units because, say, individual data represent too little of the earth's surface, the question arises whether too much is lost by the aggregation process. The so-called ecological fallacy results when conclusions based on data at an inappropriate spatial scale are used to interpret a process at another scale.

The zoning problem concerns the spatial configuration of the sample units. Study results can differ depending on the boundaries of the spatial units under study. For example, if the counties of a state were configured differently, the results based on data taken from those counties would be different.

The Spatial Association Problem

The association between spatial units affects the interpretation of georeferenced variables. When the boundaries of spatial units bisect a single entity, such as a metropolitan area or a cluster of animals, the effect that the bifurcation has on pattern analysis is referred to as spillover, and the result is spatial dependence between bisected entities. For most studies of patterns, the degree of dependence within the spatial configuration must be known. The study of spatial autocorrelation addresses the spatial association problem. Certain regression models, called spatial autoregressive models and spatial filtering models, include the spatial dependence effects as part of the model structure.

The Spatial Heterogeneity Problem

The spatial analyst must be aware of the degree to which a pattern differs from area to area within the study region. As an extreme example, a study region split between water and land will normally show wide differences in observations taken from variables representing the entire region. If the resulting heterogeneity is not taken into account, false conclusions about spatial processes might ensue. The analytical assumption that calls for a homogeneous spatial surface is called stationarity, a fundamental assumption used in geostatistics. When homogeneity cannot be assumed, analysts must find ways to understand the nature of the heterogeneity.

The Boundary Effects Problem

In spatial analytical work, there is the danger that research results will be biased by a boundary effect. It is very common when considering spatially depicted phenomena, that areas close to boundaries, such as near a nation's boundary or an ocean boundary, will be very much different than the remaining part of the region. For many studies, the boundaries of the study region are selected arbitrarily. Most statistical devices available for the analysis of mapped patterns do not take boundaries into account. Measurements in and around boundaries may alter conclusions that might be drawn from the remaining data.

The Sample Size Problem

Modern data collection methods, such as remote sensing, are capable of supplying information in amounts, detail, and combinations that can boggle the mind. The increased availability of large, georeferenced data sets and improved capabilities for visualization, rapid retrieval, and manipulation within a GIS all point to the need for ways to approach spatial pattern analysis. In recent years, exploratory spatial data analytic techniques have been augmented by data-mining routines. They are a good example of the possibilities and problems that a new technology generates. On the one hand, data mining is able to tease out of large data sets patterns of location and behavior that previously could not have been identified easily. On the other hand, without theoretical justification, it is not always clear if the mined patterns are legitimate abstract views of objective reality.

Associated with this problem is what is called the missing data problem. For example, a series of temperature readings in an area represent only a small sample of all of the possible readings. Thus, the analyst is forced to interpolate and thereby create values that are not readily available. The unavailable values are sometimes called missing data. The analyst must use valid interpolation techniques to avoid unexpected biases.

Spatial Pattern Statistics

This section briefly describes one example of a spatial pattern statistic taken from each of three areas of concern. Each concern is representative of a particular way that a point pattern may be viewed. Point pattern analysis (see Fig. 1) is designed mainly for the identification of clustering or dispersion of events or cases represented as points. K-function analysis is used as the point pattern example technique. Spatial dependence analysis is

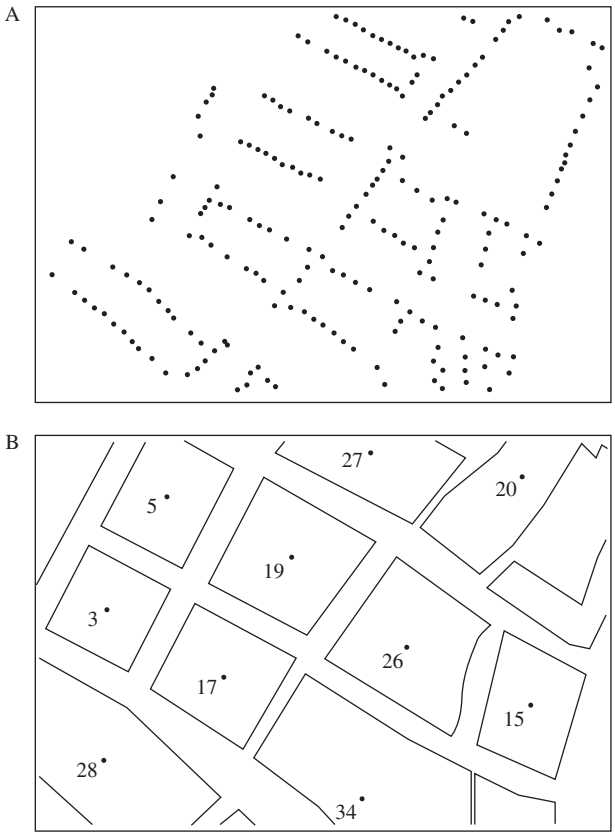

Figure 1 Types of point pattern representations. (A) Each point represents a single event; in this case, a point is a house site in a section of Iquitos, Peru. (B) Each point represents multiple events; in this case a weighted point is the sum total of houses on city blocks in a section of Iquitos, Peru.

carried out using one or more of a number of spatial autocorrelation statistics or geostatistics representations. The representative statistic in this case is the popular Moran's *I* test for spatial autocorrelation. Finally, the evaluation of patterns by focusing on individual observations is illustrated using what are called local statistics. The statistics demonstrated here are part of a family known as Getis and Ord's G statistics.

Point Pattern Analysis

There is a wide variety of point pattern statistics. Two helpful computer packages are ClusterSeer and Point Pattern Analysis. Often used is Ripley's k-function analysis, which is outlined below.

K-function is also called second-order analysis to indicate that the focus is on the variance, or second moment, of pairs of inter-event distances. All distances between all pairs of points are considered. The number of observed pairs within some specified distance (d) is compared to the expected number of pairs of points that would be obtained in a randomly created pattern of points [a test on the hypothesis of complete spatial randomness (CSR)]. The density of points, the boundaries, and the size of the sample are taken into consideration.

The k-function describes the number of pairs of points for each d. It is used in a formula [see Eq. (1)] that includes a correction for the boundary effect, stabilizes the variance, and allows the expected value [$L(d)$] to equal d. The confidence interval is generated by examining a specified number of permutations of randomly generated patterns of N points over the entire study area. If for any distance the observed $L(d)$ falls above or below the expected $L(d)$, the null hypothesis of CSR can be rejected at an appropriate level of significance. The level of significance is determined by the confidence envelope. An observed $L(d)$ value that falls below the envelope indicates that the points are dispersed at that distance, whereas an observed value above the envelope indicates that clustering is present.

The formula is

$$L(d) = \sqrt{\frac{\left(A\sum_{i=1}^{N}\sum_{j=1,j\neq i}^{N}k(i,j)\right)}{(\pi N(N-1))}}, \qquad (1)$$

where A is the size of study area, N is the number of points, d is the distance, and $k(i, j)$ is the weighted number of pairs of points, which is estimated in one of threeways:

1. If there are no edge corrections, $k(i, j) = 1$, which is the case when $d(i, j) \leq d$; otherwise $k(i, j) = 0$.
2. If a point i is closer to one boundary than it is to a point j, the border correction is employed.

$$k(i,j) = \left[1 - \cos^{-1}\frac{e}{d(i,j)}\Big/\pi\right]^{-1},$$

where e is the distance to the nearest edge.

3. If a point i is closer to two right angle boundaries than it is to a point j, the weighting formula is

$$k(i,j) = \left\{1 - \left[\cos^{-1}\left(\frac{e_1}{d(i,j)}\right) + \cos^{-1}\left(\frac{e_2}{d(i,j)}\right) + \frac{\pi}{2}\right]\Big/(2\pi)\right\}^{-1},$$

where e_1 and e_2 are the distances to the nearest vertical and horizontal borders, respectively.

Spatial Dependence Analysis

It is imperative in any type of spatial analysis to recognize and account for the degree of spatial dependence found in the georeferenced data. Variables that have not been checked for spatial dependence or models that have not accounted for spatial dependence may contribute to unacceptable bias and misunderstanding.

Moran's *I* is the best known test for spatial autocorrelation. It is a cross-product statistic of the form characteristic

of Pearson's correlation coefficient. Because spatial association is a more complex phenomenon than the simple Pearson's correlation, several important modifications of the usual correlation coefficient formulation must be introduced. Moran's I is produced by standardizing the spatial autocovariance by the variance of the data. The statistic depends on a carefully chosen spatial structural specification, such as a spatial weights matrix [$\mathbf{W}$ with elements $w(i, j)$] or a distance-related decline function. The expected value of Moran's I is $-1/(N-1)$. Observed values of I that exceed the expected value indicate positive spatial autocorrelation, in which similar observations, either high numbers or low numbers, are spatially clustered. An I below the expectation indicates negative spatial autocorrelation, in which neighboring values are dissimilar. Moran's I is defined as:

$$I = \frac{N}{S_0} \frac{\sum_{i=1}^{N}\sum_{j=1}^{N} w(i,j)(x_i-\bar{x})(x_j-\bar{x})}{\sum_{i=1}^{N}(x_i-\bar{x})^2}, \quad i \neq j, \quad (2)$$

where $\bar{x}$ is the mean of x_i

$$\bar{x} = \sum_{i=1}^{N} x_i/N$$

and

$$S_0 = \sum_{i=1}^{N}\sum_{j=1}^{N} w(i,j), \quad i \neq j.$$

The variance of I differs for different assumptions about the data. Under a randomization assumption, the variance of I is

$$Var(I) = \frac{N\left[S_1(N^2-3N+3) - NS_2 + 3S_0^2\right]}{(N-1)(N-2)(N-3)S_0^2} - \frac{K\left[S_1(N^2-N) - 2NS_2 + 6S_0^2\right]}{(N-1)(N-2)(N-3)S_0^2} - \left(\frac{1}{N-1}\right)^2,$$

where

$$S_1 = \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}\left[w(i,j)+w(j,i)\right]^2, \quad i \neq j;$$

$$S_2 = \sum_{i=1}^{N}\left[\sum_{j=1}^{N} w(i,j) + \sum_{j=1}^{N} w(j,i)\right]^2, \quad i \neq j; \text{ and}$$

$$K = \frac{N\sum_{i=1}^{N}(x_i-\bar{x})^4}{\left[\left(\sum_{i=1}^{N}(x_i-\bar{x})^2\right)\right]^2}.$$

Local Clustering Analysis

Local spatial autocorrelation statistics are observation-specific measures of spatial association. They focus on the location of individual points and allow for the decomposition of global or general statistics, such as Moran's I, into the contribution by each individual observation. Because the statistics can be used to detect local spatial clustering around an individual location, they are particularly well suited for finding "hot spots," or areas of elevated levels of the variable, or where a single measure of global association may contribute little meaning.

Local statistics that are used to find hot spots in an additive or multiplicative situation are G_i statistics. $G_i(d)$ and $G_i^*(d)$ were developed by Getis and Ord in 1992 and Ord and Getis in 1995. They indicate the extent to which a location is surrounded by a cluster of high or low values. The $G_i(d)$ statistic excludes the value at i from the summation while the $G_i^*(d)$ includes it. Positive $G_i(d)$ or $G_i^*(d)$ indicates spatial clustering of high values, whereas negative $G_i(d)$ or $G_i^*(d)$ indicate spatial clustering of low values.

The $G_i(d)$ statistic is written:

$$G_i(d) = \frac{\sum_{j=1,j\neq i}^{N} w_{ij}(d)x_j - \bar{x}_i\sum_{j=1,j\neq i}^{N} w_{ij}(d)}{S(i)\sqrt{\frac{\left\{(N-1)\sum_{j=1,j\neq i}^{N} w_{ij}^2(d) - \left[\sum_{j=1,j\neq i}^{N} w_{ij}(d)\right]^2\right\}}{(N-2)}}}, \quad i \neq j \quad (3)$$

where

$$\bar{x}_i = \frac{\sum_{j=1,j\neq i}^{N} x_j}{N-1} \quad \text{and} \quad S(i) = \sqrt{\frac{\sum_{j=1,j\neq i}^{N} x_j^2}{N-1} - (\bar{x}_i)^2}.$$

Both $G_i^*(d)$ and $G_i^*(d)$ are asymptotically normally distributed as d increases. Under the null hypothesis that there is no association between i and the j within d of i, the expectation is 0 and the variance is 1; thus, values of these statistics are interpreted as is the standard normal variate.

Spatial Pattern Modeling

Types of Models

A number of generic models are used to describe and study relationships between variables that are in some way affected by spatial location. These fall into a number of categories, briefly described below.

1. Spatial autoregressive models: These are regression models of the form

$$\begin{aligned} \boldsymbol{y} &= \rho\boldsymbol{W_1 y} + \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \\ \boldsymbol{\varepsilon} &= \lambda\boldsymbol{W_2}\boldsymbol{\varepsilon} + \boldsymbol{\mu}, \end{aligned} \quad (4)$$

where it is assumed that the dependent variable, $\boldsymbol{y}$, is spatially autocorrelated and that the nature of the autocorrelation is subsumed by the stochastic variable $\boldsymbol{W_1 y}$. $\boldsymbol{W}$ is a spatial weights matrix, and the coefficient ρ is known as a spatial autocorrelation coefficient. Each independent variable, $\mathbf{X}$, can have a spatial weights matrix associated with it, and the error term, $\boldsymbol{\varepsilon}$, might be fashioned as a spatial variable as in Eq. (4).

2. Spatial filtering models: The models are designed to divide each independent variable into its spatial and nonspatial components. The degree of spatial autocorrelation embodied in each variable is extracted from the variable and then recast as a spatial variable in the model formulation.

3. Geographically weighted regression: The purpose of this type of model is to create a series of representative equations for a complex region when it cannot be assumed that regression coefficients will be stationary over the region being studied.

4. Variogram models: These models identify the nature of the decline in spatial autocorrelation as distance increases from each site within the study region. For example, it may be assumed that as distance between sites increases, the degree of spatial association decreases according to, say, a negative exponential function.

Tests on Pattern Models

Tests on pattern models is one of the most vexing problems in spatial pattern analysis. Often, spatial analysts require multiple tests of significance. An example is the use of local statistics to identify hot spots or clusters in a spatial data set. The search procedure might require that tests be carried out on a series of, or on all, georeferenced data points in a region. This gives rise to the problem of finding the appropriate bounds or cutoff values for multiple simultaneous tests. In addition, when the test sites are near each other, it is common that some of the data required for one test will be needed for another test. In those instances, the statistical tests are not independent of each other. In a GIS data set, one can easily imagine the need for, say, 100,000 tests, one for each data point. Of course, only the spatially close sites are likely to be correlated, but conducting so many tests raises the issue of the appropriateness of the well-known Bonferroni bounds. In a different sense, the problem is known in regression analysis, in which the estimation procedure induces some correlation among the standardized regression residuals, and the net effect is that the empirical distribution may be thinner tailed than in the normal distribution.

Spatial Sampling

Peter A. Rogerson
State University of New York, Buffalo, New York, USA

Glossary

adaptive sampling Sampling of observations that is dependent upon the values of previous observations.
random spatial sampling Sampling of spatial units based upon random spatial coordinates.
spatial sampling Sampling in those instances when the sampling unit has a spatial dimension (point, line, or area).
stratified spatial sampling Selection of spatial units from spatial strata that are based upon subdividing the study area into mutually exclusive and collectively exhaustive strata.
systematic spatial sampling Systematic selection of spatial locations to achieve a spatial sample that has a uniform spatial distribution.

Spatial sampling is employed when the variable of interest has a set of spatial locations. The choice of spatial sampling locations needs to be made with particular prudence because spatial dependence is common, since sampled values from nearby locations will often lack independence.

Introduction

Like other forms of sampling, spatial sampling is concerned with selecting a sample from some larger population that is of interest. Spatial sampling is distinguished from many other types of sampling, however, by the fact that the variable of interest is distributed over geographic space. This leads to special considerations in the design of a sampling strategy because spatial variables exhibit spatial dependence—it would often be redundant to take two samples from locations in space that were very close to one another.

Different types of populations may be sampled; some are distributed over continuous space (such as the population of air pollution values in an urban area), and others consist of a set of discrete objects (such as the set of all households or the set of all census tracts).

Spatial sampling is also partially distinguished from other forms of sampling by the fact that the sampling units may themselves consist of geographic units (such as points or subareas) within the study area. There are other instances where the sampling units may not be geographic units (e.g., the sampling units may consist of families, households, or individuals), but because sampling those units yields a set of collected information on entities that have locations in space, the design and analysis of these studies also require a recognition of likely spatial dependencies in the data.

Spatial Sampling Problems, Sampling Designs, and Subsequent Inference

There are three distinct types of sampling problems:

1. Obtaining an independent, or almost independent, set of observations for use with classical statistical procedures. An example would be the use of a set of spatially sampled households in a regression analysis aimed at explaining household travel behavior as a function of socioeconomic variables.
2. Estimating a nonspatial characteristic of a spatial population. Examples include estimating a mean, a proportion, or a total.
3. Estimating a spatial quantity, such as a variogram or correlogram (which in turn summarizes spatial dependence), or an interpolated surface (e.g., a contour map).

Addressing these questions requires attention to the spatial design of the sample, which is in turn related to the subsequent use of the sample for statistical inference.

The approaches to inference following sample collection include design-based approaches and frequentist model-based approaches. In design-based approaches, the observed values are taken as fixed and nonstochastic. Inference is dependent upon the sample design and the associated probabilities of sample selection. Sampling strategies that are design unbiased (i.e., that have an expected value of an estimator that is equal to the population value) retain this property irrespective of the nature of the underlying population.

In frequentist model-based approaches to inference, the observations are taken to be random variables and are thus considered as realizations from some underlying stochastic process. For conventional designs (in which the method of sample selection does not depend upon the observations), inference can be based solely upon the stochastic model and is independent of the particular (conventional) sampling strategy. One example is model-unbiased estimators that remain unbiased regardless of the conventional sampling strategy.

Because a goal of sampling is to generalize from the sample to the population, sampling methods that lead to estimates with "good" statistical properties (for example, estimates that are unbiased, with minimum variance) are desired. Much work in spatial sampling has been devoted to assessing how well the quantities resulting from particular methods of sampling estimate their respective population values. For example, suppose that the mean commuting distance in a city is to be estimated. Figure 1 depicts two alternative sampling schemes that collect information from individuals at 10 spatial locations. The sampling plan in Fig. 1A would result in an estimate of the mean commuting distance that was highly uncertain, because so much of the city's area is not well represented in the sample. This is particularly true if commuting distance is positively spatially autocorrelated (that is, commuting distances by residents at one location are highly correlated with the commuting distances of residents at nearby locations). Any positive spatial dependence in commuting distance values implies that at least some of the information collected in a set of observations that are close together in space will be redundant.

In the commuting distance example, the population is a set of discrete objects—individuals. Similar considerations apply when sampling population variables are defined over continuous space, such as air pollution. Assuming that the variable of interest at each location is fixed (nonstochastic) at the time of sampling, there are some alternative spatial sampling strategies, described in the next section.

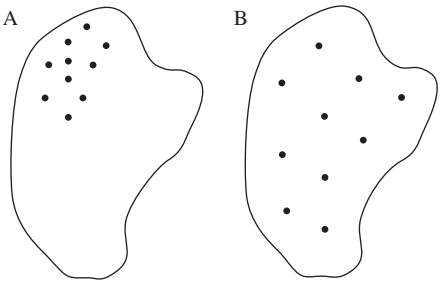

Figure 1 Alternative spatial sampling plans.

Alternative Spatial Sampling Designs

The most common spatial sampling designs are random, stratified, and systematic.

Random Sampling

Perhaps the most intuitive strategy for sampling locations in a defined study area is to choose random x and y coordinate pairs. Suppose a (possibly irregular) study area has minimum and maximum x coordinates of $x_{\min}$ and $x_{\max}$, respectively (see Fig. 2). Similarly, $y_{\min}$ and $y_{\max}$ are the minimum and maximum y-coordinates in the study area. To choose a random location, choose an x coordinate at random from the interval $(x_{\min}, x_{\max})$ and a y coordinate from the interval $(y_{\min}, y_{\max})$. If the point happens to fall outside of the study area (as with point A in Fig. 2), simply discard the point and try again. This is repeated to generate n locations. Note: If a random number generator returns a value (say, u) from a uniform distribution on the interval (a, b), this may be transformed into an x coordinate by taking

$$x = x_{\min} + (x_{\max} - x_{\min})(u - a)/(b - a).$$

The transformation is of course also used to find the y coordinate. This strategy can be used either to choose

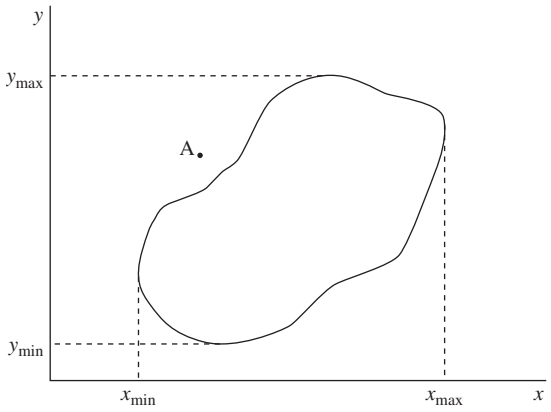

Figure 2 Hypothetical study area.

a set of point locations for variables defined over continuous space, or to randomly select spatial quadrats that in turn contain discrete objects (where in the second phase, either all objects or a sample of objects is taken from within the quadrat).

Stratified Spatial Sampling

The adequacy of estimates from spatial samples is based upon the amount of bias and the amount of precision, where the latter refers to the variance of the estimator. To reduce the variance of estimated parameters, it is often advantageous to stratify the population of sampling units according to some criteria known to affect the estimated quantity. For example, to estimate the proportion of residents in a community who have moved into their homes within the last year, it may be desirable to stratify on age, since age is a known covariate of mobility. Sampling from each stratum is then carried out, and the size of subsamples can either be proportional or disproportional to strata size. Stratified sampling can improve precision of population estimates by ensuring representation across a range of the stratifying variable known (or suspected) to be related to the estimate. Another use of stratification is to ensure precise estimates in each stratum, and in this case adequate sample sizes are necessary in each stratum.

With spatial sampling, it can be similarly advantageous to divide or stratify a geographic study area into subareas that are defined on the basis of some covariate. For example, a study of the recreational use of a county park might be carried out by first recognizing that frequency of use is likely to vary significantly with distance from the park. Concentric rings around the park would constitute strata, and the sample would consist of subsamples drawn from each stratum (see Fig. 3; note that the outermost stratum is noncircular in this example due to the irregular shape of the study region). One way to do this would be to select a subsample by randomly selecting individuals off of a list of all individuals residing in the stratum. If the goal was a precise estimate of average park usage, the number of individuals chosen in each stratum could be proportional to the number of individuals in the stratum. This would lead to an estimate of average park use that would be more precise than one obtained by random sampling. Suppose, however, that the goal was instead to obtain estimates of park use, disaggregated by distance from the park. If some strata had small populations, one could oversample in these strata to ensure more precise information about them (this is similar to the common practice of oversampling minority populations in samples stratified by race and/or ethnicity).

Systematic Spatial Sampling

With a list of N sample elements, a systematic sample of n may be chosen by dividing the list into n equal parts (where for simplicity it is assumed that N/n is an integer). The first observation is taken randomly from among the first N/n on the list; suppose we label this observation x, where $1 \leq x \leq N/n$. Then the remainder of the sample is chosen by taking as the next observations $x + N/n$, $x + 2\ N/n$, $x + 3\ N/n$, and so on.

Systematic sampling in such aspatial situations is often done as a matter of convenience. Generalizations of systematic sampling to the spatial case are desirable because they ensure comprehensive coverage of the study area. In addition, the likelihood of collecting redundant information from spatially dependent nearby locations is reduced to a minimum.

One approach to systematic spatial sampling is shown in Fig. 4. A study area is first divided into square cells, and then a point (e.g., point A) is chosen randomly within the first cell. Points are next chosen at the same relative locations in the remaining cells. There are numerous variations of this procedure. For example, when the sampling points are taken to be the center of each cell, the design is known as a centric systematic sample.

One potential though uncommon difficulty with systematic spatial sampling is that spatial periodicities may affect the estimate. For example, suppose that the housing

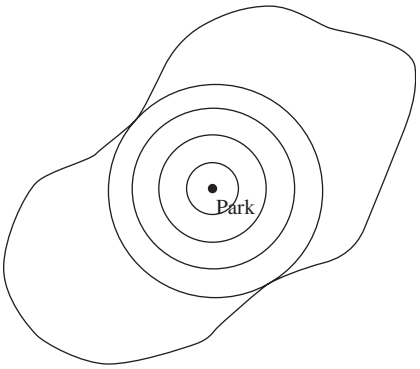

Figure 3 Sampling strata based upon distance from park.

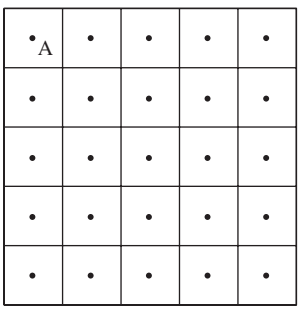

Figure 4 Systematic spatial sampling.

prices in an area are a function of location, and in particular are a function of elevation. There are some areas where housing prices are higher at higher elevations (because of the scenic amenities), and others where housing prices are higher at lower elevations (due to accessibility considerations). In either case, if hills and valleys are systematically spaced at roughly equal distances apart, it could be a mistake to take a systematic sample of housing prices because of the potential that the sampled locations would correspond entirely to high (or low) elevation locations. Judicious choice of the sampling interval is therefore called for. The problem may be avoided entirely where this possibility exists by geographic stratification.

Comparisons of the Three Spatial Sampling Methods

Many studies have compared the sampling methods described previously. When estimating the mean, all three methods yield unbiased estimates. Systematic and stratified spatial sampling are generally preferable to random spatial sampling, because the former two methods generally lead to estimates with smaller sampling variances. In addition, systematic spatial sampling is often found to have a slight advantage over stratified spatial sampling (in terms of a lower sampling variance).

Illustration

Figure 5 shows a hypothetical map of air pollution values. Suppose that it is decided to sample from the "true" map by taking observations at 16 point locations. The three types of sampling described previously were carried out as follows:

1. Random spatial sampling: coordinate pairs were chosen by randomly choosing x and y coordinates.
2. Stratified spatial sampling: the study area was partitioned into fourths by creating four square cells of equal area, and four observations were then chosen randomly within each cell.
3. Systematic spatial sampling: the study area was divided into 16 square cells of identical size. A point was chosen at random within the first cell, and the same relative positions within each of the other 15 cells were taken as sample points.

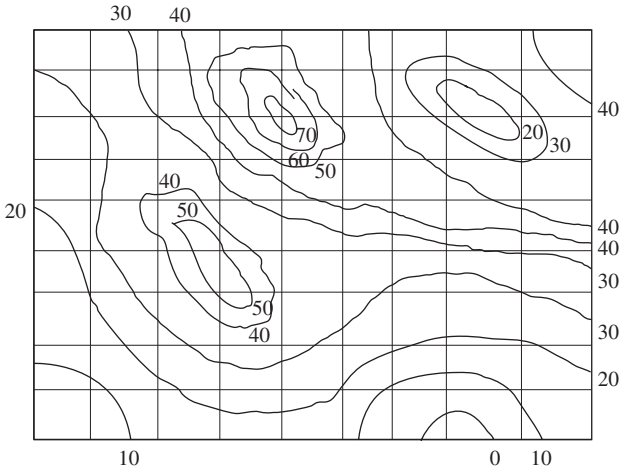

Figure 5 Hypothetical map of air pollution values.

One thousand samples of each type were taken. The results are shown in Table I. The sample means all compare favorably with the "true" mean of 30.36, found by overlaying a fine grid on the study area and sampling at the intersection of all grid lines. As expected, stratified and systematic methods led to lower variances than random sampling, and the variance of the mean under systematic sampling was less than that found under stratified sampling.

The stratified sampling used in the example may be further described as proportionate, since the size of the sample in each of the four strata was proportionate to the area of the strata. Disproportionate stratified sampling uses sampling fractions that are not proportional to, e.g., area. The 16 observations were next allocated disproportionately, under the alternative plans shown in Fig. 6; the figure also shows the mean and standard deviation associated with 1000 repetitions of each sampling plan. The sampling variance of the mean is lowest under the plan shown in Fig. 6A: this plan collects extra observations in the northwest corner of the study area, where air pollution values are most variable. Similarly, the sampling variance is highest under the plan shown in Fig. 6B; extra observations are "wasted" in the southeastern portion of the study area, where air pollution varies little from one location to the next. In general, it is useful to stratify into subareas when the subareas are very different from one another regarding the characteristic being measured. It is also useful to stratify into subareas when the variable of interest is more spatially variable within one or more subareas, as is the case here in the northwest quadrant.

Table I Comparison of Spatial Sampling Methods

Type of spatial sampling	*Mean*	*Standard deviation*
Random	30.38	3.08
Stratified	30.39	2.40
Systematic	30.24	1.95

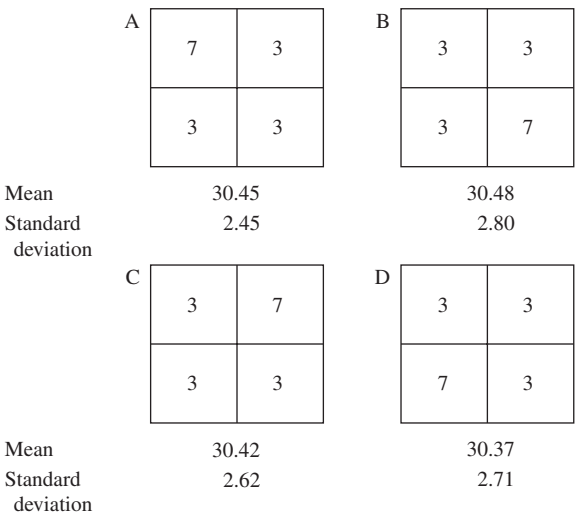

Figure 6 Alternative disproportionate stratified sampling plans. Numbers indicate the number of observations from each subarea.

This example used sampled point locations for a continuous variable; a comparison of corresponding areal sampling strategies (and then taking subsamples or censuses within those locations) would also typically result in the more precise estimates emerging from the stratified and systematic approaches.

Other Forms of Spatial Sampling

Cluster Sampling

Another type of spatial sampling is carried out via the hierarchical multistage sampling of spatial locations. For example, a sample of the census tracts in an urban area may be chosen in the initial phase (for example, via random selection of tracts, or via spatial or nonspatial stratification of tracts of different types). Then blocks may be sampled from the sampled tracts, and finally some or all of the households within the chosen tracts may be surveyed. The major benefit of this form of sampling is added convenience, since the cost of data collection can be substantially lower than alternative designs. For a given sample size, the resulting estimators will lack precision when, as is often the case, the variable of interest exhibits spatial dependence. Whether cluster sampling is effective for a fixed budget depends upon whether the additional sampling that is possible (due the lower cost of data collection) can increase the precision of the estimates sufficiently.

Adaptive Sampling

The sampling methods discussed to this point are conventional, in the sense that the method of sample selection does not depend upon the observations. One alternative to conventional designs is the set of adaptive sampling methods; these methods are particularly appropriate when the sampled characteristic is rare and spatially clustered. With adaptive sampling, the method of selecting observations may depend upon the observations. For instance, suppose that it is of interest to estimate the proportion of all individuals within a study region that walk to work. Because this is an uncommon mode of transportation, and because the location of such individuals is likely to be clustered spatially, adaptive sampling may be appropriate. One specific approach is to initially choose a census block randomly, and then canvas individuals within the block. If the sampled block reveals a high proportion who walk to work, it may then be advantageous to sample surrounding block locations, since positive spatial dependence will make it more likely that these adjacent areas will also contain individuals who walk to work.

Adaptive sampling methods can be operationally complex. Recall that in frequentist model-based approaches to inference, the observations are taken to be random variables, and for conventional designs, inference is independent of the particular (conventional) sampling strategy. With adaptive sampling, inference based on frequentist model-based approaches will depend upon both the model and the adaptive design.

Recent Directions in Spatial Sampling

The relationship between spatial dependence and spatial sampling has been the focus of recent research. For example, how spatial dependence may affect the optimal selection of a sampling method has been examined, when the objective was to estimate a map. This issue has also been addressed from the opposite perspective, to study the optimal sampling design for estimation of the nature of spatial dependence.

There is also increasing recognition of the need for space–time sampling methods, particularly within the context of environmental monitoring networks. For example, the topic of how monitoring stations may be added and/or deleted to achieve good estimations of environmental parameters that are changing over time has been discussed. Such methods are also of clear use in the context of social measurement (for example, in monitoring changes in neighborhood quality).

Spatial Scale, Problems of

Peter M. Atkinson
University of Southampton, Southampton, United Kingdom

Glossary

downscaling "Zooming in" or changing to a finer spatial resolution so as to reveal more detail in the data.
modifiable areal unit problem (MAUP) The problem associated with analyzing data defined on cells that vary in size, geometry, and orientation. The problem has two main components: aggregation and zonation.
regularization The operation of increasing the support (cell) on which a model (or data) is defined.
support The size, geometry, and orientation of the space on which a measurement, observation, or datum is defined.
upscaling "Zooming out" or coarsening the spatial resolution so as to reveal less detail in the data.
variogram A function that relates semivariance to lag (distance and direction of separation).

Spatial scale is an important concept in relation to social measurement, being inextricably tied with measurement and sampling. Importantly, the spatial variation evident in spatial data is a function of reality and the sampling framework. Therefore, it is important to distinguish between scales of measurement (i.e., those relating to the sample) and scales of spatial variation (i.e., those in data). The two most important scales of measurement are spatial resolution and spatial extent. These provide lower and upper limits on the scales of spatial variation that are detectable in data. Given a specific sample that can be modeled as a random field, the scale(s) of spatial variation in the data can be characterized using either functions of spatial resolution or functions of lag (distance and direction of separation), such as the variogram. It is possible to change the scale of measurement: Upscaling involves coarsening the spatial resolution through averaging, whereas downscaling involves increasing the spatial resolution, for example, through optimization or simulation. The variogram can be altered (regularized) as a function of support (the space on which each datum is defined). This amounts to scaling the model rather than the data. The major scale issue for social measurement is the modifiable areal unit problem. The problem is essentially that census and related data are defined on a variable support such that classical statistical techniques should not be applied directly without modification.

Defining Scale

Spatial scale has traditionally been defined by cartographers as the ratio between a distance on a map to the same distance in reality. This cartographic definition of scale is strictly correct. However, this definition may be confusing. For example, 1 : 10,000 is a larger cartographic scale (fraction) than 1 : 50,000, even though 1 : 10,000 is the smaller ratio and the 1 : 10,000 scale map covers a smaller ground area.

We often use scale in everyday language with a very different meaning. For example, a large-scale investigation, phenomenon, or process is simply a large investigation, phenomenon, or process. This use of scale, widely accepted and currently practiced in disciplines such as physics and ecology, simply equates scale to size (i.e., it renders the word "scale" redundant). This definition of scale is used in this article.

When describing spatial scale, it is important to distinguish between two types of scale: scales of measurement and scales of variation. Scales of measurement relate to sampling processes, whereas scales of variation relate to data. It is important to realize that the scales of variation observable in data are a function of (i) the sampling framework (and, therefore, the scales of measurement encompassed therein) and (ii) the phenomenon of interest in reality. Reality can never be observed independently

from a sampling framework (Fig. 1). All observation of the real world, even that obtained directly by our own senses, is essentially a filtered version of what exists in total. The importance of scale has to do with the way in which the sampling framework interacts with the phenomenon of interest in reality to produce (spatial) data.

This article draws heavily on geostatistics, a set of tools for the analysis of spatial data, meaning that the focus is on spatial variables that can be modeled as random fields. Point pattern data and object-based representations (e.g., points or cells grouped together to form higher order objects) are not covered in the same detail. The reason for this choice is that geostatistics provides a useful framework with which to explain the basic concepts relating to spatial scale, most of which can be applied to other types of data.

In addition, this article focuses on scales of variation in spatial data. Thus, scales of both temporal variation and process, although important, are not given the same attention. However, the basic concepts explained in relation to spatial data may be applied readily to scales of both temporal variation and process.

Scales of Measurement

There are two important scales of measurement; the spatial resolution and the spatial extent. To understand these properties, it is necessary to first discuss the sampling framework.

Sampling Framework

The sampling framework can be divided into properties that relate to a single observation (i.e., properties of the support) and other properties that relate to an ensemble of observations (i.e., properties of the sample).

Support

A measurement of a property defined spatially is always made on a positive space known as the support. This support has a size, geometry, and orientation. The size of support can be defined as zero (i.e., a point), but measurement is never actually possible on a point. An example is given by disease risk defined spatially. The risk is most often reported for a fixed areal unit, the support. If the risk were reported per 1×1 km cell, then the support would have a size of 1 km^2, it would be square, and it would have an orientation determined by the coordinate system used for sampling (i.e., the sampling grid) (Fig. 2A).

Sample Size

The sample size is simply the number of observations in the sample. For a sample of 100 respondents to a questionnaire, from a population of 10,000, the sample size is 100.

Sampling Scheme

The sampling scheme is the geometry of the sample. Examples include the random, stratified random, and systematic sampling schemes (Fig. 3). Systematic schemes include the square grid and equilateral triangular grid. Stratified random schemes can be stratified either by prior knowledge (e.g., disease risk is known to be less in nonvegetated areas) or by some prior sampling scheme (e.g., a square grid).

Sampling Density

The sampling density relates the actual distance units of the sample to distance units on the ground (in reality). It is an important property because it encapsulates some information related to cartographic scale.

Second-Order Properties

The properties of the sampling framework described previously are generally first-order properties because they relate to either a single observation or the sum of several observations. Two second-order properties may be defined as a function of these first-order properties; spatial resolution and spatial extent. To understand how these properties are constructed, consider the following

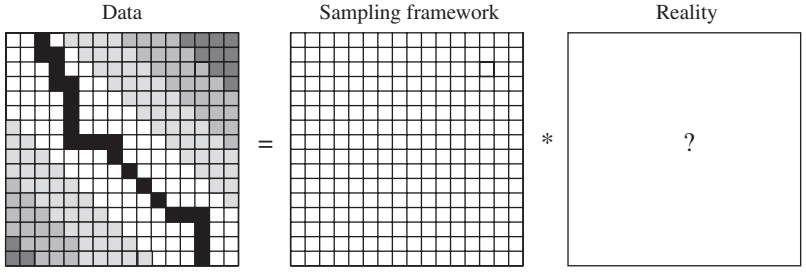

Figure 1 Data illustrated as a function of reality plus the sampling framework. Reality can never be observed independently of a sampling framework.

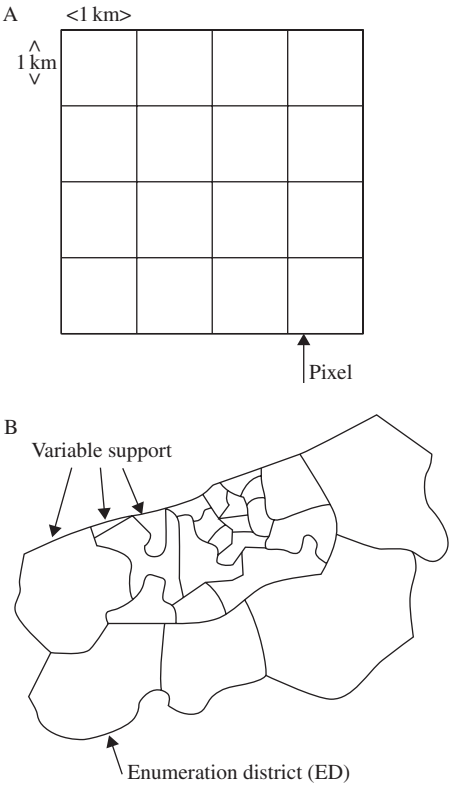

Figure 2 Data obtained on two different types of support: (A) a raster grid of square 1×1 km pixels and (B) census data for which the support is variable in size, geometry, and orientation.

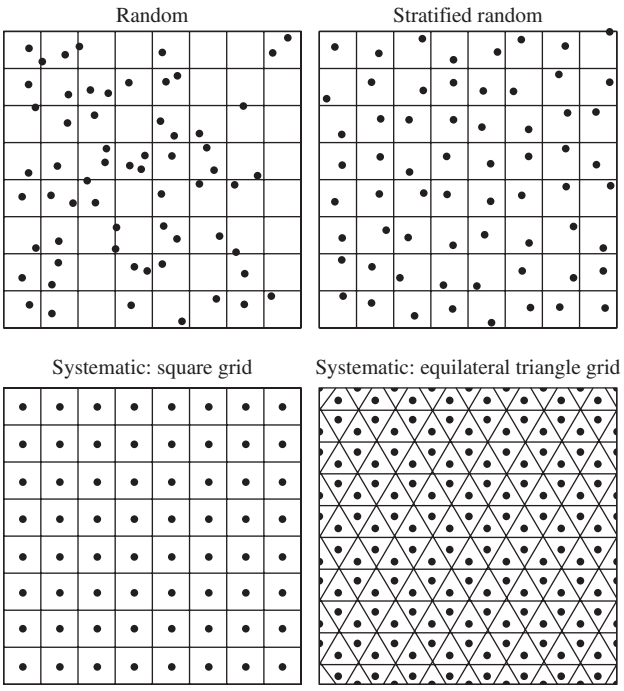

Figure 3 Four different sampling schemes.

example: Suppose that a map of disease risk has been produced with a support of 1×1 km, with 100×100 abutting observations on a square grid. The second-order properties (spatial resolution and spatial extent) are determined by the set of spatial distance and direction vectors (or lags) between each pair of constituent observations in the sample.

Spatial Resolution

The spatial resolution is defined as a function of the smallest lags between pairs of observations in the sample and the support. Since observations are often arranged to be nonoverlapping and abutting (as in the previous disease example), the spatial resolution is often equal to the support. However, it is quite possible for the spatial resolution to vary locally throughout a sample. Consider census data in which the size, geometry, and orientation of support may vary markedly from place to place (Fig. 2B). For such data, the spatial resolution depends more on the local lags between pairs of observations than on the support, and it varies locally. For point data (e.g., questionnaire respondents indexed to a point location), the support has no bearing: The spatial resolution is determined entirely by local lag. The important point is that spatial resolution is a second-order property because it depends on the relation or interaction between observations.

The spatial resolution defines a limit to the spatial detail that can be observed. It can thus be thought of as a scale of measurement. It is essentially a filter obscuring from the analyst variation that exists at a scale smaller than the smallest lag (sampling interval).

Spatial Extent

Like spatial resolution, the spatial extent is determined as a function of the set of lags between pairs of observations in a sample. Whereas spatial resolution depends on the shortest lags (sampling intervals), spatial extent depends on the largest lags. Spatial extent defines a second limit to the spatial variation that can be observed, filtering out variation that exists at a scale larger than the spatial extent. Thus, the spatial extent is a second fundamental scale of measurement.

The Set of Spatial Lags

Although it is useful to conceptualize the spatial resolution and spatial extent as providing lower and upper limits to the spatial variation that can be observed, it should be remembered that it is the set of spatial lags between all pairs of observations in the sample that provides the actual filter on reality. Why is this so? The answer lies in the nature of spatial variation. It is important to realize that spatial variation (and also spatial information) exists in the relations between data and not in them. Thus, if a value of 40 were realized by measurement, that value would

convey strictly zero information without comparison to either another value (e.g., it is less than 41) or to a priori knowledge (e.g., the measure is of human age, so the value conveys the meaning of "middle-aged adult"). In a spatial sample, the spatial variation and information exist as a function of the set of spatial lags between data pairs.

Scales of Spatial Variation

As explained previously, spatial variation exists in data as a function of the sampling framework and the phenomenon of interest in reality. It is not possible to measure reality independently of a sampling framework. Thus, when describing spatial variation (e.g., with summary statistics such as the variance) it is important to remember that the variation relates to data and not reality. It is for this reason that scales of measurement were discussed first.

The dispersion (or sample) variance s^2 will be familiar to readers. It is the square of the sample standard deviation s. The variance measures the spread of values around some unknown mean μ: this measures dispersion. Unfortunately, since the variance is aspatial (no locational information is provided) it describes only the amount or magnitude of variation and says nothing about the spatial scale of variation. To characterize the scale of variation, locational information must be used. There are several ways of doing this. Here, two are considered; the first is based on varying spatial resolution and the second on varying lag.

Characterizing Scales of Variation as a Function of Spatial Resolution

It is possible to obtain information on the scale(s) of spatial variation by making some statistic (such as the variance) a function of spatial resolution (or support). Essentially, the statistic is estimated for several spatial resolutions and the values are then plotted against spatial resolution. The plots convey some information on the scale(s) of spatial variation present in data. The techniques described in the following sections are applicable primarily to image data (e.g., a population surface model derived from census data).

Dispersion Variance

It is possible to vary the spatial resolution of data (by averaging cells successively) and calculate the familiar dispersion (or sample) variance at each step. The dispersion variance s^2 can be written more fully as $D^2(v, V)$ to indicate a variable defined on a support v within a region V. This may be obtained as

$$\hat{D}^2(v,V) = \frac{1}{N-1}\sum_{i=1}^{N}[\bar{z}_v(\mathbf{x}_i) - z_v(\mathbf{x}_i)]^2, \qquad (1)$$

where $\bar{z}_v(\mathbf{x}_i)$ is the mean of all values $\bar{z}_v(\mathbf{x}_i)$ at $\{i = 1, 2, \ldots, N\}$ locations $\mathbf{x}_i$. The plot of dispersion variance against spatial resolution reveals information about the scale(s) of variation. In particular, the rate at which the dispersion variance decreases with coarsening spatial resolution is determined by the scales of spatial variation present in the data. This relation (decreasing variance with coarsening spatial resolution) is important and is discussed later in relation to census data.

Scale Variance

An alternative to the dispersion variance is the scale variance. This is obtained by subtracting the variance obtained at a given spatial resolution from the variance obtained at the next finer spatial resolution. The scale variance $\hat{S}^2(v,V)$ may be obtained from $D^2(v, V)$ as follows:

$$\hat{s}^2\left(v \cdot 2^k, V\right) = \hat{D}^2\left(v \cdot 2^k, V\right) - \hat{D}^2\left(v \cdot 2^{k+1}, V\right), \qquad (2)$$

where 2^k varies between 0 and $\sqrt{N}$. This implies that the image is composed of $\sqrt{N}$ rows by $\sqrt{N}$ columns, and that $\sqrt{N} = 2^k$ for some value of k. One advantage of the scale variance is that peaks in the plot of scale variance against spatial resolution indicate where the scale of spatial variation is similar to the chosen spatial resolution (the plot is not monotonically decreasing as for the dispersion variance). A further advantage of the scale variance is that it is able to detect multiple scales of variation readily via multiple peaks.

Local Variance

The local variance σ^2_{vw} can be predicted for a moving $(2w + 1$ by $2w + 1)$ window applied to an image of L rows by M columns using

$$\hat{\sigma}^2_{vw} = \frac{1}{(2w+1)^2}\sum_{j=l-w}^{l+w}\sum_{k=m-w}^{m+w}\left[\bar{z}_v(j,k) - z_v(j,k)\right]^2, \qquad (3)$$

where w is usually set to 1. The local variance is different, in principle, from the previously described variances because it is local. This local variance, however, may be averaged over the whole image:

$$\hat{\bar{\sigma}}^2_{vw} = \frac{1}{L \cdot M}\sum_{l=1}^{L}\sum_{m=1}^{M}\hat{\sigma}^2_{vw} \qquad (4)$$

The average local variance $\hat{\bar{\sigma}}^2_{vw}$ can be predicted for different window sizes. The plot of $\hat{\bar{\sigma}}^2_{vw}$ against window size provides information that is similar to that provided by the dispersion and scale variances. Figure 4 shows

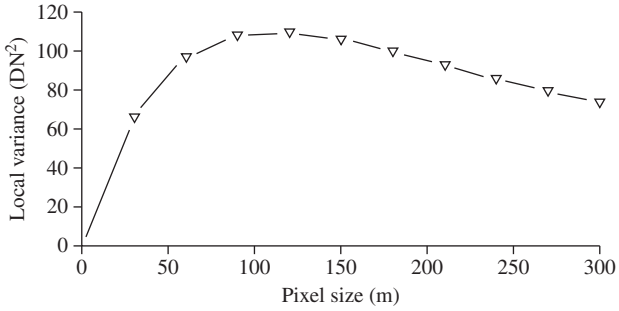

Figure 4 Average local variance plotted against pixel size. DN, digital number.

a hypothetical plot of average local variance against cell or pixel size.

Characterizing Scales of Spatial Variation as a Function of Lag

It can be difficult to interpret plots of variance against spatial resolution. Functions such as the autocovariance, autocorrelation, and variogram describe spatial correlation as a function of lag (distance and direction of separation). Of these three functions, the variogram is examined here because it is most often used in geostatistical analysis.

For continuous variables, the experimental or sample semivariance is defined as half the average squared difference between values separated by a given lag $\mathbf{h}$. Thus, the experimental or sample variogram $\hat{\gamma}_v(\mathbf{h})$ may be obtained from $\alpha = 1, 2, \ldots, P(\mathbf{h})$ pairs of pixels $\{z_v(\mathbf{x}_\alpha), z_v(\mathbf{x}_\alpha + \mathbf{h})\}$ defined on a support (or pixel) of size v at locations $\{\mathbf{x}_\alpha, \mathbf{x}_\alpha + \mathbf{h}\}$ separated by a fixed lag $\mathbf{h}$:

$$\hat{\gamma}_v(\mathbf{h}) = \frac{1}{2P(\mathbf{h})}\sum_{\alpha=1}^{P(\mathbf{h})}[z_v(\mathbf{x}_\alpha) - z_v(\mathbf{x}_\alpha + \mathbf{h})]^2. \qquad (5)$$

To provide a quantitative description of the character of spatial variation, a continuous mathematical model is fitted to the experimental variogram (most often using weighted least squares approximation). Variogram models can be divided into two general categories: unbounded and bounded. Unbounded models increase in semivariance monotonically with lag, without reaching a defined maximum. Bounded models reach a maximum value of semivariance (known as the sill variance, c) at a finite lag (known as the range, a). An example of a bounded model is given by the spherical model:

$$g(h) = c \cdot \left\{ \left(\frac{3h}{2a}\right) - \left(\frac{h}{2a}\right)^3 \right\} \text{ if } h \le a \qquad (6)$$

$$g(h) = c \qquad \text{otherwise,} \qquad (7)$$

where a is the nonlinear parameter, referred to as the range (Fig. 5A). The exponential model is bounded, but

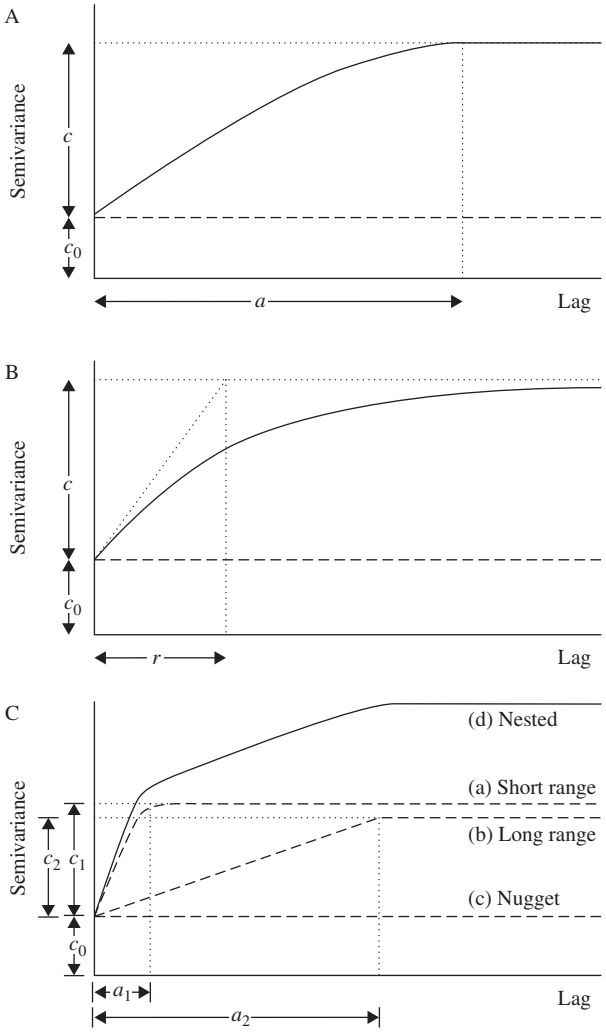

Figure 5 Examples of variogram models: (A) The spherical (plus nugget) model showing the structured (or sill) variance, c, the nugget variance, c_0, and the range, a; (B) the exponential (plus nugget) model showing the sill, nugget, and nonlinear parameter, r (which is approximately one-third of the effective range, a'); and (C) a hypothetical nested model in which short-range and long-range components are combined with a nugget component.

it never actually reaches the maximum because it is asymptotic. The exponential model is given by

$$g(h) = c \cdot \left\{ 1 - \exp\left(\frac{-h}{r}\right) \right\}, \qquad (8)$$

where c is the sill, and r is the nonlinear parameter, equal to approximately one-third of the conventional variogram model range a (Fig. 5B).

The sill variance c is equal to the *a priori* variance $D^2(v, \infty)$ (i.e., the variance of the property of interest defined on a given support in an infinite region). Furthermore, the dispersion variance $D^2(v, V)$ (i.e., the variance on a given support defined for a finite region) can

be obtained from the variogram model as the integral semivariance over that finite region. Thus, the sill variance conveys information on the amount of variation.

The range a provides a spatial limit to correlation. At lags larger than the range, pairs of data are expected to be unrelated, whereas at lags smaller than the range they are expected to be correlated. The range thus provides information on the scale(s) of spatial variation.

Often, more than one model is fitted to the experimental variogram in positive linear combination. If each model has a range, then the nested model describes the (multiple) scales of spatial variation (Fig. 5C). Nested variation is common in spatial data. In a few cases, the spatial variation is said to be self-similar or fractal, meaning that the same character of spatial variation exists at all scales of measurement. This fractal model is thus of key importance because it is the only example in which (at least the character of) spatial variation can be said to be independent of the sampling framework.

Commonly, a structured component model is fitted in combination with a nugget effect model. The nugget effect model is simply a constant semivariance with lag:

$$g(h) = c_0. \tag{9}$$

The nugget model has a sill (nugget) variance c_0 but no range (since it is flat) (Fig. 5). This so-called nugget variance describes unresolved spatial variation that exists at microscales (i.e., lags shorter than the shortest sampling interval) and measurement error.

In summary, the parameters (and type) of the fitted variogram model provide information on the amount and scale of spatial variation in sample data. However, the variogram is much more useful than simply as a description of spatial variation.

Changing the Scale of Measurement

When handling spatial data (e.g., within a geographical information system) it is often necessary to change the scale of measurement of the data (particularly the spatial resolution), most notably when one variable needs to be compared to another. Decreasing or coarsening the spatial resolution of the data (e.g., through averaging) is referred to as upscaling, whereas changing to a finer spatial resolution is referred to as downscaling (Fig. 6).

Upscaling

Upscaling is most often achieved through some form of averaging of original values to provide data at a coarser spatial resolution. For example, consider the situation in which the support is constant across space. Examples include the disease risk mapping described previously and a population surface model. Both data sets can be upscaled by calculating values for new larger cells as the averages of the two-by-two original cells that fit inside them. This kind of spatial averaging is the same as that used previously to calculate the image, scale, and local variances.

For census data (Fig. 2B), upscaling may also be achieved by averaging. However, the supports of the averages are constrained by the size, geometry, and orientation of the original supports. Essentially, the larger supports must be constructed to encompass perfectly the smaller original supports. This hierarchical system is commonly used for reporting census data. For example, in the UK census, enumeration districts (EDs) are encompassed within wards, which are themselves encompassed within metropolitan districts. Other forms of weighted averaging (e.g., the kernel density estimation used to create surface population models) involve interpolation and, thereby, some smoothing of the original data that occurs not only as a result of natural averaging but also as a result of interpolation. That is, the resulting support is larger than intended by the investigator and this causes problems in subsequent analysis.

Downscaling

Whereas upscaling is fairly straightforward given appropriate data, downscaling is relatively complex. It involves

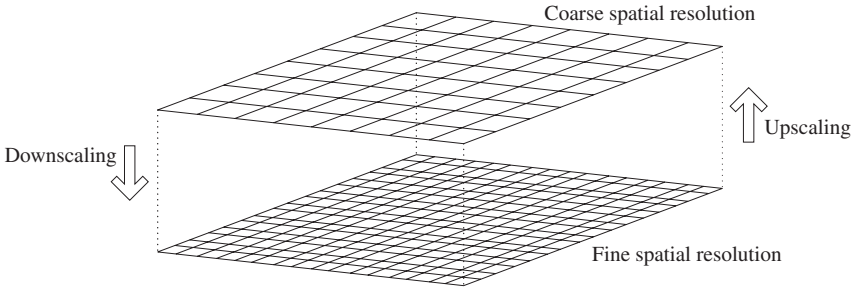

Figure 6 Two raster grids with different spatial resolutions illustrating upscaling (reducing detail) and downscaling (increasing detail).

increasing the spatial resolution of data. From theory, it is not possible to create new information (i.e., more than that provided in the original sample) by manipulation. However, in practice, downscaling may be achieved by transforming information from a nonspatial dimension into the spatial dimension or by simulating (thereby creating data but not new information about the property of interest).

Downscaling by Optimization

An example of downscaling was provided by the so-called superresolution mapping of land cover conducted by Tatem *et al*. in 2001. Multiple-waveband remotely sensed imagery was used to create a superresolution classification of land cover (e.g., woodland, grassland, and water)—that is, at a spatial resolution finer than that of the original imagery. This was achieved in two stages. First, multiwaveband values were used to predict land cover proportions per pixel using regression-type algorithms. Thus, a single pixel might be predicted to contain 70% woodland, 20% grassland, and 10% water. The prediction of land cover proportions (i.e., multivariate data) is made possible by the multi-waveband data provided in remotely sensed imagery. Second, the proportions in each pixel were allocated to subpixels within each pixel on the basis of some model of the character of spatial variation (e.g., variogram) and neighboring pixel values. This was achieved using an optimization algorithm.

Downscaling by Simulation

It is possible to create data at a smaller sampling interval than that of the original data by simulation. Simulation is most sensibly achieved if the model used takes into account both the actual values and the character of spatial variation in the original data. Such a model is provided by the geostatistical technique known as conditional simulation. Although no new information is provided, such simulated data can be useful for a variety of purposes (e.g., as input boundary conditions for spatially distributed dynamic models). For example, research has recently focused on dynamic modeling of the evolution of cities using cellular automata. Empirical data to drive such models are often provided by archive maps at coarse spatial resolution. Downscaling has the potential to provide realistic data with which to (i) run the model and (ii) evaluate uncertainty in the input data (since downscaling by simulation provides alternative realizations).

Scaling the Model

The geostatistical operation of regularization allows the variogram (or, alternatively, covariance or autocorrelation function) model to be scaled instead of the data. This is important because at the new spatial resolution, (i) the variogram describes the spatial variation evident; (ii) it is possible to obtain summary statistics, such as $D^2(v, V)$ and $D^2(v, \infty)$, from the variogram; and (iii) it is possible to (conditionally) simulate using the variogram. Thus, if it is possible to change the scale of measurement (i.e., the support) of the variogram, then it is possible to apply all of the previous functions at the new support without actually measuring on that support. A further example is provided by the image and scale variance statistics given previously, which can be predicted for different supports from the regularized variogram, without the need to coarsen the spatial resolution of the data.

The relation between the punctual or point semivariance and the regularized (defined on a support of positive size) semivariance at a lag $\mathbf{h}$ is given by

$$\gamma_v(\mathbf{h}) = \bar{\gamma}(v, v_{\mathbf{h}}) - \bar{\gamma}(v, v), \tag{10}$$

where $\bar{\gamma}(v, v_{\mathbf{h}})$ is the integral punctual semivariance between two supports of size $|v|$ whose centroids are separated by $\mathbf{h}$, and $\bar{\gamma}(v, v)$ is the average punctual semivariance within an observation of size $|v|$ (known as the within-block variance).

In words, the variation in the sample is equal to the variation in the property of interest minus the variation averaged out (i.e., lost) within the support. Thus, the variation discernible in spatial data is always less than that in reality because some variation is lost as within-block variance. This equation underpins the notion that data are always a function of the sampling framework and reality. It also explains why variance decreases as support size increases.

Figure 7 shows a punctual (point) variogram regularized to three different positive supports. Notice that the regularized variograms have a decreased sill variance (i.e., the within-block variance has been removed).

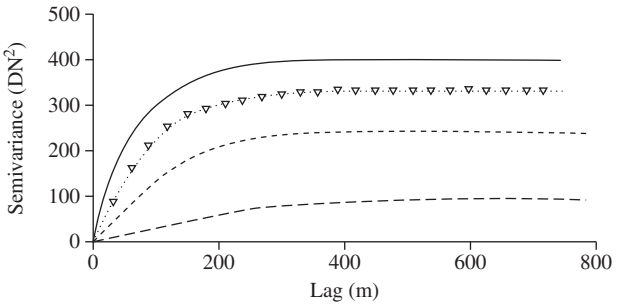

Figure 7 A punctual (point) exponential variogram model regularized to three different supports: 30 m (dotted line), 90 m (short dashed line), and 260 m (long dashed line). The symbols represent the experimental variogram observed on a support of 30 m.

Problems in Social Measurement

Here, two hypothetical examples from the social sciences in which individuals are averaged are considered; the first involves a constant support and the second a variable support.

Disease Risk

Disease risk is usually predicted as the number of infected individuals divided by the at-risk population:

$$\text{Risk} = \frac{\text{Infected}}{\text{At-risk population}}. \quad (11)$$

The at-risk population is often unknown, and in some cases it may be replaced by the total population. This value is reported for a given area (e.g., 1×1 km). There are several points to make about such a value.

First, the numbers involved affect the precision with which the value is known. The size of the at-risk population is inversely related to uncertainty: Small populations have greater uncertainty. Unfortunately, the at-risk population is likely to vary locally and, thus, uncertainty does also. For this reason, several authors have used a procedure known as empirical Bayes estimation in epidemiology to moderate extreme values that are less certain. Essentially, the information on risk (left-hand side of Eq. 11) and uncertainty (denominator in Eq. 11) is conflated into a single value (moderated risk). The smaller the denominator, the larger the moderation of the risk toward the mean. Uncertainty makes size of support an important consideration because generally, larger supports are likely to include a larger underlying at-risk population. For disease risk data, there is thus a trade-off between spatial resolution and precision of the variable.

Second, the number at risk (which inevitably will vary spatially) may affect the actual risk. For example, for contagious diseases the risk is often found to increase with population density (e.g., in urban, relative to rural, areas contagious diseases may spread more easily as a function of increased probability of contact). Thus, the scale of the process of infection may vary locally. Where the support is constant across space, this variation (in risk) may be difficult to separate from variation in uncertainty. Where the support varies locally to maintain a relatively constant underlying population, the risk and support effects may be confounded.

Despite the previously discussed issues, an advantage of disease risk data defined on a support that is constant spatially is that one cell may reasonably be compared with another, and classical statistical and geostatistical methods may be applied directly. Any scales of spatial variation existing between the 1×1 km supports may be detected and analyzed by the investigator. Spatial variation between point locations within each support will be averaged out and obscured from the investigator (Eq. 10).

The previous discussion implies that the support should be chosen carefully so as to resolve the spatial variation of interest. The tools discussed previously (e.g., the local variance plot and variogram) that describe the spatial variation in data can be helpful in making such a choice. Consider the plot of local variance against pixel size shown in Fig. 4. Most variation exists at scales of approximately 100–130 m. Thus, a new cell of up to 10 m on a side should be sufficient to resolve the spatial variation of interest. This new pixel size would be efficient because most of the information of interest would be conveyed at a much reduced data cost. The ability to make such choices about spatial resolution (i.e., scale of measurement) based on an understanding of spatial scale can be helpful to investigators.

If the support of the disease data were decreased to 100×100 m (i.e., an increase in the spatial resolution), then more variation would be revealed and, importantly, variation with a smaller range would be detectable. Problems inevitably occur as the support is decreased further: The risk per unit area is only defined for a limited range of support sizes. Although it may be possible to define risk on a 1×1 m support, it would be impossible to obtain suitable data with which to predict it. At the individual level, the actual property must be defined differently (i.e., risk per individual). In such cases, individual object-based models such as agent-based models must replace geostatistics.

Census Data

Census data are usually provided as values for census units that vary spatially in size, geometry, and orientation (Fig. 2B). This variation leads to the modifiable areal unit problem (MAUP). The main problem with such data is that since the support is not constant across space, it is not reasonable to compare values directly, and it is therefore not possible to apply classical statistical and geostatistical techniques directly to such data without modification. Why is this so? From Eq. (10), it can be seen that variation is a function of the support: larger supports lead to less variance (smoother variation) and *vice versa*. In census data, in which the supports vary hugely from place to place, comparison between data is problematic. The MAUP is often said to comprise two main components: the aggregation and zonation problems.

The Aggregation Problem

The aggregation component of the MAUP is similar to the regularization described previously. In the UK census, for example, data are presented for EDs. This is the smallest UK census unit. EDs are then aggregated into wards, metropolitan districts, and so on. The statistics associated with a given property (e.g., the number of cars per household per census unit) are affected by the level of

aggregation (i.e., EDs, wards, etc.). In particular, the variance is found to be less for larger units.

Much research in the social sciences has used correlation and regression analyses to describe the relations between variables. Researchers have found that the correlation coefficient r and regression parameters (α, β_i, $i = 1, 2, \ldots, n$) obtained were often a function of the level of aggregation. The specific case of the well-documented ecological fallacy arises when the results of an analysis conducted on aggregate data are used to describe individuals that form those aggregates. The ecological fallacy is thus a source of bias. Equation (10) provides an explanation, at least, for the ecological fallacy.

The aggregation problem for census data is much more problematic than previously implied. The ecological fallacy, for example, would hold true for image data. For census data, the problem is compounded by variation in the size, geometry, and orientation of the support across space. Essentially, a single data set of n units may comprise n different levels of aggregation and, therefore, n different variances. This problem is not resolved so readily, and it is the subject of current research.

The Zonation Problem

The zonation component of the MAUP is essentially a problem of small sample size (for aggregate statistics such as the variance). The problem is essentially that the actual realization of the sampling configuration (zonation) may have a major effect on the resulting statistics. For example, consider that a hot spot (in number of cars owned per household) exists in a given locality. If a census unit overlaps this area exactly, then the hot spot will show up clearly. If two units cross the hot spot and average its values with smaller values in neighboring areas, the hot spot will be greatly diminished in magnitude. Such effects are difficult to predict. In consequence, the single zonation provided by census bureaus such as the UK Office for National Statistics may be considered insufficient for mapping purposes. If many alternative realizations (zonations) were provided, the sampling may be adequate, and statistics such as the variance would converge to stable estimates. The problem then is that the spatial resolution is effectively increased and confidentiality may be compromised.

Conclusion

Problems of spatial scale are inevitably associated with problems of measurement and sampling. The scales of spatial variation detectable in spatial data are a function of (i) the intrinsic scales of variation that exist in the phenomena of interest in reality and also (ii) the scales of measurement encapsulated in the sampling framework. This statement is true whatever the nature of measurement: Even our own senses provide us with averages. After data are obtained, they represent the property of interest (and the statistics that describe it) defined on a given support and sampled with a given framework. Often, it is desirable to change that framework, but to do so requires some fairly sophisticated spatial statistical techniques. Of great theoretical interest is the geostatistical operation of regularization since this amounts to rescaling the model rather than the data. In the future, it would be useful to build the regularization operation into a spatial models to allow rescaling.

The problems associated with spatial scale for the social sciences are many and varied, not least because the underlying object of interest is usually the individual, and yet data are commonly reported as densities per unit area. Currently, the MAUP is the major scale issue for the social sciences because it is not possible to step beyond the initial impasse that cells should not be compared (therefore, variance, variograms, etc. cannot be estimated). It is possible to redistribute the varying areal units onto a raster (square) grid of equal cells (pixels). However, Atkinson and Martin have shown that this is valid only for very large new cells (i.e., there is much averaging involved) such that most information is thrown away. What is needed is a means of fitting a punctual (point support) model to variable areal unit data. This is the subject of current research.

James Penny†
CASTLE Worldwide, Inc., Morrisville, North Carolina, USA

Glossary

classical test theory A theory with the basis that an examinee's observed score on a test is the sum of a true score component and an independent random error component.
internal consistency Reliability of test scores based on the statistical association of responses to items within a test.
measurement error The difference between the observed score and the true score.
observed score A number that provides a description of an examinee's performance on a test.
parallel forms Tests that are considered interchangeable in that they have the same purpose, measure the same construct in the same manner, and use the same directions for administration. Statistically, parallelism requires the tests to have equal raw score means, standard deviations, error structures, and correlations with other tests.
parallel split method Estimation of reliability from the administration of a single test by the systematic division of test items to construct two interchangeable half-tests.
random error Nonsystematic measurement error that contributes to the variability of observed scores.
random split Estimation of reliability from the administration of a single test by the assignment of items by chance to construct two half-tests.
reliability Consistency of scores over repeated applications of a test across conditions that can include test forms, items, occasions, and raters.
reliability coefficient A statistical indicator that reflects the degree to which scores are free of random measurement error.
true/universe score The average of the scores that an examinee would obtain on an unlimited number of parallel tests.

Split-half reliability is a special case of the theoretical construct of reliability, which refers to the consistency of scores when a test is repeated on a population of examinees. The split-half procedure uses examinees' responses on a single test form to estimate score reliability. The test form is split by assignment of its items to two test halves. Scores from the two halves subsequently are used to estimate the degree to which scores would be similar if examinees were to complete a parallel test composed of similar items.

Introduction

Defining Reliability and Split-Half Reliability

The purpose of split-half reliability is to estimate the degree to which the results of a test would be similar if examinees were to complete a parallel test composed of a sample of similar items that measure the same construct. Split-half reliability is a special case of the theoretical construct of reliability, which refers to the consistency of observed scores when a test is repeated on a population of examinees or experimental subjects.

In classical test theory, the observed score (X) consists of two components, $T + e$, where T is a true score component of the observed score and e represents a random error component of the observed score. The true score is "conceptualized as the hypothetical average score resulting from many repetitions of the test or alternate forms of the instrument" (American Educational Research Association [AERA], American Psychological Association

[APA], & National Council on Measurement in Education [NCME]). The hypothetical difference between an examinee's observed score on a test and the examinee's true score for the instrument is referred to as measurement error.

Various sources of random measurement error contribute to the inconsistency of observed scores, and the testing community has developed procedures for estimation of reliability that take into account these error sources. In all these procedures, the purpose is to investigate the degree to which the observed scores for examinees reflect their true scores. For example, test scores for a population vary across the different occasions of a test administration. This source of score inconsistency addresses the temporal instability of examinees' test scores. When test developers want to estimate score consistency across different times, such a reliability investigation requires the use of test–retest procedures in which the same test form is administered to the same group of examinees on at least two occasions.

Additionally, observed scores of examinees vary across samples of items or tasks associated with a measure. Thus, error is attributed to the sampling of items in a content area, and reliability is assessed through the administration of parallel forms of a test. A third instance of measurement error reflects the variation of examinees' scores across items within one form of a test. It is the estimation of reliability in these instances that requires application of the split-half method or some other form of estimation of internal consistency.

Use of Split-Half Reliability

The estimation of score reliability across samples of items, as mentioned above, can be achieved through the use of the parallel form method. However, in some instances, the administration of parallel forms of a test is not possible. In such cases, test developers estimate reliability based on examinee responses to one test form. Feldt and Brennan indicated that reasons for the need to estimate reliability with only one form include (a) only one form of a test is produced because of the rare need for a second form; (b) the trait being measured is subject to rapid change, and (c) practical considerations might not permit the administration of more than one form of a test. It is these instances where the split-half method proves essential for the estimation of reliability. As Feldt and Brennan wrote,

> *For more than three quarters of a century, measurement theoreticians have been concerned with reliability estimation in the absence of parallel forms. Spearman (1910) and Brown (1910) posed the problem; their solution is incorporated in the well-known formula bearing their names.*

History

In 1910, Spearman and Brown simultaneously published articles in the *British Journal of Psychology* that outlined a method for splitting a test into two halves in order to investigate reliability. Spearman outlined the following method:

> *Let each individual be measured several times with regard to any characteristic to be compared with another. And let his measurements be divided into several—usually two—groups. Then take the average of each group; this we will term the "group average."* The division into groups is to be made in such a way, that any differences between the different group averages (for the same individual) may be regarded as quite "accidental." *It is further desirable that the sum total of the accidental variations of all the individuals should be not very unequal in the different groups; ordinarily, this will occur without further trouble, but in any case it can be arranged.*

Spearman subsequently described the method of splitting the test into two halves composed of odd items and even items that has become associated with the estimation of split-half reliability

> *A test of verbal memory, for instance, might well consist of memorizing twenty series of words. . . . Then series 1, 3, 5, . . . 19 would suitably furnish one group, while the even numbers gave the other. Any discrepancy between the averages of the two groups might, as a rule, be regarded as practically all due to the "accidents."*

Spearman offered the equation shown below for estimation of the increase of the reliability coefficient that was based on the division of measurements into two groups.

$$r_w = \frac{pr_{ab}}{1 + (p-1)r_{ab}} \tag{1}$$

where r_{ab} is the reliability coefficient based on the halves of the test, p is the number of times the test is lengthened or shortened, and r_w is the estimated reliability coefficient for the whole test. (When appropriate, subscripts across equations have been standardized to facilitate interpretation and comparison of the formulas.)

The focus of Brown's article was a study of the extent that a correlation exists between simple mental abilities and a general intellectual ability. The study was to examine the hypothesis of one single "central factor." In the study, many of the tests had two measures (parallel forms) that were amalgamated to form scores for correlation with other measurements. Brown labeled the reliability estimates for the measures as the *reliability coefficient* (r_2) *for amalgamated pair of tests*. The accompanying formula is the well-known

$$r_2 = \frac{2r_1}{1 + r_1} \tag{2}$$

where r_1 is the reliability for each test and "r_2 measures the extent to which the amalgamated results of the two tests would correlate with a similar amalgamated series of two other applications of the same test" (from Brown).

Methods for Calculation

Methods of Forming Split-Half Tests

Estimation of reliability through the use of the split-half procedure first requires the test developer to form the two halves of the test. The methods used to create the two halves include the assignment of odd items to one half and even items to another half, the random distribution of items to the two test halves, the allocation of items to form parallel halves, and the assignment of items to the two test halves to maximize item covariances.

Odd/Even Splits

Spearman described the development of the two test halves by the assignment of odd items to one half-test form and the even items to the other half-test form. More recently, Thorndike, Cunningham, Thorndike, and Hagen indicated that an even/odd split might be reasonable because items of similar form, content, or difficulty are likely to be grouped together. In essence, the even/odd split would produce two halves likely to be equivalent.

Random Splits

Early texts described the split-half method as forming chance halves of scores based on a single test administration (e.g., Brownell). In terms of random splitting, Cronbach used a test of vocabulary items to calculate the reliability estimates associated with all possible splits. He reported that the reliability coefficients ranged from 0.766 to 0.872 with a median of 0.823. He also noted that the random splits yielded tests that were not comparable in difficulty and variance. Cronbach recommended that the splits that are not comparable should be discarded. He also recommended that test developers should provide the means and standard deviations of the half tests.

Parallel Splits

The current *Standards for Educational and Psychological Testing* has taken the stance that the use of the split-half procedure to estimate reliability requires that the halves are parallel in content and statistical characteristics. Cronbach offered a method for the construction of the split-halves consistent with this guideline. Analogous to the parallel form method, the parallel split method requires the test developer to split the test items to construct two forms that are similar in content, difficulty, and range of difficulty. In order to do so, the test developer initially completes an item analysis of a subset of papers that will not be used in the subsequent reliability estimation. The information from the item analysis is used to select pairs of items with the same difficulty levels. Crocker and Algina indicated that test developers may rank order the items by difficulty and assign items with odd ranks to one form and even ranks to another form. Other considerations in the formation of parallel splits include (a) the assignment of items with similar content to the two test halves and (b) the pairing of items with the same format, such as multiple-choice with multiple-choice, true–false with another true–false. In the case of a group of items that deal with a single problem, such as a reading passage, the items are assigned intact to one half of the split.

Thus, the parallel split method illustrates that the split-half method of reliability estimation is theoretically similar to the parallel form method. This similarity is further reinforced by Cronbach in his consideration of the possibility that pairing of items in the parallel split method might introduce spurious factors in the reliability estimation. Cronbach posed the rhetorical question, "Would such a pairing be used in creating a parallel form of the test?" He then presented the parallel split method as analogous to the assignment of items to parallel forms.

Cronbach also applied the parallel splits method to the vocabulary data used for the random splits estimations of reliability. For the parallel split method, he reported that reliability coefficients ranged from 0.774 to 0.858 with a median of 0.825. In contrast to the random split method, the parallel split generally produced test halves of comparable means and variance. Given the similarity of the range of reliability estimates, Cronbach concluded the parallel split method did not offer much of an improvement over the random split for this one-factor test of vocabulary items. In 1951, Cronbach indicated that "marked variation in the coefficients obtained when a test is split in several ways can result only when (a) a few group factors have substantial loadings in a large fraction of items or (b) when first-factor loadings in the items tend to be very small or where they vary considerably."

Maximization of Item Covariances

Callender and Osburn described a method that optimizes the split-half coefficient by assigning items to the two test halves so that the sum of the item covariances is maximized. The procedure, referred to as MSPLIT, results in reliability estimates higher than KR20 and odd–even splits. The authors concluded that the procedure results in "somewhat inflated estimates of the corresponding population coefficients." If the method is applied to a subset of papers that will not be used in the subsequent reliability analysis, then the use of MSPLIT is analogous to

the use of item statistics in the formation of parallel splits. Thus, information about the test items is used to assign items in a manner that creates forms of similar content, difficulty, and variation.

Calculation of the Reliability Coefficient

Split-half reliability is typically estimated with the use of a Pearson correlation. Subsequently, the Spearman–Brown prophecy formula is applied to estimate the reliability of the full-length test. The Spearman–Brown method assumes that the two halves of the test are parallel. Parallelism requires that an examinee has the same true score across forms and the mean, variance, and error are the same across forms. If not, the estimated full length reliability for Spearman–Brown will be greater than obtained by other measures of internal consistency.

Not all calculations of split-half estimations use the Pearson correlation. Rulon provided two split-half formulas that he attributed to John Flanagan. One formula is based on the standard deviation of difference scores between the half-tests. The formula is

$$r_w = 1 - \frac{\sigma_d^2}{\sigma_w^2} \tag{3}$$

where $d = X_a - X_b$ and σ_w^2 is the variance for the whole test. Assumptions for this formula include (a) the difference between the two true scores for the two half-tests is constant for all examinees, and (b) the errors in the two half scores are random and uncorrelated.

The other formula is

$$r_w = \frac{4\sigma_a\sigma_b r_{ab}}{\sigma_w^2} \tag{4}$$

where σ_a is the standard deviation of scores for one test half and σ_b is the standard deviation associated with the other test half. Unlike the Spearman–Brown formula, these formulas do not require equivalent halves with equal variances. Both assume experimentally independent halves. Neither reliability estimate requires the application of the Spearman–Brown prophecy formula. Guttman offered the following contribution to the estimation of split-half reliability

$$r_w = 2\left(1 - \frac{\sigma_a^2 + \sigma_b^2}{\sigma_w^2}\right) \tag{5}$$

The terms σ_a^2 and σ_b^2 represent the variance associated with each test half.

If variances are equal on the two halves, the reliability estimate based on Spearman–Brown will be the same as achieved with the split-half procedures described by Rulon and Guttman. Moreover, the strict equality of variances is not required for convergence of reliability estimates across methods. According to Cronbach, if the ratio of the standard deviations for the two test halves is between 0.9 and 1.1, then Spearman–Brown gives nearly the same result as Eqs. (3) and (5).

Applications

To this point in the article, the discussion of the split-half method has focused on its application in the estimation of reliability based on a set of items administered as a single test form. Such a reliability estimate is completed to determine if results would be similar if students took a test composed of similar items. Cronbach indicated the purpose was to predict the correlation between two equivalent whole tests with two halves of a test. Thus, the method focuses on the consistency of performance across parallel sets of items.

An extension of the split-half method is seen in the estimation of interrater reliability. The scoring of constructed-response items, such as essays or portfolios, generally is completed by two raters. The correlation of one rater's scores with another rater's scores estimates the reliability scores based on a single rater. However, the reported score is often the average of the two scores assigned by the raters. If raters and observers are conceptualized as forms of a test (e.g., Feldt and Brennan), then pooling ratings is analogous to lengthening a test. Thus, the application of the Spearman–Brown prophesy formula to estimate the reliability for scores based on two raters is appropriate. As equivalence is assumed in the application of the split-half reliability estimation, the use of Spearman–Brown prophesy formula to estimate the reliability of scores based on two raters requires that the raters are equally qualified and producing ratings of similar means and variances. The addition of less qualified raters can weaken the reliability of the ratings.

Relationship to Other Reliability Coefficients

Cronbach's Alpha

In 1951, Cronbach introduced the alpha coefficient as an index of equivalence.

$$\alpha = \frac{k}{k-1}\left(1 - \frac{\sum \sigma_i^2}{\sigma_w^2}\right) \tag{6}$$

where k is the number of test items and σ_i^2 is the variance of item i. Using the split-half formula of Guttman, Cronbach demonstrated that alpha is the "mean of all split-half coefficients resulting from different splittings of a test." In addition, Cronbach

presented the split-half coefficient of Guttman as a special case of alpha. More specifically, in the case of $k = 2$, substitution in Cronbach's alpha results in

$$r_w = \frac{2}{2-1}\left(1 - \frac{\sigma_a^2 + \sigma_b^2}{\sigma_w^2}\right) = 2\left(1 - \frac{\sigma_a^2 + \sigma_b^2}{\sigma_w^2}\right) \quad (7)$$

Kuder–Richardson Formula 20 (KR-20)

In the instance where the items are dichotomous, item variance is written as $\sum p_i q_i$ and the above equation for coefficient alpha becomes Kuder's and Richardson's well-known KR-20,

$$r_w = \frac{k}{k-1}\left(1 - \frac{\sum p_i q_i}{\sigma_w^2}\right) \quad (8)$$

G-theory and Intraclass Correlations

The G- and D-coefficients of generalizability theory and Cronbach's alpha are special cases of intraclass correlations. Hoyt applied analysis of variance techniques to the estimation of reliability as the ratio of

$$r = \frac{MS_{persons} - MS_{pi}}{MS_{persons}} \quad (9)$$

where $MS_{persons}$ is the mean square for persons from an analysis of variance and MS_{pi} is the mean square for the person-by-item interaction. Hoyt's derivation, according to Cronbach, results in a formula equivalent to alpha. As such, intraclass correlations are linked to split-half reliability.

Limitations

Lack of a Unique Reliability Estimate

The lack of a unique reliability estimate received much attention in the early 1900s. For example, Brownell noted the wide variability of reliability estimates based on different splits. Cronbach wrote that "... chance element in splitting makes the reliability coefficient in error by an undetermined amount." Cronbach, however, noted this problem existed for all estimations of reliability for parallel forms. As an example, he noted that a test with four forms produces six reliability estimates, thus having no unique reliability estimate. This problem extends directly to split-half estimates of reliability owing to the different values that can arise from the different possible splits one might create for the computation.

Inflated Estimates of Reliability

Split-half reliability estimates based on an odd–even split will yield inflated reliability coefficients for speeded tests. Thus, tests designed to reflect the rate of work should use parallel form or test–retest approaches to assess reliability. Also, the use of split-half to estimate reliability when halves have unequal standard deviations can result in some inflation of estimates. When used in power equations to determine the sample sizes required to test the equality of two coefficients, Charter reported that the Spearman–Brown corrected split-half coefficients estimates may result in an underestimation of the requisite sample sizes.

Mixed Item Types

Although it is now common for an examination to be constructed using only one type of item (such as multiple-choice), more frequently national and state testing programs use tests composed of different item types, some of which do not produce dichotomous scores. If the split-halves technique is used to estimate the reliability of such tests, then the resulting reliability can be a function of the balance of item types in the two halves of the exam.

Several factors can depress the estimates of reliability for examinations containing mixed item types. These factors include (1) the relative restriction of range of dichotomous items as compared to scores produced for constructed-response items, (2) unanticipated changes in score distributions produced by mixed item types, (3) unexpected shifts in rater severity or leniency that can occur in the subjective evaluation of constructed responses but which are unlikely to influence the objective scoring of closed-form item types, and (4) unanticipated differences in difficulty that can arise with mixed item types. As mentioned earlier, the formation of parallel splits should take into account the item types in order to lessen any affect on the reliability estimates.

Item Difficulty

That test items can vary in difficulty is expected on most examinations, and this variability in difficulty can influence estimates of reliability produced using the split-half technique. If one split contains the easier items and the other split contains the more difficult items, the resulting reliability can be lower than it might otherwise be due to the potential disparate performance of students on the two sections of the exam. To lessen such influences, test developers can form parallel splits by using the statistical information from item analyses of a subset of tests that will not be used in the reliability estimation.

Item Placement

Even when a test is not explicitly designed as a speeded test, the possibility exists that elements of speededness will influence test results owing to the distribution of student ability. Students more deficient in the measured construct are often more likely to show fatigue earlier on the test than are the more able students, and for this reason, those less able students are more likely to perform more poorly on the items toward the end of the test. Hence, the latter test items have the potential to appear more difficult than the earlier items, producing the possibility of lower observed test reliability depending on which items are selected for the two halves.

Domain Sampling

Some examinations are constructed to assess a narrow domain. For example, one can easily find Italian vocabulary examinations targeted for particular levels of development. However, one can also find examinations designed to assess broader domains. To continue the example, one might consider an examination of students' grasp of the Italian language that addresses vocabulary understanding and their comprehension of reading passages.

The broader the domain sampled by the examination, the greater the possibility that the examination will exhibit multidimensionality, owing to the greater variety of cognitive skills required by students to successfully address the items and content. The degree of multidimensionality could influence the estimates of reliability produced by the split-half technique, depending on which items are assigned in which halves of the exam. Cronbach found that the parallel split is advantageous when group factors exist in a test and these group factors have loadings in the items that are larger than does the general factor.

Current Status and Directions for the Future

Nearly a century after the introduction of the split-half method, the role of split-half reliability is prominent enough to warrant explicit guidelines for its use in the current *Standards for Educational and Psychological Testing*. The literature in the social sciences continues to report reliability estimates based on the split-half method. In addition, test manuals often report split-half reliability estimates with other forms of reliability. A next step for the testing community is greater adherence to the recommendations advanced by AERA/APA/NCME for use of parallel splits in the formation of the test halves.

State Data for the United States

David M. Hedge
University of Florida, Gainesville, Florida, USA

Renée J. Johnson
University of Florida, Gainesville, Florida, USA

Glossary

analytic leverage The ability to explain social or political phenomenon with as few variables or little information as possible.
ecological fallacy Erroneously using group-level data to draw inferences about individuals.
measurement error Occurs when the procedure for assigning values fails to achieve either validity or reliability. The result is that differences in the values assigned to cases reflect flaws in the measurement process and not actual differences.
pooled cross-sectional, time series design Research design that examines variations across space and time.
significance tests A way of judging whether a particular value for a population parameter is plausible.

As the states assume greater authority for the governing of the United States, they truly can serve as "laboratories of democracy" by offering social scientists a unique context within which to examine basic questions concerning politics and policy. To achieve that potential, analysts must have access to valid and reliable state data and must address a number of issues concerning measurement and design. Fortunately, considerable progress has been made in recent years on both counts. There is an unprecedented amount of data available on the states, and social scientists are addressing several relevant methodological issues, including tests of statistical significance, ecological inferences, and the tradeoff between case studies and multistate analysis.

The States as Laboratories

The American states have frequently been hailed as "laboratories of democracy," a description often attributed to U.S. Supreme Court Justice Louis Brandeis in *New State Ice v. Liebmann* in 1932. The American states can also serve as laboratories about democracy. During the past several decades, there has been a marked resurgence of the American states. State governments have become more responsive to their citizens, the institutions of state government have been strengthened, and the states are assuming more responsibility for the day-to-day governing of the United States. However, what really commends the states as laboratories is their sheer diversity. Although a number of states have modernized their political institutions, many have not. Also, a review of the evidence suggests that some states are simply better at educating their children, reforming welfare, or regulating firms within their borders. It is those variations in politics and performance that offer scholars a unique opportunity to test fundamental propositions about politics and governance. Whether the states can play that role, however, depends in large part on the ability of scholars to obtain reliable and valid data on the states and successfully address key methodological issues surrounding the use of that information.

Sources of State Data

In 1982, Malcolm Jewell chided political scientists for doing too little systematic, comparative research on state politics. In seeking to reinvigorate the field, Jewell

argued that "the first need is for a much more comprehensive and systematic collection and analysis of comparative state political data" (p. 643). Although things were beginning to change when Jewell made his plea, few political scientists had the resources to mount a major data collection effort across multiple variables and states. Instead, scholars interested in doing comparative state politics research drew on just a handful of sources, most notably the "Statistical Abstract of the United States," the "U.S. Census of the Governments," and the Council of State Government's annual "Book of the States."

Much has changed since Jewell first issued his challenge. Today, political scientists have access to a stunningly large amount of data, much of which are available online or through various data archives scattered throughout universities and private organizations. The challenge today is to (i) identify available data and (ii) assess its validity and reliability. Neither task is easy. Although the amount of data on the states is seemingly boundless, there have been few efforts to catalog or archive the bulk of that information. The problems of reliability and validity are especially pronounced. Scholars who use what is essentially archival data have no control over what data are collected and, in many cases, too little information about how those data were collected.

Four kinds of data are available: data on (i) the states' economic and social characteristics (the "control variables" in much research), (ii) elections and parties, (iii) political institutions, and (iv) state policy outputs and outcomes. These data can be assessed through a variety of sources, including original data sources, data archives, and data links. Several online and published sources provide selected original data on some or all of the states in a particular area (e.g., health care or criminal justice statistics). In some cases [e.g., the Urban Institute's state database or data provided through the Inter-University Consortium for Political and Social Research (ICPSR)], data are available as downloadable data files. More typically, data are presented in tables and charts. In other instances, data and information have to be gleaned from narratives describing state programs. Data can also be accessed through a small number of data archives, including the ICPSR and Florida State University's State Politics and Policy Data Archive. Finally, a number of online sites provide links to a variety of data sources.

Original State Data Sources

U.S. Government

The U.S. government is the major source of original data on the American states. In addition to the Census Bureau, a variety of federal agencies provide considerable information on the condition of the American states and their citizens. The following is a partial listing of these agencies and the kinds of data they offer:

- Administration for Families and Children (Health and Human Resources): Data on Temporary Assistance for Needy Families (TANF) program spending, enrollment, recipient profiles, and workforce participation rates. Selected years available online at http://www.acf.dhhs.gov/acf_research_planning.html#stats.
- Bureau of the Census: "Statistical Abstract of the United States" (http://www.census.gov/statab/www). Online version of the "Statistical Abstract." Available for 1995–2002.
- Bureau of Economic Analysis, http://www.bea.doc.gov (Department of Commerce): State-level data on personal and gross state product, multiple years. Available online at http://www.bea.doc.gov/bea/regional/data.htm.
- Bureau of Justice Statistics, http://www.ojp.usdoj.gov/bjs (Department of Justice): Crime data since 1960 from the FBI's Uniform Crime Reports, homicide trends, and law enforcement activities. Available online at http://149.101.22.40/dataonline.
- Centers for Medicare and Medicaid Services, http://cms.hhs.gov/researchers/default.asp (formerly HCFA, Department of Health and Human Services): Links to extensive data sets on Medicare, Medicaid, and SCHIP enrollment and spending. Medicare enrollment data available online for the years 1985–2001.
- Energy Information Administration, http://www.eia.doe.gov (Department of Energy): "State Data Energy Report"—Data on state energy sources, consumption, and activities, 1960–1999. Available online at http://www.eia.doe.gov/emeu/sedr.
- National Center for Education Statistics, http://nces.ed.gov (Department of Education): "Digest of Education Statistics"—Comprehensive data set on enrollment, attendance, teacher/student ratios, teacher salaries, student achievement, expenditures, and reforms. Available online for the years 1996–2000.
- National Center for Health Statistics, http://www.cdc.gov/nchs/datawh.htm (Centers for Disease Control): Comprehensive source of state-level data on the health of the U.S. public, including mortality rates, women and children's health, the distribution of CDC expenditures, and environmental and occupational health concerns. Current data available online. Data for previous years available in hard copy.

Associations of State Officials

The National Conference of State Legislatures (NCSL), the National Governor's Association (NGA), the National

Center for State Courts (NCSC), and the Council of State Governments (CSG) do an excellent job of providing information on state politics, political institutions, and, increasingly, information and data on state policy issues and innovations. These associations also provide links to state agencies and other sources of information:

- CSG, www.statesnews.org: The CSG's annual "Book of the States" is a valuable source of information on the states' constitutions, political institutions, and finances.
- NCSC, http://www.ncsconline.org: Through its collaboration with the National Court Statistics Project, the NCSC has compiled an extensive caseload database for all states beginning with the year 1998.
- NCSL, www.ncsl.org: The NCSL offers a wealth of data on the states' legislatures, including information on campaign finance legislation, term limits, partisanship, and legislative compensation. Current data are available online. The NCSL also provides a limited amount of information concerning state policy initiatives across a number of areas.
- NGA, www.nga.org: The NGA offers online information summarizing state policy initiatives, including welfare, child health, the use of tobacco settlement funds, pharmaceutical regulation, and Medicaid programming.

Think Tanks/Research Organizations

Increasingly, some of the best data on state politics and policy are provided by think tanks located in Washington, DC, and elsewhere. Much of these data are online. The following is a sampling of these organizations and the kinds of data they offer:

- The Annie E. Casey Foundation, http://www.aecf.org/kidscount: KIDS COUNT is a project of the Annie E. Casey Foundation and represents a state-by-state effort to track the status of children in the United States. It provides various indicators of child well-being for each state.
- Environmental Defense Fund, www.edf.org: Environmental Defense Scorecard provides state rankings on health hazards from air pollution, air pollution levels, animal waste, and toxic chemicals (http://www.scorecard.org/ranking).
- The Henry K. Kaiser Family Foundation: State Health Facts Online (http://www.statehealthfacts.kff.org) Extensive online source of the latest state-level data on the health and health coverage of the states' citizens and state and federal health policy.
- Heritage Foundation, www.heritage.org: The foundation provides online information on charter schools in each of the states at www.heritage.org/schools. Includes Heritage's thumbnail sketch of each state's charter school legislation, an evaluation of state programs, and a count of charter schools/students in the state.
- Initiative and Referendum Institute, http://www.iandrinstitute.org: The institute offers, both online and in various publications, data on the incidence, nature, and outcomes of initiatives and referendum in each of the states for recent years.
- The National Institute on Money in State Politics: Follow the Money (http://www.followthemoney.org/database/enter.phtml) is an online source of data on campaign finance in the states. Covers the 1998, 2000, and 2002 elections.
- National Network of State Polls, http://www.irss.unc.edu/irss/nnsp/nnspindex.asp: The National Network of State Polls archive of state polls is the largest available collection of state-level data. It is part of the data archive of the Odum Institute for Research in Social Science. The archive contains approximately 60,000 items from more than 530 studies, contributed by 29 survey organizations in 22 states. More than 600,000 respondents contributed to the surveys.
- State Politics and Policy Quarterly Data Resource, http://www.unl.edu/SPPQ: Downloadable data set contains more than 40 state-level variables for multiple years. Set covers demographic, crime and policing, economic, state spending and taxing, and education data.
- State Policy Documentation Project (SPDP), http://www.spdp.org: A joint project of the Center for Law and Social Policy and the Center on Budget and Policy Priorities. SPDP tracked policy choices on TANF cash assistance programs and Medicaid in the 50 states and the District of Columbia from 1998 to 2000. The information presented on this Web site was collected through surveys completed by a key policy advocate in each state, confirmed by state agency staff, and verified against state statute and regulation by SPDP staff.
- The Urban Institute, http://www.urb.org: The Urban Institute's "Assessing the New Federalism" is a major, multiyear effort to assess the devolution of responsibility for social programs to the American states. Two major sources of data are available online—a large, downloadable state database and a case studies series that focuses on the efforts of 13 states. The state database (http://newfederalism.urban.org/nfdb/index.htm) includes more than 400 variables referencing state health and welfare programs, the states' poor population, and the states' economies. It is updated on a regular basis. The state case studies series (http://newfederalism.urban.org/html/state_ focus.html) reports additional data on

13 states—Alabama, California, Colorado, Florida, Massachusetts, Michigan, Minnesota, Mississippi, New Jersey, New York, Texas, Washington, and Wisconsin—in three case study reports. The first two involved site visits by institute researchers in 1996, and the third was compiled from the 1997 "National Survey of America's Families."

State Data Archives

- State Politics and Policy Data Archives—Florida State University, http://www.pubadm.fsu.edu/archives: During the past several years, scholars at the Askew School of Public Administration have maintained an archive on state data from published articles. A dozen downloadable data sets are available from articles published between 1992 and 1997.
- Inter-University Consortium for Political and Social Research (ICPSR), http://www.icpsr.umich.edu/org/index.html: The ICPSR is the largest archive of social science data in the world. Included in its vast holdings are the data files used in numerous published studies throughout the years, historical data on the states, as well as data from various federal agencies.

State Data Links

There are an increasing number of online sites that provide links to various data sources, many of which provide state-level data. The following are examples:

- *State Politics and Policy Quarterly*: In addition to its own data file, the journal also provides links to a dozen or so data sources at http://www.unl.edu/SPPQ/links.html.
- U.S. Bureau of the Census, Census State Data Centers, http://www.census.gov/sdc/www: The Bureau of the Census provides a link to each state's official data centers. These centers are official repositories of the census files for the state.
- University of California at Irvine, Social Science Data Archives, http://data.lib.uci.edu: This site is typical of sites offered at various universities in the United States that provide links to data sources, many of which report state-level data.

Methodological Issues

Although the states provide a unique and valuable setting for systematically studying politics and policy in the United States, there are several methodological challenges to researchers in this field, including the relative tradeoffs between case studies and multistate analysis, the use of significance tests, and issues of ecological inference.

Case Studies, Small-*N* Research, and Multistate Analysis

One of the principal reasons scholars choose to study state politics is its potential to serve as a laboratory of democracy. Given the variation in state politics, institutions, and policies, the states offer researchers a unique opportunity to examine the interactions between these variables in a rigorous fashion and, ultimately, test broader theories of politics and policy. The relative (to case studies and small N studies) advantages of 50 state analyses are obvious. Including all (or most) of the states allows the researcher to observe the often substantial differences in the phenomenon being studied (e.g., legislative professionalism, voter turnout, and educational achievement), analyze the influence of multiple variables, and draw upon statistical techniques to systematically sort their relative impacts. Also, of course, including each of the 50 states in the analysis allows the researcher to generalize study conclusions to the larger "universe" of American states.

In other words, the use of 50 states enhances the potential for analytical leverage. According to King *et al.* (1994), leverage entails "explaining as much as possible with as little as possible" (p. 29). Fifty-state studies attempt to utilize a few variables, usually institutional (e.g., party balance in legislatures or identity of the governor), economic (e.g., unemployment rate or fiscal health), and/or social (e.g., interest group organization and public opinion), to explain a state-level political phenomenon. In doing so, most 50-state studies are attempting to capitalize on the concept of leverage. There has been much debate about the success of 50-state studies in providing elegant explanatory models of state political processes. Some of this concern stems from the small R^2 that these models achieve compared with that obtained in other subdisciplines in political science. Nevertheless, many political methodologists argue that R^2 is not the most important way to measure the effectiveness of one's models.

The obvious advantages aside, 50-state studies often encounter methodological problems, some of which can neither be avoided nor corrected. First, many, perhaps most, multistate studies are cross-sectional, either by design or by necessity. In some instances, data on one or more key variables are simply unavailable. In other instances, the researcher's concern is only with a single point in time (e.g., the 2000 presidential election). In examining only one point in time, researchers can make mistakes in their inferences about the dynamics of the process. Where the necessary data are available, pooled, time series, cross-sectional analysis can and

should be used to more systematically model those processes. Pooled cross-sectional studies capture both the effects of space (variations across the 50 states at any point in time) and the effects of time to provide insights into the dynamic effects of political, social, and economic indicators. Nevertheless, pooled, cross-sectional, time series analysis has its own unique problems regarding modeling of both cross-sectional (state-by-state) variation and time-serial (over time) variation because each of these variations may have unique underlying explanations.

Because 50-state studies invariably rely on secondary data sources over which researchers have little control, these studies are especially susceptible to problems of incomplete and noncomparable data. Indeed, because of missing or invalid data many "50-state" analyses are not 50-state studies at all. Our 2002 analysis of state welfare policy provides an example of how easily this can happen. In examining the political and social correlates of state welfare policies, we, like researchers before us, included measures of the public's ideology and the level of interparty competition. As we proceeded with our analysis, our *N* quickly shrunk to just 44 states. Nebraska was excluded from the analysis because it is, after all, a nonpartisan legislature. Alaska and Hawaii were also excluded because of missing data on Erickson *et al.*'s public opinion variable. Also, for good measure, we excluded Nevada because of concerns about the validity of that state's public opinion score (Nevadans are not liberal despite what their score suggests). Two other states, Wisconsin and Vermont, were excluded from the analysis because they failed to report data on a child care variable that we were considering. Another concern is that states do not necessarily collect the same data in the same way. Criminologists, for instance, have long been skeptical of crime data reported by state and local officials because these data are often manipulated for political and fiscal reasons.

These and other data problems suggest the need to reconsider the role of the case study in state research. Historically, the bulk of research on the states concentrated on a single or small number of states. This approach is criticized on obvious grounds. Limiting the number of states included in the analysis limits the ability of the analyst to generalize his or her findings to other states and to sort out the influence of multiple variables. However, case studies can be particularly helpful in illuminating the richness and detail of state politics. Studies of one state can more accurately capture the nuances and complexities of political conditions. Often, a particular state may be unique in its institutional structure (e.g., Nebraska and its unicameral legislature) or innovative in its policy approach (e.g., Wisconsin and welfare reform) such that it warrants the type of in-depth examination a case study provides.

For example, Dan Smith analyzed roll call votes on three bills in Colorado to discover the determinants of legislative member voting on "counter-majoritarian" legislation. Colorado was an excellent domain for his analysis for several reasons. First, only 24 states allow direct legislation; Colorado has a long history of utilizing this process. Second, Colorado has had some very controversial issues on their ballot (school choice, abortion, term limits, etc.) that have received considerable national attention. Third, three bills introduced during the 1999 legislative session proposed legislation that was in direct opposition to recently passed ballot initiatives by the Colorado electorate. Thus, not only does Smith's analysis help state politics researchers to understand ballot initiatives in Colorado but also it provides a contextual understanding of how ballot initiatives might operate in other states. Studying one state also provides a good opportunity to compare local government performance while holding governmental structure constant. For example, Kevin Smith utilized school districts within the state of Florida to understand the dynamics of school choice.

Small and large *N* analyses are not mutually exclusive. State politics can benefit from combining 50-state analyses with more in-depth analysis of a small number of states. In his investigation of the relationship between state government and state economic performance, Brace utilized case studies of Arizona, Michigan, New York, and Texas to provide a rich description of different styles of state government interventions on the economy. In addition to case studies, Brace provided a comprehensive and concise model of the effect of state institutional, economic, and political characteristics on their economies across the 50 states.

The Question of Statistical Significance

An additional complication to the study of state politics is the question of statistical significance. There has been ongoing discussion regarding the appropriate use of null hypothesis significance testing in political science. Gill argues that the null hypothesis as traditionally taught and used in political science is deeply flawed and widely misunderstood. Although we do not intend to revisit this thoroughly discussed issue, we do think it is important to note how this debate uniquely affects the use of state data.

Despite the warnings of Gill and others, multistate analysis almost invariably proceeds by assessing claims against a null hypothesis (usually of no affect). However, because these studies usually encompass all 50 states, the data represent population, not sample, data. The test of statistical significance is typically taught and used to make inferences about a population using a subset of that population (preferably employing some form of random sampling technique). What is unusual about state data is that they often represent the population. As such, the normal process

of utilizing tests of statistical significance to make inferences to an unknown population parameter does not apply.

There is a counterargument to this logic. State politics and policy data, like much of political science and social science data more generally, are often plagued with measurement error. As such, the estimates that state research creates can still be thought to be estimates of unknown population parameters. With this conceptualization, hypothesis testing may still seem to be useful. Nevertheless, many argue that confidence intervals or, perhaps, more complex estimation techniques such as Bayesian methods are better suited to this type of data.

Ecological Inference

Problems associated with ecological inference frequently impede analysis of state data. According to King (1997), ecological inference "is the process of using aggregate (i.e., "ecological") data to infer discrete individual-level relationships of interest when individual-level data are not available" (p. xv). Often, 50-state studies collect aggregate state-level data on an outcome measure and its covariates and proceed to make inferences to individual-level behavior. In the study of public policy outcomes, ecological inferences are often utilized when recommending public policy action.

For example, in the field of state education policy, there is an extensive debate over the role of vouchers and school choice in improving education. One of the concerns in this literature is the effect that providing a school voucher to an individual to attend a private school has on that particular individual's performance in school. In order to accurately assess this situation, the researcher would need to compare individual student performance for those with vouchers and those without vouchers as well as those who would have attended private school without the voucher and those who only attended a private school because of the voucher. Because of confidentiality of individual student information, obtaining this information is either not legal or impractical. Instead, state politics researchers must rely on aggregate state data to make these inferences. Typically, researchers examine aggregate school-level variables, such as dropout rates, achievement scores, and percentage who attend college, and compare schools with a low proportion of voucher students to schools with a high proportion of voucher students.

There are several ways in which state-level problems with ecological inference can be solved. One way is to engage in the collection of individual-level data. State welfare policy researchers are often interested in making recommendations about which types of welfare programs are most successful at reducing the number of individuals on welfare and/or increasing the number of welfare recipients finding work. One of the ways in which this issue is studied is by using aggregate data. Typically, researchers collect data on welfare outcomes in the 50 states and analyze the effect that political, institutional, economic, and social factors have on welfare outcomes. From these findings, state policy researchers often make inferences to individual-level behaviors. However, using typical statistical methods, aggregate-level data do not provide the type of information necessary to make these individual-level inferences. Instead, researchers could survey former welfare recipients to determine whether they were subject to workforce participation requirements and whether they left welfare and found work. However, there are several limitations to this approach. First, generating a random sample of individuals that includes enough individuals who have been on welfare and have been subject to a program that involved workforce participation requirements is costly and impractical. Additionally, relying on individual survey responses may also introduce error into the model. Because being on welfare and out of work may be embarrassing to certain individuals, survey respondents may provide inaccurate information.

King argues that researchers can utilize information contained in aggregate data to solve some ecological inference problems. One problem with aggregate data is the assumption of constant parameters. In the school choice example, this means that aggregate models assume that voucher students across all types of schools attend college at the same rate. Obviously, characteristics of the individual schools might lead to some schools having high rates of college attendance and some having low rates of college attendance irrespective of the number of voucher students. To address this problem, King recommends specifying a model with random, rather than fixed, coefficients. A second problem is that standard regression models do not provide bounded parameter estimates even though results less than 0 or greater than 1 are not practically possible. A manifestation of this problem in the school choice example would involve predicting that more than 100% of voucher students attend college or fewer than 0% of nonvoucher students attend college. King's solution involves truncating the range of values to reasonable bounds for these coefficients. The reasonable bounds may include the entire range of possible values (0 and 100%) or, utilizing prior knowledge (often through Bayesian techniques) of school choice, the bounds may be limited to plausible values (20 and 80%).

Statistical Disclosure Control

Mark Elliot
University of Manchester, Manchester, United Kingdom

Glossary

analytical validity The veridicality of a data set in terms of analytical results produced by its users.
attribution The certain association or certain disassociation of a variable level (attribute) with a particular population unit.
data intruder An individual, group, or organization seeking to identify population units within an anonymized data set.
identification The association of a record within an anonymized data set with a particular population unit.
key variable Information known to a data intruder about a population unit that is also present on an anonymized data set.
reidentification A method of assessing the disclosure risk through matching experiments.
table linkage The combining of multiple smaller tables into larger tables with a higher potential for disclosure.
unique(ness) A record that is distinct from all other records with respect to a set of variable levels within a sample (sample uniqueness) or population (population uniqueness).

Statistical disclosure control concerns preventing the identification of individual population units and/or the disclosure of information about individual population units through statistical processes such as matching identification information to records within anonymized data sets. Research into statistical disclosure control is concerned with the development of statistical and computational methods in three categories: disclosure risk assessment methods, disclosure control methods, and information loss assessment methods. All three present complex and difficult challenges to researchers whose work encompasses diverse academic disciplines, including statistics, mathematics, computer science, psychology, and social policy.

Introduction

The issues of statistical disclosure have become increasingly important with the exponential increase in computing power and the near-universal availability of Internet connectivity. The concept of statistical disclosure could be defined as follows.

The revealing of information about a population unit through the statistical matching of information already known to the revealing agent (or data intruder) with other anonymized information (or target data set) to which the intruder has access, either legitimately or otherwise.

Disclosure is viewed as a potential problem because information that is released in an anonymized form has invariably been collected with assurances of confidentiality by the data gatherer. This is perceived by national statistical agencies as being particularly important for national censuses, where there is a legally enforced obligation for all members of a given population to participate and where a breakdown of trust in the confidentiality of the process might lead to a reduction in the cooperation of the population and therefore undermine the purpose of the census.

Disclosure, Identification, and Attribution

Statistical disclosure has two components: identification and attribution. Identification is the association of a particular record within a set of data with a particular population unit. Attribution is the association or disassociation of a particular attribute with a particular population unit. The relationship between the two is complex and they can take place independently of one another.

Attribute disclosure can occur without identification if it can be inferred from the anonymized data that all

population units who possess a set of attributes $(X_1, \ldots, X_n)$ also possess attribute X_{n+1} (positive attribute disclosure) or if all population units who possess a set of attributes $(X_1, \ldots, X_n)$ do not possess attribute X_{n+1} (negative attribute disclosure). Therefore, if a data intruder has an identification record including attributes $(X_1, \ldots, X_n)$, then X_{n+1} can be attributed or disattributed to the identification record. Conversely, if an intruder already knows all attributes within a record (or cell within a table), then identification can take place without attribution. These two situations encapsulate the disclosure risk problem for aggregate tabular data, where one is more concerned about attribution. Such data are often released as full population data, making verification of attributions simple.

Identification disclosure, as represented in Fig. 1, is usually regarded as paradigmatic of the disclosure risk situation for microdata (that is, files of records of individual population units). The situation in Fig. 1 can best be described as follows: a data intruder has a set of information or identification variables, which identifies a population unit, and a further set, the key or the key variables, which is also present in a target data set. The association of the key for the population unit with that of a record in the target data set leads to the inference of identification and the attribution or disclosure of the target variables for the population unit.

Actual and Perceived Risk

Another key distinction is between actual and perceived risk. Perceived risk is a complex psychosocial process and impacts at three different loci: the data intruder, the data gatherers, and the population.

The perception of disclosure risk by the data intruder clearly affects whether an attempt will be made. However, disclosure may be a secondary goal for an intruder in service of a primary goal, such as embarrassing the data gatherer. In 1999, Elliot and Dale developed an 11-point taxonomic system for assessing the risk that an intruder will attempt an intrusion, based on the perception that the intruder's own goals will be achieved.

The relationship between actual and perceived disclosure risk is nonlinear and attempts to model these processes have been limited. Although some progress has been made, most practical disclosure control and risk assessment research assumes that the probability of an attempt being made is unity and that the consequences of a successful attempt will be catastrophic in terms of loss of public confidence. Even with this substantial simplification, the processes of assessing and controlling disclosure risk are highly complex. Although the research issues have become considerably clearer, no definitive conclusions have been reached. The situation has been further complicated by the demands for measuring the impact of disclosure control on data quality.

Key Selection

One difficult issue in the analysis of disclosure risk is that of key variable selection. This is particularly an issue for microdata files, which can contain hundreds of variables, and thus analyzing all the possible combinations of variables produces a combinatorial explosion and is fcomputationally intractable. Although advances using high-performance computing have enabled a more comprehensive approach, the issue of which combinations of variables to select is still complex. The usual resolution of this issue is the development of "scenarios of attack." These are scenarios that specify the information that an intruder is likely to have access to. Another approach is to set a base key of common variables and then add each other variable in turn to examine its additional impact. This is useful in assessing which variables contribute most to the overall risk of the file.

Whatever decision is made about key variable selection one needs, when engaged in practical disclosure control for microdata, to be aware that it is always possible that the intruder will have access to information that lies outside the specified key.

Disclosure Risk Assessment

The first step in any well-formed disclosure control regime is an appropriate type of disclosure risk assessment. In the early days of disclosure control, measurement of risk was not well understood and proxy measures

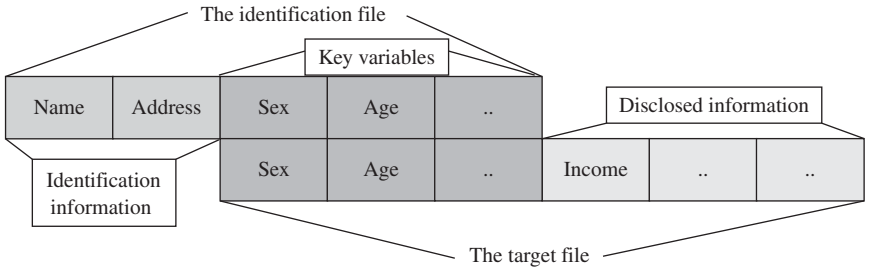

Figure 1 An illustration of the key-variable-matching process leading to disclosure.

such as thresholds on raw frequency counts, were often used. However, measures have become more sophisticated and, although not fully conceptualized, the problems are well defined. Furthermore, increases in computing power have allowed for more in-depth analyses.

Risk Assessment for Microdata

There are essentially two analytical frames for measuring risk for microdata, which both have their uses. The first (file-level risk) focuses broadly on the whole of the data set in question; the second (record-level risk) focuses on individual population units. A third theme in microdata risk assessment is the use of matching or reidentification experiments.

File-Level Metrics

Measuring risk at the file level provides a broad way of summarizing risk for a set of data. This allows the appropriate decisions to be made regarding the level of coding for variables and sampling fraction for a file. The archetypal file-level measure is the level of population uniqueness. This is the proportion of population units that are unique on a given key. The rationale for this metric is as follows: if the intruder knows that an individual is unique in the population on a given set of attributes, and she or he finds a record with such attributes in a target file, then identification disclosure has taken place.

A variation of the population uniqueness metric is the proportion of sample unique records that are also population unique. The argument for this metric is that an intruder with access to a target data set will focus on the records that are unique within the sample on a given key and then attempt to find population units that correspond to those records.

However, these measures are flawed since they presuppose that the intruder information is 100% compatible and there is no obvious systematic way of adjusting them to allow for more realistic assumptions. Furthermore, the measures require that the data holders themselves will have access to population data, which, although a reasonable assumption for full census outputs, will not be the case for outputs from microcensuses or surveys. A final issue with these measures is that they are insensitive to variations in risk across a data set; i.e. they do not identify which records within a data set are risky.

Risky Records

To understand the risky records problem, consider the following situation: a neighbor of yours is a 16-year-old widow; examining a data set you find a record for 16-year-old widow who is coded as residing in your area. You infer that the record is that of your neighbor, because your common-sense demographic knowledge tells you that 16-year-old widows are very rare and therefore there are unlikely to be other such individuals in your locality. Such a record is called a risky record or a special unique.

A crucial aspect of disclosure risk assessment is to identify risky records. Some approaches, such as that of Skinner and Holmes, use statistical models of two-way interactions. Elliot and Manning have used a computational modeling technique that combines the sample uniqueness of combinations of variables within a key. These techniques appear to be successful in identifying sample uniques that are more likely to be unique within the whole population and therefore more risky. The advantage of these approaches is that disclosure control techniques can be targeted on the identified risky records and therefore hopefully do less damage to the data.

Matching

An important method for assessing disclosure risk pioneered by Muller *et al.*, and refined by Winkler, is the use of matching or reidentification experiments. In this method, the risk assessor attempts to match records on two files for which she or he has identification information, in order to establish the empirical probability of matching correctly. These experiments are very useful because they are closer to what an actual data intruder would do if attempting to identify a person in an anonymized data set. However, they have the major disadvantage in being *ad hoc*, i.e., specific to the data sets concerned. It is therefore difficult to draw general conclusions from these experiments.

The *ad hoc* and time-consuming nature of matching experiments indicates that it would be useful if a means could be used that allowed such experiments to be simulated in a more general way. Skinner and Elliot have developed a method for doing just this. By using a bootstrapping-like method called data intrusion simulation, Skinner and Elliot have shown that it is possible to obtain an accurate estimate of the bottom-line matching probability—the probability of a correct match given a match against a sample unique.

Risk Assessment for Tabular Data

Where data are released as a set of tables (or aggregated data) rather than as a sample of microdata, different issues present themselves. In principle, it is possible to view microdata as being derived from a single large table. However, release practices regarding the two forms of output are different and consequently the disclosure risk issues are also different.

(1) Aggregated data are often released as a set of tables (often many in number), whereas microdata are usually released as a single file. Each table will usually contain only a small number of variables, typically one to four.

(2) Aggregated data are often released at much lower levels of geographical detail than microdata.

(3) Aggregated data are often released with counts of whole populations, whereas microdata are usually released as a sample (typically less than 5%).

Many of the metrics that have been discussed here thus far are meaningless for aggregate data. The specific issues that arise are as follows: (1) avoiding cells within tables with low counts, particularly 0's (which can lead to attribute disclosure) and 1's (which give rise to identification), and (2) taking care that tables cannot be easily linked.

Table linkage occurs when information within cells from two or more tables is linked to produce a larger table or fragments of microdata. This can arise directly from uniques or empty cells; however, it need not do so, as Tables I–IV demonstrate. In Table I, there are three individuals who have attribute A and who also have attribute D. In Table II, there are only two individuals who have attribute A and who also have attribute E (and therefore do not have attribute F). Therefore, one can infer that at least one individual has attribute triple (A,D,F). Similarly, one can also infer that at least two individuals have attribute triple (A,C,F) and that eight individuals have the triple (B,C,E) and one individual has the triple (B,D,E).

As the number of tables increases, so does the possibility of linkage. In Table III, there are nine individuals who have attributes E and C. Of these, between seven and nine individuals must have attribute B (from Table II). One can already see from Tables I and II that at least eight individuals have this combination, so one can infer that at least one individual has the attribute triple (B,C,F). In fact, the combination of these three tables allows one to infer the three-dimensional Table IV.

This type of linkage is a simple example of a more general form, which might allow potential data intruders to produce more complex data structures than were originally intended.

A key issue for understanding disclosure risk for tables of counts is the notion of bounds. For each cell within a linked table or one that has been perturbed by disclosure control, there is effectively a feasible maximum (upper bound) and a minimum (lower bound). If the bound's width (upper bound minus lower bound) is too narrow, then it is relatively easy for an intruder to recover the exact counts and perhaps disclosive tables; however, a wide bound width may be achievable only through strong perturbative disclosure control, which may render the tables unusable. The exact calculation of the bounds on a cell is important but difficult and much research has been devoted to developing an efficient algorithm for their calculation.

The foregoing assumes that the aggregate data are in the form of tables of counts. Where cell entries are in the form of magnitudes (such as is frequently the case with business data), a different set of issues arise. One problem is that it might be possible for a firm make quite detailed inferences about their competitors by subtracting themselves from the totals. Estimating whether a cell is sensitive is difficult. Although several different sensitivity rules have been proposed, there is no agreement on the best approach. In 2001, Cox provided a useful discussion of the issues.

Table I Artifical Aggregate Data

	Variable 1	
Variable 2	*A*	*B*
C	4	10

E	2	11
F	5	2

Table III Artifical Aggregate Data

	Variable 2	
Variable 3	*C*	*D*
E	9	4
F	5	2

Risk Factors

For any given set of data, there are several central factors that affect the overall risk of the file. The major ones are the sampling fraction, the size of key (the number of potential key variables and the level of detail on the key variables), and data divergence.

Sampling Fraction

The impact of sampling fraction is fairly straight forward—universally, the larger the sampling fraction, the larger the risk. There are two elements to this. First, the larger the sample, the higher the probability that any given

Table IV Extended Table Derived from Tables I–III

	Variables 1 and 2			
Variable 3	*A and C*	*A and D*	*B and C*	*B and D*
Definitely E	0	1	8	2
Definitely F	3	1	1	0
E or F	1	1	1	1

population unit is in the sample. This has a linear impact on risk. Second, as records are added to a sample, uniques that are not population uniques may have their statistical twins added to the sample and thus the proportion of sample uniques that are population uniques increases. For census-type aggregate data, the sampling fraction is not usually relevant as such data are most frequently released as 100% population data.

Data Divergence

Data divergence is a term used for inconsistencies between data sets (data–data divergence) or between a data set and the world (data–world divergence). There are many reasons for such inconsistencies, such as errors in response, errors in coding, errors in data entry, and data aging. Data divergence generally reduces the probability of correct attribution or identification.

Size of Key

In general, it is understood that the size of the key, in terms of both the number of variables and the number of possible values that a variable might take, is directly related to the disclosure risk. However, because variables tend to be heavily intercorrelated, the impact of adding an additional variable to a key on any risk metric decreases as the size of the key increases, whereas the divergence effect of adding an additional key is closer to linear. Therefore, larger keys can become difficult for an intruder to handle effectively. For aggregate data, the size of the key is limited by the number of dimensions in the table (or the number of variables in a set of linked tables).

Disclosure Control Methods

Disclosure control methods do not neatly divide into aggregate and tabular types. Most techniques can be applied to both. With aggregate data, it is possible to apply pretabulation disclosure control. This essentially means that disclosure control is applied to the microdata before it is converted to tables. This has the advantage that all tables produced will be consistent in margins and totals, which is not always the case when posttabulation methods are applied.

Recoding

Recoding is a basic tool of disclosure control. The essence of recoding is to take raw data and collapse categories of a variable so that the variable's attributes with low frequencies are conjoined. A typical example is age, where single years of age might be recoded to age groups of 5 or 10 years, or occupation, where specific occupations might be grouped together (usually in accordance with a recognized occupational classification). A special case of recoding is topcoding, in which frequencies tend to become smaller toward the top of the variable's range. Again, age is an obvious example and it is common practice to group all ages above, say, 90 into a single attribute.

The usual practice is to apply all recodes universally across a file, so-called global recoding. However, it is possible to use localized recoding if a variable is highly correlated with location. One example is country of birth. In many populations, people born outside their country of residence are concentrated in urban areas, so providing the detail of country of birth for individuals outside these areas is potentially disclosive. One way to circumnavigate this is to provide two variables: a crude recoded variable covering the whole population and a more detailed variable for those areas in which the nonindigenous population is relatively prevalent.

The major advantage of recoding is that the impact on data quality is visible. Although some secondary analysis will be prevented by the loss of information, there is no possibility of the method introducing analytical invalidity, which some of the perturbative methods risk doing. Against this, global recoding, because it affects the entirety of a data set, can sometimes be of relatively small benefit in terms of risk reduction for the cost in terms of information loss. With localized recoding, this problem is ameliorated, but at the cost of complicating subsequent data analysis.

Cell Suppression

Cell suppression is a method of disclosure control that is specific to aggregate or tabular data (that is, where data are released in the form of tables of counts rather than full individual records or microdata). Suppressing a cell simply means leaving the cell blank. A decision is made that a cell is sensitive because it has a low or zero count and therefore could give rise to attribute disclosure.

A problem with this method is that it is never sufficient to suppress simply the sensitive cell. First, if only cells of a small range of values (e.g., 0 and 1) are suppressed, then the cells that are suppressed are identifiable as having a small range of values. Second, by simple subtraction of known individuals, it may be trivial to recover cell values. Therefore, it will often be necessary to suppress a larger range of cell counts to disguise which cells are the sensitive ones. To give a simple example, in Table V it is desired to suppress the cell (C,A) with a frequency of 1. However, it will be simple to infer its value from the marginal totals and the other cells in the table; this means that it will also be necessary to suppress at least one other cell in each row and column containing the sensitive cell (complementary suppressions). In order to ensure that these cannot be recovered, further cells

may also need to be suppressed (see Table VI). The result is that many cells in any given table may end up being suppressed and the table would have limited analytical value.

Rounding

Rounding methods of disclosure control are applicable to aggregate data. The idea is to disguise the exact frequency count for a cell by rounding every cell in a table to a given base (typically 3, 5, or 10). Thus, Table V could be rounded to base 5, as shown in Table VII.

There are several variants on rounding—the variant shown in Table VII is random rounding, where cell counts can be rounded (either up or down). One problem with this approach is that cell counts may not add up to the subtotals and totals, which is analytically awkward and can also be used to make more accurate inferences about the range of possible counts (or bounds) in the unrounded table, in some instances leading to the recovery of the exact counts. Controlled rounding circumnavigates this by enforcing additivity, ensuring that all counts within a table add up to their respective totals. However, even this may be problematic if multiple overlapping tables are rounded separately, with common marginal cells being rounded to different values.

Table V Table with Sensitive Cell (C,A)

	Variable 1			
Variable 2	*A*	*B*	*C*	*Total*

A	15	20	15	45
B	5	10	20	30
C	**5**	25	10	30
Total	20	50	40	105

Masking and Blurring

Masking and blurring describe a class of methods for protecting confidentiality by adding noise to the data. With tabular data, this can be achieved through adding and/or subtracting numbers to cells (a process called barnardization). With microdata, values can be manipulated by changing them to adjacent (or simply different) values (postrandomization). Another technique used with microdata, called suppress and reimpute, uses various techniques to overwrite sensitive values with values that are likely in the context of the data set.

Data Swapping

Data swapping is the exchange between records in a data set of values for particular variables (either sensitive/target variables or key/matching variables). If values of potential key variables are swapped, then the intruder's matching task is much more difficult. If sensitive information is swapped, then the intruder cannot be certain if, for a given match, the information disclosed is accurate. Swapping can be performed randomly. However, it is more usual for data to be swapped with records that share the same values on other variables. This leads to less distortion of the data and reduces the risk of inconsistent value combinations.

A particular type of data swapping is termed record swapping. This is the simple exchange of a record with another in a different geographical area, effectively data swapping the records' geographical codes. This can be particularly good for maintaining the overall structure, while disguising a particularly important key variable. As with the more general data swapping, the swaps are often with records that share values on certain variables.

Measuring the Impact on the Data

A great deal of research has been conducted on disclosure risk assessment and disclosure control methodology. However, the impact on the data of disclosure control is much less defined. There have been attempts to obtain measures of information loss to indicate how much information the disclosure control processes have discarded. However, these can be misleading. The mathematically based models do not necessarily correspond to what users want to do with the data. Some user analyses may be unaffected by a given disclosure control regime, whereas others may be badly affected. It is generally assumed that the more complex an analysis, the more likely it is to be affected by the statistical disclosure control methods

applied to the data, although this has not been thoroughly tested.

Alternatives to Disclosure Control

As the demand for data and the technological possibilities for disclosure continue to increase, data holders seek alternative ways to provide information to bona fide data users. The two most explored of these are safe settings and simulated data.

Safe Settings

Another approach to disclosure risk is to look at the users in terms of who is allowed access and how and where the analysis is conducted. The so-called "safe settings" approach looks to set up "data laboratories," where users can run analyses in a controlled environment. This has a major advantage in that the data holders will know exactly who is using the data, what they are doing with it, and so on. It has a severe disadvantage for the users in terms of ease of access and does not encourage exploratory data analysis, which is a key virtue of much microdata release. A variant on this, which is being explored by several statistical agencies, is the virtual safe setting, where the data are stored behind a firewall, but can be indirectly interrogated by the user who can run analyses without accessing the actual data.

Simulated Data

There has been much interest in the possibilities presented by simulated data, which are microdata that have been produced artificially from one or more statistical or computational models. The simulated data are produced through a variety of techniques, such as multiple imputation and mutation algorithms. Sometimes, simulated data are combined with real data and sometimes the data used are fully simulated. Clearly, the disclosure risk with such data is considerably lower. The key question is whether such data can produce analytically equivalent results to real data and most work with simulated data is concerned with assessing this issue. Results are mixed; simulation seems to work well when analyses are simple, but more complex analyses' results can be problematic.

Concluding Remarks

Research into statistical disclosure control has made considerable advances. The parameters of the field are now well defined and there is a wide a range of methods for dealing with issues of confidential data release. As yet, the relationship between disclosure risk and data utility/analytical validity is not well understood. The goals of the field, to be able to specify precisely the disclosure risk for a given data release and to optimize the playoff between data quality and disclosure risk, are still some way from being realized. However, it is possible to look forward to a situation where the data release methodology becomes fully specified.

Statistical/Substantive, Interpretations and Data Limitations

Ronda Priest
University of Southern Indiana, Evansville, Indiana, USA

Glossary

alpha (α) A predetermined probability level such that one rejects the null hypothesis.
alternative hypothesis (H_A) The hypothesis that contradicts the null hypothesis, stating that the parameter is a value opposite that of the null.
null hypothesis (H_0) The hypothesis that is tested, stating that the parameter has no effect.
power of the test The probability of rejecting the null hypothesis when it is false.
***P*-value** The calculated probability of the observed data or data more extreme, given that the null hypothesis is true.
type II error The null hypothesis is not rejected even though it is false.

Statistical/Substantive: Data Limitations and Interpretations is the general discussion of statistical significance tests, their overuse and sometimes misuse in the social sciences, and the need for researchers to focus more on practical and theoretical interpretations of their findings.

Introduction

This article discusses the difference between statistical significance and substantive significance. A measure of statistical significance reveals the probability that the value of a statistic could have resulted from chance factors associated with the random manner that observations are gathered for analysis. Substantive significance refers to the extent that a statistic suggests the presence of an important theoretical or practical finding. In evaluating research findings, it is important to clearly distinguish between these two types of significance. Statistics with high statistical significance may have varying degrees of substantive significance, and statistics with low (or even no) statistical significance may or may not have low substantive significance.

Substantive significance has not received as much attention and is study/variable/theory specific. Mentioned only briefly in standard statistics texts, substantive significance (a.k.a. theoretical, practical, meaningful) refers to the theoretical importance or practicality of the result. The social sciences need to pay more attention to reporting the substantive importance of their statistical findings. The goals of social research are reached when the scientific community's main focus is on the size of effects and their theoretical and practical significance utilizing techniques such as descriptive statistics and confidence intervals.

Statistical Significance Testing

Overview of the Process

Tests of statistical significance provide measures of the likelihood that differences among outcomes are actual, and not just due to chance. All significance tests have these basic elements: assumption, null hypothesis (H_0), theoretical or alternative hypothesis (H_A), test statistic (*e.g.*, t), *P*-value, and conclusion. First, regardless of the type of statistical significance test, certain assumptions must be met. These assumptions vary somewhat, but include factors such as: (1) type of data, (2) theoretical form of population distribution, (3) method of sampling (usually random sampling), and (4) sample size.

Second, one develops a null hypothesis about some phenomenon or parameter. For example in its simplest form

$$H_0: \mu = \#$$

A null hypothesis is the opposite of the research hypothesis

$$H_A: \mu \neq \#$$

Next, data are collected that bear on the issue and an appropriate statistic (e.g., proportions, mean, regression coefficient) is calculated that measures the association between an independent and dependent variable. A statistical test of the null hypothesis that determines there is no relationship between the predictor (independent) variable and the dependent variable is then conducted via a test statistic. The test statistic typically involves a point estimate of the parameter to which the hypothesis refers, for example the Student's t test:

$$t = \frac{\bar{x} - \mu_0}{\{s/\sqrt{(n-1)}\}},$$

where $\bar{x}$ is the sample mean, μ_0 is the value of the parameter assumed under the null hypothesis, S is the standard deviation, and n is the sample size.

The test statistic is used to generate a P-value. The P-value is the probability, when H_0 is true, that the test statistic value is at least as contradictory to $H\mathrm{d}_0$ as the value actually observed.

Finally, the P-value is compared a predetermined cutoff value (α) that is usually set at 0.05 or 0.01. When a P-value below α is attained, the results are reported as statistically significant. From this point several interpretations of P often are made.

Interpretation of the *P*-value

Sometimes the P-value is interpreted as the probability that the results obtained were due to chance. For example, small P-values are taken to indicate that the results were not just due to random variation. A large value of P, say for a test that $\mu = \#$, would suggest that the sample mean $\bar{x}$ actually recorded was due to chance, and μ could be assumed to be value assumed under the null hypothesis.

The P-value may also be said to measure the reliability of the result, that is, the probability of getting the same result if the study were repeated. Significant differences are often termed "reliable" under this interpretation. Ironically, while tests of statistical significance measure the reliability of a test statistic, measures of statistical significance sometimes prove to be unreliable themselves.

Finally, P can be treated as the probability that the null hypothesis is true. This interpretation is the most direct, as it addresses the question of interest. These three common interpretations are all incorrect. Small values of P are taken to represent evidence that the null hypothesis is false. However, several studies have demonstrated this is not necessarily so. In reality, a P-value is the probability of the observed data or data more extreme, given that: (1) the null hypothesis is true, (2) the sample size was adequate according to the type of test, and (3) the sampling was done randomly.

Problems with Null Hypothesis Testing

Is the Null Hypothesis Really True?

Most null hypotheses tests, are designed to determine if some parameter equals zero (e.g., $\mu = 0$), a specific value (e.g., $\mu = 100$), or that some sets of parameters are all equal (e.g., $\mu_1 = \mu_2$). Yet rarely is the true value of the parameter exactly equal to the value listed in null hypothesis.

Second, truly random samples are seldom collected in the social sciences. Generally, sampling is done without replacement, resulting in differences in probabilities for each element. Nonresponse and missing data are also key problems in securing true randomness. Suffice it to say, the sampling procedures must be critically examined before conclusions of significance can be made. Replication of findings across studies can help reduce the problems of strict nonrandomness in social sciences (discussed below).

Effects of Sample Size

Finally, the probability of rejecting the null hypothesis when it is false (as it typically is) is greater as the sample size increases. The power of the test is the ability to detect a false null hypothesis. Specifically, for a particular value of the parameter from the alternative hypothesis:

$$\text{Power} = 1 - P(\text{Type II error}),$$

where a Type II error is the failure to reject H_0 when it is, in reality, false.

Holding α constant, power increases as sample size increases. It is generally recommended for a test to have high power. However, in an attempt to raise the power of a test, the P-value can be made as small as one wishes. In other words, to guarantee a rejection of the null hypothesis, one only needs a large enough sample. For example, in testing to see if the mean of a population (μ) is 100. The null hypothesis then is $H_0: \mu = 100$, versus the alternative hypothesis of $H_A: \mu \neq 100$. One might use a Student's t test

$$t = \frac{\bar{x} - 100}{\{s/\sqrt{(n-1)}\}}.$$

Clearly, t can be made arbitrarily large (and the P-value associated with it arbitrarily small) by making either $(\bar{x} - 100)$ or n large enough. As the sample size increases, $\bar{x}$ and S will approximately stabilize at the true parameter values. Hence, a large value of n translates into a large value of t, which generates a small P-value. While minimum sample sizes are strictly adhered to in choosing an appropriate test statistic, maximum sample sizes are not set. Alternatively, α is not usually adjusted according to the sample size. For example, for larger sample sizes (e.g., $n > 1000$), the set significance should be adjusted to a smaller value (e.g., $\alpha = 0.01$ or 0.001).

Even more arbitrary is the tendency for researchers to adhere to a standard set significance of 0.05 or 0.01. P-values less than or equal to α are deemed significant; those greater than α are nonsignificant. This rule promotes the nonsensical distinction between a statistical significant finding if $P = 0.04$, and a nonsignificant finding of $P = 0.06$. Such minor differences are delusive anyway, as they derive from tests whose assumptions often are only approximately met (e.g., a random sample).

Statistical significance is often an imperfect method for determining the reliability of a statistic. However, if the assumption of the tests are met, attention is paid to sample size, and if care is taken to interpret P-values in relation to confidence intervals, statistical significance tests can be the starting point for further analysis, but never the end point.

Moreover, under the best of circumstances, a statistical significance test never indicates the effect size or whether the results are of any theoretical or practical use.

Substantive Significance

Researchers want to answer three basic questions: (1) Is an observed effect real or should it be attributed to chance? (2) If the effect is real, how large is it? and (3) Is the effect large enough to be theoretically interesting or practically useful?

The first question concerning whether chance is a possible explanation for an observed effect is usually addressed with a null hypothesis significance test. As stated earlier, a null hypothesis significance test tells us the probability of obtaining the effect or a more extreme effect if the null hypothesis is true. A significance test does not tell us how large the effect is or whether the effect is important or useful. To do so, one needs to examine substantive (practical/meaningful) significance. Suggestions for analyses regarding the last questions include (1) effect size, (2) confidence intervals, and (3) replication.

Effect Size Measures

The general approach of obtaining some kind of scale-free effect size measure as the indicator of practical meaningfulness or importance has become popular and its use has been widely advocated in recent years. Effect size is generally reported as some proportion of the total variance accounted for by a given effect. Also, termed measures of association strength, R^2 or η^2 are the most common examples. The general formula can be expressed as

$$R^2 = SS_{\text{a source}}/SS_{\text{total}}.$$

The numerator represents the sum of squares from a source of interest. In a model that contains one explanatory factor, the source of interest is obviously the only explanatory variable in the model. For a model containing multiple factors, the source of interest may include either a subset of factors or all the explanatory factors in the model. In the former case, η^2 is used, in the latter, R^2. R^2 is interpreted as the proportion of variance explained by all the factors in the model. Due to an upward bias in R^2 (the maximization property of the least-square principle), numerous "bias correcting" counterparts have been proposed such as ω^2 and ε^2. However, in interpretation, they are conceptually the same.

In interpreting the result, Cohen recommends that an effect size between 0.10 and 0.25 be considered small, one between 0.25 and 0.50 be considered medium, and one above 0.50 be considered large. However, Cohen also stated that these are arbitrary standards and should be interpreted in terms of the theoretical relevance of the effect size for the problem being investigated. Therefore, R^2 and other measures of association suffer some of the same limitations of statistical significance testing. In other words, there is still a question about what constitutes a substantive finding. Too strong of an adherence to effect size conventions tend to cloud the distinction between the size of an effect and substantive significance. In fact, Cohen also stated that effects as small as 1% of explained variance can be theoretically important and large effect sizes may be rather uninteresting, depending on the theoretical hypotheses.

Confidence Intervals

While a significance test provides a way of judging whether a particular value for the parameter is creditable the estimation method of confidence intervals provides a range of the most plausible values for a parameter. A confidence interval is defined as a range of numbers within which the true population parameter is believed to fall. They have the form

$$\text{Point Estimate} \pm (z - \text{score})(\text{standard error}),$$

where the point estimate is the value calculated from the sample (e.g., a mean or proportion).

Generally, testing a hypothesis about a parameter value is not as informative as estimating that parameter

using a confidence interval. Yet researchers have been reluctant to use confidence intervals as widely as tests of significance. A confidence interval contains all the information provided by a significance test, and in addition provides a range of values within which the effect parameter is likely to fall. A confidence interval is just as useful as a null hypothesis significance test for deciding whether chance or sampling variability is an explanation for an observed effect.

Unlike a test statistic, for example a difference among means, point estimates and confidence intervals use the same unit of measurement as the data. This facilitates the interpretation of results and makes inconsequential effects harder to ignore. It should be noted that confidence intervals require the same assumptions as statistical tests, they can suffer from the same violations (e.g., population distribution and nonrandom sampling). However, if we accept significance tests as proof of a finding, why not use the more informative interval estimate?

Replication

All social scientists agree that replication and meta-analysis are better vehicles for accumulating knowledge than statistical significance testing. Multiple studies not only provide replication of specific empirical findings, they also provide a means for eliminating rival hypotheses and establishing the boundary conditions of observed outcomes. The best evidence of replicability involves conducting a true replication of results. Next best alternatives include thoughtfully comparing the effect sizes in a given study with the effect sizes reported in previous research. Finally, internal replicability analysis of sample results can be conducted.

Conclusion

Unfortunately, all too often the primary focus of research is on rejecting a null hypothesis and obtaining a small *P*-value. The focus should be on what the data tell us about the phenomenon under investigation. This is not a new idea. Critics of significance testing have been saying it for years. For example, Yates, a contemporary of Ronald Fisher, observed that the use of the null hypothesis significance test has caused scientific research workers to pay undue attention to the results of the tests of significance they perform on their data, and too little to the estimates of the magnitude of the effects they are investigating. The emphasis on statistical significance testing, and the consideration of the results of each study in isolation, have had the unfortunate result that researchers have often regarded the execution of a test of significance as the principal goal. Too strong an emphasis on null hypothesis significance tests detracts researchers from interpreting the theoretical relevant outcomes of research.

Science is only thoroughly accomplished when researchers focus on theoretical or practical significance. These questions are best addressed with a combination of effect size measures, descriptive statistics, confidence intervals, and replication.

One of the appeals of null hypothesis significance testing is that it appears to be an objective, scientific procedure. On the other hand, deciding whether effects are useful or theoretically significant obviously involves an element of subjectivity. However, researchers have an obligation to make this kind of subjective judgment. No one is in a better position than the researcher who collected and analyzed the data to decide whether the effects are trivial or not. Ironically, researchers make a variety of complex decisions in the design and execution of a research study, but in the name of objectivity they are not expected nor even encouraged to decide whether the effects are practically or theoretically significant. Unfortunately, there are no statistics that directly measure the practical significance of effects. Yet, reporting the results of a significance test alone surely do not.

Glossary

balance sheets A method of clearing up some problems of definition that arise from many different ways of defining national income.
classes of consistency Different requirements used to assess the coherence of national accounts with basic characteristics of economic variables, such as arithmetic identities, accounting identities, knowledge of past behavior and technology, expectations about future behavior and technology, transitional possibilities, all remaining aspects of the problem, and all long-term aims.
equivalent subsets of transactions A process of selection and aggregation of variables based on an operational definition of economic variables that makes measurement possible.
national accounts A system of accounts that provides a display of the basic structure of an economic system reduced to its simplest terms. The main message conveyed by the measurement framework of an accounting structure is of mutual interdependence among its parts. An important feature of this system is consistency in treatment of concepts.
system of multiple classifications A system designed to transform theoretical distinctions into different ways of organizing the balance between subdivision and consolidation.

This article explores John Richard Nicholas Stone's contribution to the creation of national accounts. Its objective is to examine Stone's views on measurement by focusing on his work on national accounts. It is organized into three parts. The first part presents a very brief account of the earlier history of national accounting, centered on Stone's views of it, with subsequent reference to the role of war in the development of national accounts. The second part examines Stone's contribution to the conceptualization and elaboration of a general structure of national accounts and his early views on measurement. Finally, the third part investigates his work on related areas, such as regional accounts and demography, and the significance of these topics to the development of his views on measurement.

Introduction

Throughout his work, John Richard Nicholas Stone expressed a sustained interest in measurement issues. His contribution to economics covered a wide range of areas, such as: empirical analysis of consumer behavior, with emphasis on the measurement of market demand and linear expenditure systems; economic growth, with the construction and analysis of large disaggregated macroeconomic models; economic demography, where he developed new approaches to the issues of population and migration forecasting; and education, where he developed mathematical models of educational planning. His work also covers topics such as index-numbers, time series and cross-section surveys, environmental and sociostatistics, models of financial markets, and optimization problems related to economic growth. Stone's contribution to these topics was shaped by his concern with integrating theory and facts, abstract and practical reasoning, and expressing the results in a measurable form so that they could be used to solve concrete problems.

In no other area did Stone's work achieve more recognition than in the field of national accounts. His Nobel Prize contribution to the development of systems of national accounts has been widely acknowledged by economists and Stone has been called "the father-figure

of national accounting," "the leading international authority in the field of national accounts," "a genius at the National Income and Expenditure," "the leading English political arithmetician, arguably the most distinguished of those who have followed the tradition started by Sir William Petty," and praised for being "one of the discipline's most creative and productive applied economists." In addition, Stone's work on national and social accounting has, according to Deaton, "had a profound influence on the way that measurement is carried out in economics, and his econometric model building has changed the way that economists analyze those measurements." The relevance of Stone's work to measurement in economics should not be underestimated. Even John Maynard Keynes, who was skeptical about measurements in economics, is reported to have exclaimed—about Stone's work on national accounts—that "We are in a new era of joy through statistics."

But Stone did not simply "measure" economics, if by that we understand straightforward "quantification" of phenomena, that is, the direct expression of economic variables in terms of number, degree, or amount. Measurement for Stone meant something more complex, involving not a mere listing of economic quantities or a conceptual mould to which all statistics must conform, but rather a coherent framework for observing behavior. Together with Colin Clark and James Meade, Stone was responsible for changing attitudes toward measurement in economics.

British Empiricists and the Development of National Accounts

The origins of national accounting can be traced back to William Petty's early estimates of capital, income, and expenditure for 17th century England. With Petty, the general boundaries of *Political Arithmetick* were established and an emphasis on measurement, as a way of objectively settling arguments, was advocated. Subsequently, Petty's views on economic measurement were consolidated by Charles Davenant's and Gregory King's work on national income. Stone delves into the history of early British empiricists and argues that there is a strong element of continuity between his work and the work of previous generations. It is interesting to examine his interpretation of the contribution of these early political arithmeticians. Issues of precision and rigor seem to have a minor role in Stone's assessment of their measurements. For instance, Stone does not seem to be bothered by the fact that Petty assumed that all income is spent on consumption or by the highly speculative nature of his estimates. He notes that, "In any case the fact that Petty had poor data and that many of his estimates were guesses and often biased guesses does not invalidate the usefulness of his method." Stone refers here to Petty's innovative use of quantitative data to formulate an argument. Similarly, Stone praises Davenant's contribution to political arithmetic, arguing that "though not original, [it] was invaluable." The lack of precision of Davenant's estimates was less important for Stone's assessment of his contribution than Davenant's "list of principles to be kept in mind by the political arithmetician."

Stone's assessment of Petty and Davenant can be partially explained by his evolutionary attitude toward measurement, according to which, the actual data were relevant not merely for their precision but for the knowledge they transmitted. His appraisal of Gregory King's contribution to measurement of economic aggregates follows the same lines. Stone notes that King "must have relied to a large extent on his power of estimation based on a wide acquaintance with all kinds and conditions of man and a good understanding of how national accounting magnitudes should fit together" and that "Without aiming at strict accuracy one could hope to talk sense." Though Stone conflated the meaning of the words accuracy and precision in his discussion of the British empiricists, we could, perhaps, better understand the message he conveys if we distinguish between them. If we use the word accuracy to express the correctness or truthfulness of something and the word precision to refer to exactness or rigor of estimates, then it could be said that good measurement for Stone seems to be mainly about achieving accurate estimates rather than merely achieving precise ones. This notion is reinforced by his criticism of Lindert and Williamson's attempts at replacing King's *guesses* by more precise statements. Stone's argument is that King's estimates, though imprecise, were accurate and coherent among themselves. It is interesting to note that Stone criticized Petty's and King's estimates of the world population for not being accurate.

From this very brief outline of Stone's assessment of the work of early British empiricists, we can form a first picture of his views on measurement. The first, though obvious, point is that measurement provides a good perspective with which "to talk sense" about the world. The second point is that the validity of measurements should not depend exclusively on their precision but rather on their accuracy, that is, on their ability to express the truthfulness of something. Finally, the third point is that coherence is an important element behind the accuracy of estimates. The above references to the British empiricists seem to suggest that guesses and speculations in measurement are not bad things per se, but that their validity depend on the coherence of the story they are telling. These appear to be the lessons that Stone assimilated from the early British empiricists.

The history of modern national accounting starts with A. L. Bowley's, Colin Clark's and Simon Kuznets's estimations of the principal macroeconomic accounting values for the United Kingdom and United States, respectively, for some years in the 1920s and 1930s. Both have been described as coauthors of "the statistical revolution" that followed the revolution in macroeconomic theory of the 1930s. Production of unofficial statistics boomed during the 1930s, in countries like Hungary, Germany, Sweden, Canada, Australia, Netherlands, United States, and United Kingdom, with important contributions being provided by Ragnar Frisch, J. B. D. Derksen, and Erik Lindahl. During the 1940s, when new institutions were created with the aim of calculating national statistics, many contributors, such as Milton Gilbert, Morris Copeland, George Luxton, E. F. Denison, O. Aukrust, and J. Tinbergen, to quote just a few, helped the development of national accounting. It was not uncommon to find a variety of diverse isolated statistics—such as production levels of food or minerals—being used to characterize the evolution of national income. Indeed, the beginnings of this "statistical revolution" seem to be characterized by statistics being produced without much coherence.

The development of the national accounts was very much influenced by the occurrence of the Second World War (see, for instance, the work of Ruggles). Being a "centrally planed operation," the war involved the coordination of a vast amount of activities within unified systems of control. The assembly of aggregate statistics in a clear, easy-to-read, easy-to-use form was important during the war, when centrally planned operations had to be decided and production and finance had to be restructured in a coordinated manner. In the United Kingdom, the war produced a change in attitude toward the compilation and use of statistics. But what possible uses could national aggregates estimates have during the war? Stone discusses this issue in detail. The budgetary aspect influenced decisions concerning taxation and the evolution of the national debt; it also indirectly concerned demand pressures due to the government's increasing expenditures of war. The allocation of resources in a war economy involved a whole range of physical controls, and financial disequilibria could through exchange rates and price increases invalidate these attempts to control the allocation of resources.

For Stone, in war or peacetimes, any important measure of social control and government intervention depended on the information provided by the description of the economic system as whole offered by national income statistics. Measurement of these aggregates could not necessarily indicate the right sort of policies to pursue, but would, according to him, bring out clearly the nature of the problem and for this reason would be essential for administrative policy purposes under any circumstances. It was also the war that brought James Meade and Richard Stone together and provided the environment for the development of the first stages of national accounting. Stone's involvement with national accounts is abundantly commented and illustrated by himself and by others, such as Meade, Deaton, Pesaran, Harcourt, and Pesaran and Harcourt. The brief outline that follows draws on these references.

When Colin Clark—Stone's greatest influence—left for Australia in 1937, he bequeathed to Stone and his first wife, the statistical supplement called *Trends*, which appeared in the monthly *Industry Illustrated*. In *Trends*, Stone produced statistics and graphs of British economic time series with occasional articles on a topical subject. Partly for this work, when the war became imminent, earlier in 1939, Stone was invited to join the Ministry of Economic Warfare. Later, by suggestion of Austin Robinson, he left the Ministry in August 1940 to join James Meade for Central Economic Information Service of the Offices of the War Cabinet to work on national income accounts. Meade's system, as Deaton puts it, "was a system of empty boxes." Though Meade had developed the original conceptual framework of national accounts, it was through Stone that it was operationalized. They worked together until April 1941, when the new budget split the Economic Information Service into an Economic Section, to which Meade was attached, and a Central Statistical Office (CSO), where Stone became responsible, thanks to Keynes's intervention, for the national accounts. It was during this period that a new conception of measurement emerged from the collaboration between Stone and Meade: a conception that saw the measurement of national income not merely as a quantification of isolated single magnitudes but as a quantification of an *integrated accounting system* in which magnitudes from different sources had to agree. Although Stone and Meade were not the first to create the concepts of national accounts or to estimate national aggregates, they were the first to put forward a notion of measurement based on criteria of systematization and consistency among aggregates. When Meade learned that Stone was leaving the CSO to assume the post of the first director of the Department of Applied Economics at Cambridge, he considered it "a very serious blow" and "a real disaster for Whitehall."

At the end of the war, before assuming his new post, Stone accepted an invitation by Winfield Riefler to visit the Institute for Advanced Study in Princeton. At the Institute he met Alexander Loveday, the head of the Intelligence Department of the League of Nations, who asked him to write a report on national income statistics for the League. The report, published by the United Nations in 1947, was a landmark in the literature of national accounts; it established the measurement standards for the field for many years ahead and contributed to a reconceptualization of measurement in economics.

The Measurement of National Accounts

Richard Stone started his work on national accounts just like everybody else did in the 1930s, by measuring different indices of industrial product and comparing them to other aggregate measures. In 1939, Stone and his first wife Winifred calculated a new measure of mining and manufacturing output using the census of production and employment statistics. They assembled information on movements in production from three different sources and discussed the measurement problems involved in putting together statistics with different degrees of reliability. Their solution to these problems consisted in defining as a standard the material considered most accurate (as for instance, the census and import duty inquiry data) and dismissing those that were extremely difficult to measure (such as the engineering group indices). Assessment of reliability of individual items was an intrinsic part of measurement. It was pursued directly, by confronting different indices that purported to represent the same things, and indirectly, by analyzing their logical significance. In the latter case, the accuracy of adjustments was of crucial importance. Their emphasis on the importance of the plausibility and reliability of data was compatible with what could be called the *Principle of Broad Limits*. Although adjustments were an intrinsic part of measurement, they should be pursued within broad limits, and rough estimates should be used even when they were not very (relatively) precise—as long as they were accurate. In this work, Stone's concern was with the quality of individual series. Expressions such as confidence and creditability were used as a criterion of assessment of these individual and isolated series.

A distinct approach emerged from Stone's first work in collaboration with Meade. In 1941, they put forward the notion of balance sheets as a method of clearing up some problems of definition that arose from many different ways of defining national income. Agreement on definitions, such as those of net investment, direct and indirect taxes, became the first stage in the measurement of national accounts. These definitions should be settled in ways that could be of interest and use to economists, allowing statistical crosschecking. Major problems of definition should be solved in order to assure proper measurement. As a logical consequence, tables would have to balance. Minor problems of definition could be solved through adjustment, since it would be impossible to treat all of them at length. It is not an exaggeration to say that Meade's and Stone's 1941 paper represented a watershed in the literature of national accounts. While the previous focus on measurement had been on the assessment of the reliability of individual series, they put forward the idea of considering all series together in a consistent way. Their tables of national income were not national accounts in the strict sense of the word, but contained the basic measurement principle of coherence which would come to characterize the accounts later.

Interest in studying the variations in economic activity in a peacetime economy led Stone, in 1943, to investigate U.S. figures. He joined the discussions between Simon Kuznets and the U.S. Department of Commerce on the definition and measurement of national accounts, adding his own disagreements to theirs. Stone's discordances with methods used in American estimates revealed that in his view: (i) measurement criteria should not be decided *a priori*. If one were dealing with a situation facing consumers, he would agree with Gilbert's proposition (that market prices were more important than costs to the determination of equilibrium prices). However, if the situation to be analyzed was about productivity, then he would consider factor cost as a more relevant criterion than market prices. Concepts should be rearranged according to the purpose in hand; (ii) measurement of government activity indicated people's attitudes to government. Kuznet's interpretation of government, as if it were a commercial activity, was rejected by Stone as being "a thoroughly inconvenient way of looking at the matter." It might be speculated that wartime experience provided a different perspective on government activities that influenced Stone's disagreement with American (peacetime) position. Finally, Stone criticizes Kuznets's use of maximum errors on the basis that (1) Kuznets does not define the range of his maximum errors and that (2) the reliability of estimates could be better assessed by using concepts analogous to probable or standard errors. Incomparability problems between the American and British figures led Meade and Stone to emphasize what could be called the *Principle of Flexibility* in national accounts, according to which there are many admissible ways of defining the national income, and that there is nothing absolutely right or wrong about any of these definitions. The national income must be measured according to the definition which is most suitable for the particular purpose in view.

A major breakthrough in the measurement of the national accounts came with the memorandum on *Definition and Measurement of the National income and Related Totals* that Stone wrote for the United Nations in 1947. The boundaries of measurement of national aggregates were extended from a simple concern with measuring a collection of single magnitudes to a more complex concern with measuring a coherent system of magnitudes. In the model of an advanced industrial economy that Stone adopted as his working system, he defined three basic forms of economic activity: production, consumption, and accumulation, which became four when transactions with the rest of the world were added. By recording the incomings and outgoings of the basic forms of economic

activity in four accounts, Stone suggested a systematic method of collecting information. This conceptual basis provided a greater uniformity of content in the estimates for different nations. It also permitted Stone to advocate a change of emphasis from the measurement of individual aggregates to the measurement of structures of transactions. The basic forms of economic activity when put together would provide a display of the basic structure of an economic system reduced to its simplest terms. The main message conveyed by the measurement framework of an accounting structure is of mutual interdependence among its parts. An important feature of this system is consistency in treatment of concepts—even for those that are recognized as arbitrary. To a certain extent, all concepts involve a degree of arbitrariness and conventions that are intrinsic to measurement.

Stone suggests that measurement and economic theory should be tailored to each other's needs. On the one hand, the social accounting system should preserve conceptual distinctions that are needed for economic analysis. On the other hand, economic analysis should restate its needs in a terminology that could be measured. These elements could be regulated through a process of selection and aggregation based on the notion of equivalent subsets of transactions. By using this notion, the general meaning of economic variables could be defined operationally in a way that measurement becomes possible. Since there is no uniquely right way of combining accounts, the principle of flexibility could be used to establish the proper combination between subdivision and consolidation for each case. Yet, some types of accounts are never to lose their identity under consolidation. A degree of invariance is needed in order to cope with the complexity of irrelevant features of economic systems. What could be called the *Principle of Invariance* is of particular importance in the cases of nonmonetary transactions and systems of taxation, since it provides a very useful assumption of homogeneity that could be used to measure economies where a market basis exists.

Stone puts forward a more elaborate proposal for multiple classifications in social accounting. According to him, the problem of choosing suitable criteria of classification could *prima facie* have three solutions: (1) the limited solution, where the transactor classification is removed or reduced to a minimum; (2) the solution of Procrustes, where a single classification of transactors is applied; and (3) the proper solution, where we can choose many classifications according to their usefulness. He claimed that only the accounting system could endow the system of classifications with some flexibility. No doubt, flexibility was, for Stone, an essential element of proper measurement. How could he otherwise explain and measure different systems of classification? How could he harmonize a consumers' classification of products with a producers' classification? Or to connect, for instance, government expenditures on health, education, etc., with the different industries that are producing these goods? Thus, a system of multiple classifications could transform theoretical distinctions into different ways of organizing the balance between subdivision and consolidation. Stone summarized these distinctions by claiming that he was "not impressed either by purely theoretical arguments which do not concern themselves with the problems of data collection and processing nor with purely practical arguments which do not concern themselves with theoretically desirable distinctions."

Now, it is important to note that the criteria Stone suggested for measurement were not enough for the solution of all conceptual and practical problems involved in the actual measurement of national accounts. Stone was then forced to recognize that when measurement barriers cannot be overcome, conventions must be introduced, not as a matter of principle but of convenience.

Stone's conceptualization of measurement seems to have evolved from a simple emphasis on the reliability of isolated series, passing through the use of balance sheets to cross-check statistics, to an emphasis on coherence or consistency as the landmark of his contribution to the national accounts. While commentators like Deaton appear to suggest that consistency is defined at a logical value, it seems closer to Stone's views to suggest that consistency was achieved at a conceptual level. When discussing the meaning of consistent projections in multisector models, Stone considers consistency (i) in a restricted sense, in which certain identities must be satisfied and (ii) in a wider sense, "to include consistency with everything we know, everything we expect, and everything we desire to achieve." In order to constrain this very broad definition, Stone formulates seven classes of consistency based on: arithmetic identities, accounting identities, knowledge of past behavior and technology, expectations about future behavior and technology, transitional possibilities, and all remaining aspects of the problem and all long-term aims. Models will meet the different requirements in different degrees according to their uses. Stone does not discuss how a balance could be achieved among these different classes but observes that following theory might be a way of keeping consistency. He comments that,

> *Measurement is important in economics, which is largely a quantitative subject. But left to themselves facts are not very coherent, they need interpretation by the investigator. Theory helps him to do this in a way which makes them consistent with what he knows.*

It is interesting to note how Stone uses *prima facie* the notions of coherence and consistency conveying the same meaning. However, a closer reading reveals that he uses coherence to express a feature of the systems and consistency to express a property of the investigator's assessment

of the systems. As discussed below, this distinction is important to analyze Stone's discussion of adjustment techniques.

The Development of National Accounts

It is also interesting to note that Stone, though recognizing the importance of stepping out of the economic ivory tower to contextualize the accounting framework, pursued a strategy of measurement based on a progressive evolution from the simplest terms of economic structures. In concrete terms, a tension between standardization and extension was manifested in the way Stone handled the inclusion of social and demographic variables into the general framework of national accounts.

Stone did not introduce these characteristics directly as classification criteria in the economic accounts, but rather treated them separately in independent socio-demographic accounts. This was not merely a question of convenience or flexibility of the systems, as it could *prima facie* seem to be the case. This was mainly a consequence of his emphasis on starting measurement from simplest structures and then making the picture more complex by progressively adding new information. Yet, consistency of national accounts, if pursued in a wider sense, would have to refer to a more complex picture of reality. Two of the main areas explored by Stone were regional accounts and demographic accounts.

In broad terms, the regional accounting system developed by Stone was an extension of the system usually applied to individual countries. While a series of new problems arose, such as those concerning the definition of regions or lack of information about interregional flows, old problems related to international accounts became irrelevant, such as the different accounting systems used by different countries and their different units of account. Stone proposed a model where accounts for regions were ordered by type of account and region. When simple national schemes were applied to regions they generated independent relationships that could be used either to make indirect or residual estimates of some of the flows or to adjust an inconsistent set of direct estimates. Yet, the concept of region and of regional structure was not without its difficulties. As Stone put it, "we can apprehend, though we may not be able to formulate precisely, the concept of regional structure." The solution he proposed consisted in finding a geometric analogy between the concept of region and the concept of distance. But because regions should not be distinguished merely by their size, he suggested that this measure should be divided by the region's population. Moreover, to reduce the impact of large transactions he suggested that every transaction should be normalized, and to take into account the correlation between transactions, he transformed them into a set of hypothetical orthogonal transactions. Thus, by using a geometric analogy he was able to give a definition of cluster for measurement purposes. In many cases, regional differences in price levels could not be ignored. Conventional methods, based on pairwise comparisons, could not produce coherent results if more than two countries were involved. The solution would lie in a version of the principle of invariance, consisting in imposing the concept of an average quantity structure. The application of national accounting techniques to regional matrices implied a rejection of the assumption of proportionality between inputs and outputs in favor of linearity, which demanded much more information. As Stone observed, these models suffered from problems of standardization and communication (among their diverse components) that required new mathematical tools, such as matrix algebra. The extension of SNAs would put pressure on further standardization of national accounts.

Stone's work on demographic accounting started with his interest in including education and demographic trends in the Cambridge Growth Model. He repeatedly mentioned the importance of combining demographic and environmental with economic statistics for a proper study of society. However, the statistical approach he used to measure demographic variables followed very closely the approach used to measure economic variables. Stone acknowledged that "The statistical problems encountered in constructing socio-demographic matrices are, *mutatis mutandis*, similar to those encountered in constructing economic matrices." The unit of measurement of demographic accounts, instead of being the pound, was the human individual. The categories used to group units, instead of being industries and products, were based on age groups and within-age-groups based on activities and occupations. Instead of total output, total population; of intermediary product, surviving part of population; of final output, deaths and emigrations; of primary inputs, births and immigrations, and so on. Apart from a straightforward inversion of the role of inputs and outputs in demographic models, the main difference between them and the narrow national accounts consisted in the notion of *life sequences* (such as medical sequence, changes of marital status, and regional migration) used by Stone. They were used to produce a framework of dynamic accounting structure. His work on demographic accounts marked a tendency, pointed out by Johansen, according to which "Stone gradually turned from accounting formulations towards the representation of national accounts in the form of a large 'social accounting matrix' or 'transaction matrix'." It seems that extensions of the SNA, through the inclusion of regional and demographic accounts, would lead to an abandonment of the (formal)

original principle of coherence behind the concept of national accounts. The formal basis of coherence would also be extended to accompany the new bases of measurement. The use of matrix algebra and transaction matrices replaced the former notion of accounts, providing the flexibility needed to assemble complex sets of information. Nevertheless, by using the same standards of measurement, extension of SNAs appeared to involve more, rather than less, standardization of entries.

Final Remarks

Basic data, untailored by human hands, were for Stone, incomplete, inaccurate, inconsistent, and subject to many types of errors. He recognized what he called the "problem of measurement" as pervasive in all sciences. Quite often, according to Stone, the problem of data collection is to organize the large quantities of economic statistics available. In concrete terms, as he argues, "we never start from a *tabula rasa* and the practical problem is not to devise an ideal data collection scheme *ab initio* but to introduce more design and coherence into the one that already exists." Measurement starts then with attention to the existing methods of collection and tabulation and the use of common definitions and classifications and standard dates and intervals. In addition, new types of data can be collected. Boundary regions should be delimitated before what Stone, Champernowne, and Meade called "the practical work of measurement" begins.

The practical work of measurement was a reference to the transformation of direct into consistent measurement. Because initial estimates could not alone produce a consistent and complete set of measures, the boundaries of measurement would have to include the practical work of transforming quantities into empirical facts. Stone lamented that "yet, even nowadays, it is not generally accepted that the task of measurement is unfinished until estimates have been obtained that satisfy the constraints that hold between their true values."

Ultimately, measurement for Stone was about defining systems or stories that could "talk sense about the world." As he remarked: "Just because a theory is coherent there is no particular reason why it should also give a good account of reality." Although it is difficult to distinguish the precise sense in which Stone used the word "coherent" here, there is evidence to suggest that he held a stochastic view of measurement. He did not elaborate on that. Yet, it could be inferred from his writings that he saw measures as estimators of true values of variables. And, it seems, according to him, that this is the best we could aspire to. Accuracy and truth were beyond the potentiality of measurement, because at the end, the best measures would still be conditional to our best subjective impressions. It could be suggested that in the face of the increasing complexity of the measurement of national accounts, the notion of practice (or practical imperative) developed into an important element in Stone's concept of measurement. Thus, it can be said that measurement for Stone was an intrinsic element in this search for integration between theory and practice.

Stratified Sampling Types

Garrett Glasgow
University of California, Santa Barbara, California, USA

Glossary

disproportional allocation The allocation of a sample to strata in a way that does not reflect the actual proportion of the strata in the population; also known as oversampling.
optimal allocation The allocation of a sample to strata in a way that minimizes the variance of estimated population parameters; in some cases known as Neyman allocation.
poststratification The process of allocating the sample to strata after the sample has been drawn.
proportional allocation The allocation of a sample to strata in proportion to the actual proportion of the strata in the population.
quota sampling A nonrandom sampling technique for allocating the sample to strata.
strata A set of mutually exclusive and collectively exhaustive subpopulations of some population; one such unit is a stratum.
stratum weight The proportion of the population a stratum represents.

Stratified random sampling is the process of dividing the sampling units within a population into a set of mutually exclusive and collectively exhaustive groups, known as strata. Simple random samples are then drawn from each strata and combined to form a stratified random sample. Because strata are usually selected to be more homogeneous than the population as a whole, stratification can lead to large improvements in the precision of estimated parameters. Stratified sampling is also used when one or more strata in the population are relatively rare, and an oversample of this subpopulation is desired.

What is Stratified Random Sampling?

Introduction to Stratified Random Sampling

As with any other type of sampling, stratified random sampling is a method by which some observations are drawn from a population in order to make inferences about the population as a whole. Simple random sampling accomplishes this by giving each sampling unit in the population an equal probability of being drawn, and then drawing a sample of the appropriate size. Stratified random sampling begins by dividing the sampling units into a set of mutually exclusive and collectively exhaustive groups. These subpopulations are known as strata. Once the strata have been determined, a simple random sample is independently drawn from each, and the resulting subsamples are weighted and combined to form a stratified random sample.

For example, it may make sense to use stratified random sampling in a survey of individual opinions on tax expenditures on law enforcement, and stratify the sampling units into urban and rural households. It might be expected that individuals in relatively high-crime urban areas will have different opinions on the proper level of tax expenditures on policing than residents of rural areas. In this case, stratification would lead to more precise estimates of public opinion on this issue. Populations can of course be stratified by variables other than geographic location (such as gender or age), and populations can be stratified by multiple variables.

Why Stratified Random Sampling?

There are a number of reasons why a researcher may opt for a stratified random sample. First, stratification may

produce a gain in precision for estimates of characteristics of the whole population. Imagine a population that is heterogeneous, and thus requires a large simple random sample in order to get a reasonably precise estimate of the population characteristics. It may be possible to divide this heterogeneous population into a number of homogeneous strata. If this is the case, precise estimates of the characteristics of each of these homogeneous strata can be obtained with relatively small simple random samples, because the characteristics being measured vary little from one unit to another within each strata. These estimates can then be combined to form a more precise estimate of the population characteristics as a whole. Thus, stratification will be beneficial whenever a heterogeneous population can be divided into relatively homogeneous strata.

Second, a stratified random sample may be superior in terms of cost or administrative convenience. For example, a survey research center may have offices in major cities, and thus create strata based on metropolitan region, with each office responsible for sampling only in its area. This may also reduce the cost per observation in the survey, enabling a larger sample size than a simple random sample.

Third, stratification may be used to address differences in sampling problems across different parts of populations. For example, different sampling methods might be required or desired for different strata. Telephone interviews might be most convenient for rural strata, and face-to-face interviews most convenient for urban strata.

Fourth, estimates of population parameters may be desired for certain subpopulations within the general population. Stratification allows the researcher to place each subpopulation in a stratum and draw an independent sample for this group. This approach is especially useful if one or more strata are relatively rare in the population. In this case, an oversample of this strata can be used to estimate population parameters for these strata.

Properties of Stratified Random Sampling

Notation

In a stratified sample, the population of N sampling units is divided into H exhaustive and mutually exclusive subpopulations, such that $N_1 + N_2 + \cdots + N_H = N$. Once the strata are determined, independent simple random samples are drawn from each strata, denoted by $n_1, n_2, \ldots, n_H$, respectively. The total sample size is denoted n. It is standard to let the subscript h denote the stratum and i denote the individual unit within the stratum. Then y_{ih} denote the value of variable y obtained for unit i in stratum h.

Let μ represent the true population mean of some parameter of interest y in the stratified population, and let μ_h represent the true mean of y in stratum h in this population. Further, let σ_h^2 indicate the true variance of y in stratum h. Note that the formulas for variance presented here ignore the finite population correction (fpc). In finite populations, estimates of the variance are multiplied by the term $1 - (n/N)$, which adjusts the variance downward as the sample becomes a larger fraction of the population. In practice, the fpc is usually ignored if N is large, which is what will be assumed here.

Finally, let W_h refer to the stratum weight of stratum h. This is simply the proportion of the total population contained in the subpopulation defined by stratum h.

$$W_h = \frac{N_h}{N}. \tag{1}$$

Estimation of Population Parameters in Stratified Samples

The purpose of sampling is to obtain information about a population. This is most often done by estimating population parameters using the information in the sample. This section discusses the properties of parameter estimates obtained from stratified random samples. The estimation of a population mean is presented here. Estimates of population totals (population means multiplied by N) and population proportions (population means with ones indicating observations of interest and zeros indicating observations not of interest) follow directly from this discussion.

The true population mean μ for some parameter of interest y in a stratified random sample is simply the sum of the individual stratum means, weighted by their stratum weights:

$$\mu = \sum_{h=1}^{H} W_h \mu_h. \tag{2}$$

An unbiased estimate of this population mean is denoted $\bar{y}_{st}$ (st stands for stratified). Let $\bar{y}_h$ be the sample mean of y in stratum h. Then the population mean is estimated as

$$\bar{y}_{st} = \sum_{h=1}^{H} W_h \bar{y}_h. \tag{3}$$

This is simply the sum of the individual stratum means, weighted by their stratum weights. This estimate is not necessarily the same as the sample mean $\bar{y}$, which is calculated as

$$\bar{y} = \sum_{h=1}^{H} \frac{n_h}{n} \bar{y}_h. \tag{4}$$

The difference between these estimators is in the weights placed on the strata. In $\bar{y}_{st}$, the sample means from each strata receive their population weights, W_h.

However, the weights placed on the sample means from each strata in $\bar{y}$ will depend on the fraction of the sample allocated to the different strata in the population. Obviously, $\bar{y}_{st}$ and $\bar{y}$ will be equivalent when

$$\frac{n_h}{n} = \frac{N_h}{N} = W_h \tag{5}$$

for all strata.

Setting the sample fraction of each stratum to match the stratum weight is known as stratification with proportional allocation, since strata sample sizes $n_1, n_2, \ldots, n_H$ are proportional to population stratum weights $W_1, W_2, \ldots, W_H$. Proportional allocation is only one way in which to allocate the sample to the strata; other allocation strategies are discussed below.

The variance of the estimate $\bar{y}_{st}$ is given by

$$V(\bar{y}_{st}) = \sum_{h=1}^{H} W_h^2 \frac{\sigma_h^2}{n_h}. \tag{6}$$

Of course, the true variance of y in stratum h is not generally observed. An unbiased estimate of σ_h^2 is given by

$$s_h^2 = \frac{1}{n_h - 1} \sum_{i=1}^{n_h} (y_{ih} - \bar{y}_h)^2, \tag{7}$$

which makes the estimate of the variance of $\bar{y}_{st}$

$$\hat{V}(\bar{y}_{st}) = \sum_{h=1}^{H} W_h^2 \frac{s_h^2}{n_h}. \tag{8}$$

This formula reveals that the variance of $\bar{y}_{st}$ depends only on the variances of the estimates of the individual stratum means $\bar{y}_h$. This means that were it possible to divide a heterogeneous population into perfectly homogeneous strata, the population mean μ could be estimated without error. From this, it is easier to see how stratification into groups that are more homogeneous than the population as a whole can improve the precision of parameter estimates.

Further, this formula reveals that altering the relative sample sizes for the strata (n_h) will alter the variance of $\bar{y}_{st}$. In fact, for any fixed sample size, there exists a stratified random sampling strategy that yields an estimate of μ of minimum variance. This is known as stratification with optimal allocation. This and other sample allocation strategies are discussed in the next section.

Sample Allocation among Strata and the Construction of Strata

An important consideration in stratified random sampling is the allocation of sampling units among the strata. This allocation strategy will depend on the goals of the survey. A common goal in stratified random sampling is to improve the precision of estimates of population parameters. If properly used, stratification nearly always results in more precise estimates of population parameters than those obtained from a comparable simple random sample. However, if strata sample sizes are poorly chosen, stratified random sampling may produce samples that yield less precise estimates of population parameters than simple random sampling. Another common goal in stratified random sampling is to obtain precise parameter estimates for a subpopulation of interest. Three sample allocation strategies are discussed in the following sections: proportional allocation, optimal allocation, and disproportional allocation; the construction of strata is also considered.

Proportional Allocation

Proportional allocation sets the sample size in each stratum equal to be proportional to the number of sampling units in that stratum. That is, $n_h/n = W_h$. Proportional allocation yields a self weighted sample (no additional weighting is required to estimate unbiased population parameters). For example, $\bar{y}_{st} = \bar{y}$, as previously discussed. This was regarded as an important advantage in the past, but modern computational power makes this less of a concern.

Proportional allocation will yield population parameter estimates at least as precise as those obtained from simple random sampling. Depending on the differences between the strata means, the gain in precision from stratified random sampling can be vary large, with gains increasing as the differences between the strata means increase. Proportional allocation is useful if precise estimates are desired for the larger strata in the population, as large sample sizes are allocated to the large strata.

However, proportional allocation often will not produce the most precise parameter estimates possible. The precision of parameter estimates within each stratum is determined by the sample size, not the ratio of the sample size to the population size. Thus, the precision of the estimates can often be improved by allocating more of the sample to the smaller strata. This can greatly improve the precision of the estimates from the smaller strata without greatly reducing the precision of the estimates from the larger strata, improving the overall precision of the population parameter estimates.

Optimal Allocation

As previously discussed, for a fixed sample size there exists an allocation of sample sizes across strata that minimizes the variance of estimated population parameters. This allocation is known as optimal allocation.

Optimal allocation will yield population parameters estimates at least as precise as those obtained from a simple random sample of the same size, and usually

these estimates are much more precise. Further, optimal allocation often yields parameter estimates that are more precise than a stratified random sample of the same size that relies on proportional allocation, although the gain in precision here is usually less than that realized by switching from a simple random sampling approach to a stratified random sampling approach. The gain in precision for an optimal allocation over a proportional allocation will depend on the strata standard deviations, with gains increasing as the differences between the strata standard deviations increase.

For a fixed sample size n, the sample size in stratum h under optimal allocation is given by

$$n_h = n\frac{W_h\sigma_h}{\sum_{k=1}^{H} W_k\sigma_k} = n\frac{N_h\sigma_h/N}{\sum_{k=1}^{H} N_k\sigma_k/N} = n\frac{N_h\sigma_h}{\sum_{k=1}^{H} N_k\sigma_k}. \quad (9)$$

Each strata is sampled in proportion to the product of the standard deviation of the parameter of interest and the fraction of the population the stratum represents. Strata that are more heterogeneous are sampled more heavily in order to reduce the variance of parameter estimates from those strata, thus reducing the variance of estimates of population parameters. This allocation is also known as Neyman allocation.

This allocation strategy assumes that the costs of sampling are equal across strata. If this is not the case, a slightly more complicated optimization problem must be solved. Optimal allocations when sampling costs differ across strata can seek to minimize the variance of population parameter estimates for a fixed cost, or minimize costs for a fixed variance. The optimization problem is the same in either case.

Let c_h be the cost of obtaining one observation from stratum h. Thus, the entire cost of the survey will be $C = c_0 + \sum_{h=1}^{H} n_h c_h$, where c_0 represents any overhead cost for the survey. Under this cost constraint, the sample size in stratum h under optimal allocation is given by

$$n_h = n\frac{N_h\sigma_h/\sqrt{c_h}}{\sum_{k=1}^{H} N_k\sigma_k/\sqrt{c_k}}. \quad (10)$$

Each stratum is sampled in proportion to the product of the standard deviation of the parameter of interest and the fraction of the population the stratum represents, and in inverse proportion to the square root of the sampling cost in that stratum. In general, larger fractions of the sample will be allocated to strata that are relatively large, relatively heterogeneous, and less costly to sample from. Note that when sampling costs are identical across strata, the cost terms cancel out, and optimal allocation for a fixed cost becomes equivalent to optimal allocation for a fixed sample size.

Disproportional Allocation

In some cases, the sample may be deliberately allocated across strata in a disproportionate way (meaning the sample size in each stratum is not proportional to the number of sampling units in that stratum). Disproportionate allocation is often used if a particular stratum is of special interest but is too small a proportion of the population for reliable statistical inference without increasing the number of observations from this stratum. This is also known as oversampling, because observations from this stratum are overrepresented in the sample relative to its stratum weight. For example, a study might seek to compare the opinions of World War II veterans to the opinions of the U.S. population as a whole. As most sampling strategies would likely end up with very few World War II veterans, a stratified random sample with disproportionate allocation might be used, placing World War II veterans (or a subpopulation likely to contain a high proportion of World War II veterans) in one stratum, and oversampling this stratum to ensure enough World War II veterans in the sample for a meaningful comparison.

Oversampling will not bias estimates of population parameters as long as the appropriate strata weights are used. However, poorly selected strata sample sizes can result in less precise estimates of population parameters than even simple random sampling. Thus, disproportionate sampling is generally used only to gather a large sample on a particular stratum of interest, and not as a strategy to improve the precision of estimates on overall population parameters.

The Construction of Strata

How many and what type of strata to define in a stratified random sample will be determined by the goals of the study. In some cases, the strata will be determined by a desire to examine a particular subpopulation of interest, such as in the study described in the preceding section. In other cases, the strata will be defined in such a way as to minimize the variance of estimates of population parameters. It is this case that is considered here.

In order to gain the most from stratification, strata should be selected so that the differences between strata means are as large as possible and so that each stratum is as homogeneous as possible. Theoretically, increasing the number of strata will improve the precision of estimates of population parameters. However, in most practical applications, little improvement is seen beyond $H = 6$ or so. Further, additional strata may add to the cost of the study. Thus, most stratification strategies rely on a relatively small number of strata.

Once the number of strata is determined, boundaries between the strata must be selected. One method that has been found to be practical and efficient is known as the

cumulative square root of the frequency method. This method works when the stratifying variable y can be organized into ordered categories. The square root of the frequency of each category of y is calculated, and the cumulative distribution of these terms is examined. This cumulative distribution is denoted cum $\sqrt{f(y)}$, and the dividing points between strata are then selected to create equal intervals on the cum $\sqrt{f(y)}$ scale. For instance, if three strata were desired, and the square root of the cumulative frequency of the last category of y was 60, the dividing points between the three strata would be the values of cum $\sqrt{f(y)}$ closest to 20 and 40. In cases where the frequency distribution of y is not available, the frequency distribution of a variable highly correlated with y can be substituted. This method has been found to perform well for a variety of distributions of y.

Obviously, this method will not work for many variables that could be used for stratification (such as geographic variables). Like the determination of the number of strata, the construction of strata boundaries will often depend on judgement, trial and error, and knowledge of the characteristics of the sampling problem at hand in order to define relatively homogeneous strata with means that differ from each other.

Other Stratification Issues

Poststratification

In some instances, it is inconvenient or impossible to divide the population into strata before sampling. This is most often the case when the variable used to stratify the population can only be observed after sampling. For example, it will be impossible to stratify a public opinion poll by gender if the sample is drawn using randomly dialed telephone numbers, as it will be impossible to determine the gender of respondents until they are in the sample. Poststratification is often used when a simple random sample does not reflect the distribution of some known variable in the population.

In this case, a simple random sample is conducted, and then observations are placed in strata. Estimates of population parameters are carried out as with a stratified random sample. For example, a population mean would be estimated as the sum of the individual stratum means, weighted by their stratum weights. This estimate will be similar to that obtained from a stratified random sample with proportional allocation as long as the sample size is large in each stratum (generally larger than 20). Note that poststratification should not be used if the stratum weights are not known or cannot be closely approximated, because inaccurate stratum weights can lead to very poor estimates of population parameters.

The poststratification estimator will not have the same variance as an estimate obtained from a stratified sample, as the sample size in each stratum is no longer fixed but is a random variable. The approximate variance of $\bar{y}_{\text{pst}}$ (pst stands for poststratified) is given by

$$\hat{V}(\bar{y}_{\text{pst}}) = \frac{1}{n}\sum_{h=1}^{H} W_h s_h^2 + \frac{1}{n^2}\sum_{h=1}^{H}(1 - W_h)s_h^2. \qquad (11)$$

The first term in this equation is equivalent to the variance of the estimate of $\bar{y}_{\text{st}}$ that would be obtained from a stratified random sample under proportional allocation. The second term gives the increase in the variance of $\bar{y}_{\text{pst}}$ due to poststratification. This second term is always nonnegative, although it will be small as long as n is large.

Double Sampling for Stratification

The preceding discussion assumes that the strata weights W_h are known constants before sampling begins. However, in many instances the strata weights will be unknown. In some cases, the relative size of the strata may be determined through non-sample information (voter registration rolls, census information, etc.). For cases in which this is not true, preliminary information will have to be gathered from the population to construct strata before stratified random sampling can begin.

Double sampling (also known as two-phase sampling) is the process of first gathering preliminary information on which to base stratification, and then drawing a stratified random sample from this first sample, using information obtained in the first sample to determine the appropriate strata weights. This strategy will be viable in cases in which observations on the variables on which to base stratification are easy to obtain. The phase 1 sample is generally a large simple random sample used to estimate the strata weights. The phase 2 sample gathers the information of central interest to the study by drawing a smaller stratified random sample from the elements first drawn in the phase 1 sample.

Stratum weights for each stratum h are estimated by

$$\hat{W}_h = \frac{n'_h}{n'}, \qquad (12)$$

where n' is the sample size of the phase 1 sample, and n'_h is the number of observations falling into stratum h in the phase 1 sample. $\hat{W}_h$ is an unbiased estimator of W_h, assuming the phase 1 sample is random.

The phase 2 sample then randomly draws the appropriate number of elements (n_h) from the n'_h elements identified as belonging to stratum h. Estimates of population parameters are then obtained from the phase 2 sample in a straightforward way, replacing W_h with $\hat{W}_h$.

The variance of population parameter estimates using the phase 2 sample will not be the same as that of parameter estimates from a stratified random sample for which stratum weights are known. This is because stratum weights are no longer fixed, but are random variables. The approximate variance of $\bar{y}'_{st}$ (an estimate of μ using the phase 2 sample) is given by

$$\hat{V}(\bar{y}'_{st}) = \sum_{h=1}^{H} \hat{W}_h^2 \frac{s_h^2}{n_h} + \hat{W}_h \frac{(\bar{y}_h - \bar{y}_{st})^2}{n'}. \qquad (13)$$

The first term in this equation is identical to the variance of the estimate of μ with a stratified random sample that did not employ double sampling, except $\hat{W}_h$ replaces W_h. The second term gives the increase in variance due to the estimation of the stratum weights. Although this second term grows larger as the differences in the stratum means increase, the advantages of stratification over simple random sampling also increase as the differences between the stratum means increase. Thus, even though double sampling for stratification increases the variance of estimated population parameters, it may still result in large increases in precision over simple random sampling.

Quota Sampling

Quota sampling is the nonprobability equivalent of stratified random sampling. Like stratified random sampling, the population is first divided into strata. For a fixed sample size n, the n_h required in each stratum for proportional stratification is determined. A quota is set for each stratum of n_h observations, and the researcher continues sampling until the quota for each stratum is filled. For instance, if a population is known to be 70% men and 30% women, a survey of 100 people using quota sampling would ensure that 70 of the interviews were with men and 30 were with women. Subjects for the interviews are selected based on convenience and the judgement of the interviewer.

Quota sampling is generally less desirable than stratified random sampling for two reasons. First, because the selection of sampling units is non-random, the usual sampling error formulas (such as the estimation of variances on our estimated parameters) cannot be applied to the results of quota samples with any confidence. Second, because the observations included in a quota sample are selected nonrandomly, this may introduce bias into the sample that a random sample would not. That is, while a quota sample will be representative of the population on the variables used to define the strata, it may not be on other variables. Randomized samples will most likely be more representative on uncontrolled factors than an equivalent quota sample.

Structural Equation Models

David Knoke
University of Minnesota, Minneapolis, Minnesota, USA

Glossary

confirmatory factor analysis A multivariate equation model with one or more unobserved common factors describing or explaining the relationships among empirical measures.
random error Unpredictable error resulting in normally distributed variation around a measure's true value.
reliability The extent to which different operationalizations of the same concept produce consistent results.
structural equation model A multivariate equation model combining relations among unobserved constructs with links to empirical indicators.
validity The degree to which the operationalizations of a variable accurately reflect the concept that they purport to measure.

Structural equation models (SEM) are a family of analysis methods that represent translations of a series of hypothesized cause–effect relationships among variables, for making quantitative estimates of model parameters and their standard errors, for assessing the overall fit of a model to data, and for determining the equivalences of model parameters across several samples. The techniques for analyzing multivariate relationships among systems of equations build directly on multiple regression, exploratory factor analysis, and path models. Although SEM methods can be applied to complex problems, such as nonrecursive models that estimate reciprocal causal effects, space constraints allow only a basic exposition.

Reliability and Validity Issues

An important advantage of structural equation models (SEM) is their capacity to combine empirical observations with relations among unobserved constructs into a single integrated system. Measurement theory seeks to represent a latent (unobserved) construct with one or more observable indicators (operational measures or variables) that accurately capture a theoretically intended concept. Two desirable properties of any empirical measure are high levels of reliability and validity. Reliability indicates the extent to which different operationalizations of the same concept produce consistent results. Reliability refers to the replication of measurement results under the same conditions; a perfectly reliable instrument must generate identical scores when the re-measurement conditions are unchanged. Alternative or multiple measures are reliable indicators of the same construct to the extent that they correlate highly. Validity is the degree to which the operationalizations of a variable accurately reflect the concept that they purport to measure. Many validity issues concern how well or poorly a particular instrument, whether consisting of a single or multiple empirical indicators, represents its intended latent concept. To be valid, a measure must demonstrate at least moderate reliability. In the extreme, if a measure has zero reliability, its validity would be attenuated relative to a more reliable measure. Multiple indictors may vary in their validity as measures of the unobserved concept they are intended to measure. Some measures may be very reliable but not valid; that is, an instrument might very precisely measure a particular phenomenon, yet be invalid for some purposes. For example, individual height can be very reliably measured, yet is worthless as an indicator of a person's physical health. A multiple-item health battery is less reliably measured, yet is far more valid for measuring physical health. Unfortunately, researchers never obtain perfect measurements in the real world; every empirical measure is subject to some degree of measurement error. Measurement theory is therefore also a theory about how to estimate magnitudes and sources of errors in empirical observations.

Measurement reliability assumes random errors. If random error occurs when a measure is repeated several times on the same cases under the same conditions, then the resulting variations in scores form a normal distribution about the measure's true value. The standard error of that distribution represents the magnitude of the measurement error: the larger the standard error, the lower the measure's reliability. In classical test theory, the observed score (X) of respondent i on a measuring instrument (such as an aptitude test score or a survey item) arises from two hypothetical unobservable sources: the respondent's "true score" and an error component:

$$\text{True}_i \longrightarrow X_i \longleftarrow \text{Error}_i$$
$$X_i = T_i + \varepsilon_i.$$

On the assumption of random error, the error term is assumed to be uncorrelated with the true score. Both sources make unique contributions to the observed score variance in a population: $\sigma_X^2 = \sigma_T^2 + \sigma_\varepsilon^2$. The ratio of true score to observed score variances is defined as the reliability of measure X:

$$\rho_X = \frac{\sigma_T^2}{\sigma_X^2} = 1 - \frac{\sigma_\varepsilon^2}{\sigma_X^2}.$$

This formula demonstrates that reliability ranges between 0 and 1: if the entire observed variance is error, $\rho_X = 0$; but if no random error exists, then $\rho_X = 1$. Rearranging the reliability formula also reveals that the true score variance equals the observed score variance times the reliability: $\sigma_T^2 = \rho_X \sigma_X^2$. Similarly, for two parallel measures (i.e., items having equal variances), the true score variance can be estimated as the product of their correlation ($\rho_{X_1X_2}$) and the variance of either measure; that is, $\sigma_T^2 = \rho_{X_1X_2}\sigma_X^2$. Hence, reliability equals the correlation of two parallel measures, $\rho_X = \rho_{X_1X_2}$, while the correlation between a true score and its indicator equals the square root of the reliability: $\rho_{TX_1} = \sqrt{\rho_X}$. The measurement theory principles summarized in this section are encompassed within structural equation models and are used in the next section on the confirmatory factor analytic approach to modeling the relationships between observed indicators and latent constructs.

Confirmatory Factor Analysis

Factor analysis refers to a family of statistical methods that represents the relationships among a set of observed variables in terms of a hypothesized smaller number of latent constructs, or common factors. The common factors presumably generate the observed variables' covariations (or correlations, if all measures are standardized with zero means and unit variances). In confirmatory factor analysis (CFA), a researcher posits an *a priori* theoretical measurement model to describe or explain the relationship between the underlying common factors and the empirical measures. Then the analyst uses statistical fit criteria to assess the degree to which the sample data are consistent with the posited model, that is, to ask whether the results confirm the hypothesized model.

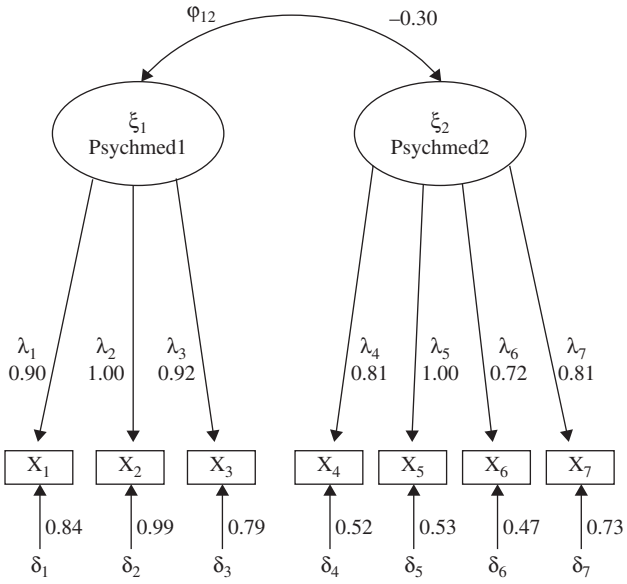

Figure 1 A two-factor confirmatory factor analysis model with seven psychiatric medicine indicators.

Figure 1 hypothesizes that observed measures of three harmful and four beneficial effects of psychiatric medicines (X_1 to X_7) load on separate but correlated latent factors (ξ_1 and ξ_2), labeled Psychmed1 and Psychmed2. Data for the estimates are from 1070 respondents in the 1998 General Social Survey. The seven λ_i are the factor loadings of each observed variable on the two common factors, and the seven δ_i are the observed variables' unique error terms. This diagram implies that the latent constructs are responsible for the covariation among the observed variables. Each observed score is a linear combination of its shared unobserved factor plus its unique error term. These relationships can also be seen by writing the implied measurement equation for the first and seventh indicators: $X_1 = \lambda_1\xi_1 + \delta_1$ and $X_7 = \lambda_7\xi_2 + \delta_7$. Note the similarity of each factor analytic equation to classical test theory's representation of an observed score as a sum of a true score plus an error term.

Figure 1 assumes that all seven error terms are uncorrelated with both factors and among themselves (although alternative models allow such specifications). Hence, the only sources of an indicator's variance are its common factor ξ and its unique error term,

$$\sigma_{X_i}^2 = \lambda_i^2\sigma_{\xi_k}^2 + \Theta_{\delta_i}^2,$$

where $\Theta^2_{\delta_i}$ signifies the variance of the error in X_i. Because ξ_k is unobserved, its variance is unknown and because it is unknown, it may be assumed to be a standardized variable with a variance equal to 1.0. Therefore,

$$\sigma^2_{X_i} = \lambda^2_i + \Theta^2_{\delta_i}.$$

Again, note that this formula closely resembles the classical test theory in which the variance of a measure equals the sum of two components—the true score variance plus the error variance. When both components are standardized, their sum must equal 1.0. A CFA model exhibits another similarity to the classical test theory. The reliability of indicator X_i is defined as the squared correlation between a factor and the indicator (if that indicator loads on only one factor). This value is the proportion of variation in X_i that is statistically "explained" by the common factor (the "true score" in classical test theory) that it purports to measure, $\rho_{X_i} = \rho^2_{\xi X_i} = \lambda^2_i$. Finally, the covariation between any two indicators in a multiple-factor model is the expected value of the product of their two factor loadings times the correlation between the factors. Because the error terms are uncorrelated with the factor and with each other, this simplifies to $\sigma_{X_i X_j} = \lambda_i \lambda_j \varphi^2_{\xi_k \xi_l}$.

As noted above, an unobserved common factor has no definite scale, meaning that both the origin and the unit of measurement are arbitrary. Researchers usually fix a factor's origin by assuming it has a mean of zero. The measurement unit must be scaled by one of two ways: (1) fixing the unobserved factor's variance to unity; or (2) forcing the factor loading of one indicator (λ_i), called the reference indicator, to take a specific value (typically by setting it equal to 1.00). This latter procedure forces the factor's true score variance to equal the reliable portion of the reference indicator's variance.

The CFA example for psychiatric medicine effects in Fig. 1 illustrates the second technique for setting the two factor scales by constraining the factor loadings of the X_2 and X_5 indicators equal to 1.00. Although the seven estimated loadings are all positive, the two factors have a negative covariation (−0.30). This inverse relationship is not surprising, given the substantive wordings of the seven GSS items, emphasizing harmful or beneficial effects, respectively. Because respondents generally do not regard psychiatric medicines as simultaneously harmful and beneficial, a negative covariation occurs between the latent constructs represented by these two sets of empirical indicators.

CFA solutions can represent relationships in both unstandardized and standardized forms. Because a structural equation model consists of both structural and measurement levels of analysis, standardization may be done separately at each level: (1) the standardized solution scales the factors to have standard deviations of one, but leaves the observed variables in their original metrics, and (2) the completely standardized solution transforms the standard deviations of both latent and observed variables to unity. Figure 2 displays the completely standardized solution for the two-factor psychiatric medicine model. The correlation between the two latent factors is −0.57, indicating that they share 32.5% of their variation [$r^2 = (-0.57)(-0.57) = 0.325$]. Unlike the factor model in Fig. 1, the completely standardized solution does not require constraining any indicators to have loadings equal to one. Hence, their magnitudes can easily be compared to assess the indicators' relative importance. Further, in both standardizations, the sum of a squared factor loading plus its square error term equals 1.00, showing that all the variation in an observed indicator is determined by these two sources. For example, the first indicator in Fig. 2 has a standardized factor loading of 0.63 and an error term of 0.78; the sum of their squared values is $(0.63)^2 + (0.78)^2 = 0.397 + 0.608 = 1.00$, within rounding.

Assessing Model Fit to Data

Parameter significance and overall correspondence between the data and the model's parameters are two important concerns of model testing. SEM computer programs estimate standard errors for all free parameters in confirmatory factor analysis or structural equation models. Thus, analysts can test the null hypothesis that a particular parameter is zero in the population, using

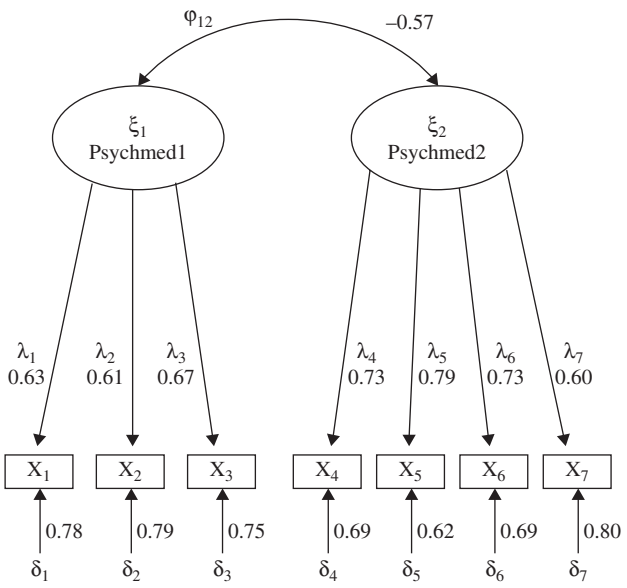

Figure 2 Completely standardized solution for a two-factor confirmatory factor analysis model with seven psychiatric medicine indicators.

appropriate one- or two-tailed t-tests or Z-tests, depending on sample size. All the factor loadings, residuals, variances, and covariances in the CFA model in Fig. 1 are significant at $p < 0.05$. However, testing the significance of individual parameters cannot reveal whether the model as a whole fits the sample data.

Statistical tests for overall model fit involve a comparison of two variance-covariance matrices: (1) the observed matrix ($\mathbf{S}$) of covariances among the K empirical indicators in the sample data; and (2) the expected matrix [$\mathbf{\Sigma}(\boldsymbol{\theta})$] of covariances among the same K indicators, computed from the model's estimated parameters ($\boldsymbol{\theta}$). An SEM program fits a model to the data by minimizing a fit function $F[\mathbf{S}, \mathbf{\Sigma}(\boldsymbol{\theta})]$. (Iterative maximum likelihood estimation is the default procedure of most programs, but alternative methods may be more appropriate for some model specifications, such as generalized least squares or weighted least squares.) The fit function involves discrepancies between the observed and predicted matrices: $F[\mathbf{S}, \mathbf{\Sigma}(\boldsymbol{\theta})] = \ln|\mathbf{\Sigma}| - \ln|\mathbf{S}| + \mathrm{tr}(\mathbf{S}\mathbf{\Sigma}^{-1}) - p$; where $|\mathbf{\Sigma}|$ and $|\mathbf{S}|$ are determinants of each matrix, tr indicates "trace," the sum of the diagonal elements of the matrix, and p is the number of observed variables in the model. The fit function is always nonnegative and equals zero only if a perfect fit occurs; that is, if $\mathbf{S} - \mathbf{\Sigma} = 0$. For a large sample N, multiplying $F[\mathbf{S}, \mathbf{\Sigma}(\boldsymbol{\theta})]$ by $(N-1)$ yields a test statistic distributed approximately as a χ^2 with degrees of freedom equal to $d = [k(k+1)/2] - t$, where t is the number of estimated parameters. Because the minimum fit function χ^2 test statistic increases proportional to sample size, N, obtaining low χ^2 values with large samples often proves difficult. The CFA model in Fig. 1, based on $N = 1070$ cases, has $\chi^2 = 24.1$ for df (degrees of freedom) $= 13$ ($p = 0.03$), indicating that the model does not fit the data perfectly.

SEM computer programs print numerous goodness-of-fit indexes that can be used to assess overall model fit. Many indices are normed within a 0 to 1 range, with higher values reflecting better fits, but others have arbitrary metrics. Some fit indexes are functions of sample size, like χ^2, while others vary with degrees of freedom. For example, the widely used root mean square error of approximation (RMSEA) measures the mean of the squared discrepancies between observed and predicted matrices per degree of freedom. Small RMSEA values (<0.05) indicate a "close fit." The RMSEA for the CFA model in Fig. 1 is 0.029, indicating that the model fits the data quite well. One useful classification system distinguishes absolute, relative, and adjusted goodness-of-fit measures. Absolute indexes assess whether a specific model leaves appreciable unexplained variance. Relative fit indexes compare the specific model to possible baseline or null models estimated using the same data. Adjusted measures ask how well the model combines both fit and parsimony, taking into account the degrees of freedom used in the model specification. Analysts remain divided about criteria for selecting fit index and evaluating good fit. Several major points of consensus have emerged: (1) a strong substantive theory is the best guide to assessing model fit; (2) χ^2 should not be the sole basis for determining fit; (3) analysts should not rely on a single measure of overall fit; (4) other model components, such as equation R-squares and magnitudes of coefficient estimates, should be taken into account; and (5) rather than attempt to assess a single model's fit in some absolute sense, several models should be examined for plausible alternative structures.

Structural Equation Models

This section extends confirmatory factor analysis models to models with two or more latent variables having multiple indicators. Structural equation models combine factor analysis principles with path analysis and other path modeling methods in specifying a set of linear equations representing hypothesized relations among latent constructs and their multiple indicators. Structural equation models consist of two interrelated components, a measurement model and a structural model. The measurement model, which specifies how the latent constructs are indicated by their observed indicators, describes these indicators' measurement properties (reliabilities and validities) and is analogous to CFA. The structural equation model specifies causal relationships among the latent variables, describes their direct and indirect effects, and allocates explained and unexplained variance of the dependent constructs.

The observed indicators are partitioned into exogenous variables whose variation is predetermined outside the model, and endogenous variables whose variation is explained within the model. In the matrix algebra notation, a generic system of structural equations is denoted by $\boldsymbol{\eta} = \boldsymbol{\beta}\boldsymbol{\eta} + \boldsymbol{\Gamma}\boldsymbol{\xi} + \boldsymbol{\zeta}$, where $\boldsymbol{\eta}$ is a vector of unobserved endogenous variables, $\boldsymbol{\xi}$ is a vector of unobserved exogenous variables, $\boldsymbol{\varsigma}$ is a vector of unobserved errors, and $\boldsymbol{\beta}$ and $\boldsymbol{\Gamma}$ are the matrices of structural parameters to be estimated. The measurement model is specified by two equations: $\mathbf{Y} = \boldsymbol{\Lambda}_{\mathbf{Y}}\boldsymbol{\eta} + \boldsymbol{\varepsilon}$ and $\mathbf{X} = \boldsymbol{\Lambda}_{\mathbf{X}}\boldsymbol{\xi} + \boldsymbol{\delta}$, where $\mathbf{Y}$ and $\mathbf{X}$ are vectors of the observed endogenous and exogenous indicators, the two $\boldsymbol{\Lambda}$ parameter matrices specify how the observed indicators are linked to the unobserved constructs (equivalent to factor loadings in a CFA model), and the $\boldsymbol{\varepsilon}$ and $\boldsymbol{\delta}$ vectors contain the error terms of the indicators.

An SEM implies a covariance structure for the observed variables. Estimating the model assumes empirical data from a random sample of N cases for which all the indicators have been measured. A computer program then uses an iterative algorithm to fit the specified SEM to the sample covariance matrix ($\mathbf{S}$) of the indicators. The program simultaneously estimates the free parameters of

both the structural and the measurement models, estimates standard errors for each parameter, and calculates various goodness-of-fit indexes for the whole model. Several SEM computer programs perform these computations, for example, LISREL, AMOS, EQS, MPLUS, and SAS CALIS. Most programs no longer require analysts to specify their models in formal matrix algebra language, but use simple programming instructions to denote the hypothesized relations among latent and observed variables. Some SEM programs allow a researcher to draw a diagram on a computer screen, then translate it into software commands that estimate the model parameters.

Diagrams are indispensable tools for conceptualizing and interpreting a SEM. In the simple example in Fig. 3, the structural model depicts an exogenous "political ideology" construct causing variation in an endogenous "federal help" construct. The measurement model consists of two observed indicators of politics (conservative political views and party identification) and four indicators of help (attitudes against the federal government's responsibility for solving social problems: not helping with poverty, not helping with any problems, not helping with medical bills, and not helping African Americans). Parameter estimates for the completely standardized solution were computed by LISREL from a covariance matrix computed for 1594 respondents in the 1998 GSS. The overall model fit is very good ($\chi^2 = 15.7$, df = 8, $p = 0.052$; other fit indexes have quite acceptable values), and the individual parameter estimates are all highly significant. The estimated structural parameter (0.63) means that a difference of one standard deviation in political ideology is associated with a three-fifths standard deviation difference in attitude toward the federal government's role in solving social problems. Given that all indicators were measured with conservative responses scored high and liberal responses scored low, the positive sign means that more ideologically conservative respondents favor more individualistic solutions to social problems (i.e., less federal government involvement).

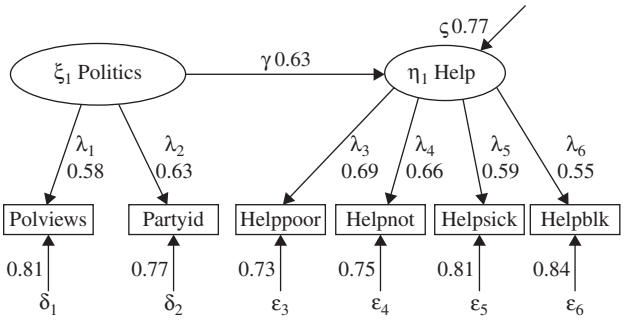

Figure 3 Completely standardized solution for a simple structural equation model.

SEM programs allow an explicit statistical test of the hypothesis that two or more parameters are equal in the population. Constraining a pair of parameters to be equal (rather than letting them freely take differing values) requires estimating only one parameter instead of two. As a result, one degree of freedom is then available to assess whether constrained and unconstrained models' χ^2 statistics differ at a chosen α-level. If no significant difference occurs between the two models, then the more parsimonious version with equal parameters (i.e., the model with fewer unconstrained parameters) would be preferred. In the model in Fig. 3, the standardized parameters of the four help indicators seem to have roughly similar magnitudes (ranging between 0.55 and 0.69). Some alternative models that specified equal loadings for several pairs of indicators did not produce significantly worse fits to the data. However, a model that hypothesized equal loadings for HELPOOR and HELPBLK was rejected (χ^2 difference of $24.9 - 15.7 = 9.2$ for $df = 1$, $p < 0.01$). Another model, hypothesizing equal factor loadings for the first three indicators (HELPPOOR, HELPNOT, HELPSICK), did not produce a significantly worse fit compared to the model with no equality constraints (χ^2 difference of $19.2 - 15.7 = 3.5$ for $df = 2$). The three help indicators each had estimated parameters equal to 0.76, while the HELPBLK indicator had a lower value (0.66).

Model Identification and Modification Strategies

For a model to be estimable, both its measurement and its structural equation portions must be identifiable. An SEM or CFA model is identified if every unknown parameter has a unique value that can be estimated by fitting the model to the data. A model is "underidentified," and not estimable, if the number of unknown parameters to be estimated exceeds the available degrees of freedom (the number of indicator variances and covariances). In such instances, a model can be respecified to ensure identification by constraining sufficient numbers of the unknown parameters to fixed values (typically set to zero). "Just identified" models, with precisely as many unknown parameters as available degrees of freedom, always produce trivially perfect fits but may provide useful baseline estimates against which to test other models with positive degrees. "Overidentified" models, with positive degrees of freedom, reveal whether the model specifications reasonably represent relationships in both the measurement and structural models. For a complicated SEM, a researcher's *a priori* identification of all parameters may become difficult because fulfilling all the formal requirements to assure identification can often be quite complicated. SEM computer programs usually ascertain whether a hypothesized

model is not identified, if they cannot calculate unique estimates with standard errors for the unknown parameters. Nevertheless, model and parameter identification remain relevant concerns, because SEM computer programs may occasionally produce solutions for unidentified models. Model modification strategies contain additional important concerns. Unless a model fits the data well, researchers seldom fit a single hypothesized model to their data, then stop after making the decision to accept or reject that specification without proposing any alternative. The more common practice involves model generation strategy, an exploratory approach that incrementally respecifies parameters and fits a series of alternative CFA or SEM to the same data. The analyst's ultimate objective is to find an overidentified model that fits the data at an acceptable level (using the various goodness-of-fit indexes), while also yielding plausible and meaningful interpretations of the estimated parameters. Exploratory modifications of a tentative initial model should not rely entirely on statistical criteria, but should also take into account existing theory and empirical knowledge about a substantive area. Important procedures for locating sources of model misspecification include examining parameter estimates for unrealistic values or anomalous signs inconsistent with theoretical expectations; assessing squared multiple correlations (R^2) for each equation for evidence of weak or nonlinear relations; and inspecting residuals, standardized residuals, and model modification indices to pinpoint expected parameter changes and fit improvement, for example, by correlating error terms. By repeating these steps for successively modified models, analysts may obtain a final version that fits the sample data reasonably well and provides a plausible interpretation.

Unfortunately, a final SEM or CFA model with an improved fit to the data is unlikely to be the "true" or "best-fitting" model, in the sense that its successive improvements involved capitalizing on chance covariation in the sample data. Instead, it is probably one of several alternative models of equivalent overall fit that approximate the unknown true population SEM. A more robust approach to SEM generation cross-validates the modified model results with an independent sample. Alternatively, researchers can randomly split a sufficiently large sample in half, using the first subsample to estimate the modified model and the second subsample to cross-validate that specification. Recent developments in automated algorithms, such as TETRAD and TABU, assist researchers in their search for true model specifications and parameter estimates.

Strengths and Limitations of SEM

Both CFA and SEM methods, implemented in a variety of computer packages, provide researchers with powerful data analysis tools. Applied judiciously, these methods have important advantages over traditional multivariate methods, such as linear regression, that assume no errors in observed measures. If an SEM model is true, then its structural parameters linking the latent constructs take into account the biases of less reliably and validly measured indicators. However, the price paid for these advantages is susceptibility to erroneous parameter estimates and model fits if analysts misspecify the true measurement and structural relationships. For example, covariation in cross-sectional data offers no clues to asymmetric or reciprocal causation; even the temporal sequences among repeated measures in longitudinal panel designs are not an infallible guide to causal order. Because SEM methods by themselves do not enable researchers to distinguish among many alternative models with statistically equivalent fits, analysts face heavy requirements to apply logic and theory jointly to distinguish incredible from plausible alternative model specifications. The protean qualities of SEM methods should spur researchers to work harder at improving their theoretical understanding of the social processes they seek to explain.

Structural Item Response Models

Cees A. W. Glas
University of Twente, Enschede, The Netherlands

Glossary

differential item functioning Items that have different item parameters in different groups of respondents.
item response model Stochastic measurement model with distinct person and item parameters.
Markov chain Monte Carlo estimation Estimation procedure that generates the posterior distribution of parameters via simulation.
maximum marginal likelihood estimation Estimation procedure based on a likelihood function that is marginalized with respect to nuisance parameters.
multilevel item response model Item response model where person or item parameters are nested in a hierarchical structure.
structural item response model Item response model with an additional model for person or item parameters.
testlet model Item response model where items are clustered in subtests which are usually called testlets.

Structural item response theory models are models that consist of two parts: an item response theory model with distinct person and item parameters, and an additional model that specifies the structure of either the person and item parameters (or even both). Structural item response models support modeling of differences between groups of respondents and complex response formats. Further, structural item response theory models can play a role as alternative models in tests of model fit for more basic item response models.

Introduction

Item Response Models

Item response theory (IRT) models are stochastic models for two-way data, say, the responses of persons to items. An essential feature of these models is parameter separation, that is, the influences of the items and persons on the responses are modeled by distinct sets of parameters. To illustrate parameter separation, consider the two-way data matrix in Table I. The first 3 persons responded to the first 3 items, persons 4, 5, and 6 responded to items 4, 5, and 6, and the last two persons responded to items 1, 2, and 6. Since different respondents took different tests, their total scores cannot be compared without additional assumptions. For instance, it is unclear whether the score 9 obtained by person 3 represents the same ability level as the score 9 obtained by person 5, because they might have responded to items of a different difficulty level.

In the present, highly hypothetical case, the data were constructed according to a very simple deterministic linear model given by $y_{ik} = \theta_i + b_k$, where y_{ik} stands for the response of person i to item k. The person parameter θ_i can be viewed as the ability of person i and the item parameter b_k can be viewed as the easiness item k. The values of θ_i and b_k, and the way in which they account for the data, are shown in Table II. It can now be seen that person 3 has an ability level $\theta_3 = 1$, while person 5 has an ability level $\theta_5 = 2$.

Table I Data Matrix with Observed Scores

	Item						
Respondent	1	2	3	4	5	6	*Score*
1	2	3	1				6
2	4	5	3				12
3	3	4	2				9
4				4	5	3	12
5				3	4	2	9
6				2	3	1	6
7	3	4				1	8
8	2	3				0	5

Table II Effects of Items and Persons Separated

	Item						
Respondent	1	2	3	4	5	6	θ_i
1	0 + 2	0 + 3	0 + 1				0
2	2 + 2	2 + 3	2 + 1				2
3	1 + 2	1 + 3	1 + 1				1
4				3 + 1	3 + 2	3 + 0	3
5				2 + 1	2 + 2	2 + 0	2
6				1 + 1	1 + 2	1 + 0	1
7	1 + 2	1 + 3				1 + 0	1
8	0 + 2	0 + 3				0 + 0	1
b_k	2	3	1	1	2	0	

Of course, in practice, this kind of deterministic model never fits the data, so to calibrate item and person parameters on a common scale, a statistical model with the property of parameter separation must be used. A natural choice is an IRT model, many of which are outlined in the present volume. For dichotomous items, the 1-, 2-, and 3-parameter logistic models (1PLM, 2PLM, and 3PLM, Birnbaum) are used most often. The 3-parameter logistic model is given by

$$p(y_{ik}=1\,|\,\theta_i,a_k,b_k,c_k)=c_k+(1-c_k)\Psi(a_k(\theta_i-b_k))$$
$$=c_k+(1-c_k)\frac{\exp(a_k(\theta_i-b_k))}{1+\exp(a_k(\theta_i-b_k))}, \quad (1)$$

where a_k, b_k, and c_k are the discrimination, difficulty, and guessing parameters, respectively. The 2PLM follows upon introducing the constraint $c_k=0$ and the 1PLM follows upon introducing the additional constraint $a_k=1$. Note that $\Psi(a_k(\theta-b_k))$ stands for the logistic function evaluated at $a_k(\theta-b_k)$. In an alternative, but for all practical purposes, equivalent formulation, the logistic function is replaced by the normal ogive function, $\Phi(a_k(\theta-b_k))$, which stands for the standard normal function integrated to $a_k(\theta-b_k)$. The choice between the two formulations is often determined by computational convenience. Generalizations of the 2PLM to models for responses to polytomous items include the graded response model and the nominal response model with special cases as the rating scale model and the partial credit model. Multidimensional models where the latent ability parameters are multidimensional were developed by McDonald. All these models share the feature of parameter separation and the possibility of using incomplete designs to calibrate item and person parameters on a common scale.

It should be noted that estimation of the model parameters from data in incomplete designs has its limitations. First, the design should be linked. In the example given above, the design would not be linked if only the data of the first six respondents were available, because in that case the data matrix would break down into two separate data matrices that would have no persons or items in common. The responses of the last two persons serve as a link between these two data matrices. Second, the common procedures to obtain consistent estimates of the parameters assume that the design is ignorable. In the present framework, Rubin's theory of ignorability entails that the test administration design should not depend on unobserved data. Therefore, an item administration design is ignorable in applications where the design is *a priori* fixed, but also in some applications where this is not the case, such as in multistage testing and in computerized adaptive testing.

Besides the possibility that item and person parameters can be calibrated on a common scale several other applications of IRT deserve mention. First, IRT can be used to support the construct validity of a test. If it can be empirically shown that a test is unidimensional, this can be viewed as empirical evidence that all items of the test measure the same construct. Second, the fitted IRT model implies a scoring rule for the test. For instance, if the 1PLM holds, a meaningful variable can be created by summation of the item scores for each person, and this variable is a sufficient statistic for θ. If the test proves multidimensional, multidimensional IRT models give insight in the structure of the test content. Further applications of IRT are the evaluation of differential item functioning, optimal test construction, and computerized adaptive testing. Finally, IRT provides a solution for the attenuation problem, that is, the problem that the correlation between observed scores is often attenuated by the unreliability of the measurement instruments. When properly estimated the correlation between latent variables does not suffer from this problem.

Structural Item Response Models

In this article, structural IRT models are defined as a mixture of an IRT model and a model that specifies the structure of either the person or item parameters (or both). If independence between respondents and items is assumed, a structural IRT model can be generally defined by the likelihood function

$$L(\theta,\delta,\lambda,\tau;y,x)=\prod_i^I\prod_k^K p(y_{ik}\,|\,\theta_i,\delta_k)^{d_{ik}}g(\theta_i\,|\,\lambda,x)$$
$$\times h(\delta_k|\tau,x), \quad (2)$$

where y_{ik} is the response variable and d_{ik} is a design variable assuming a value 1 if the item was responded to

and zero otherwise. Further, $p(y_{ik} \mid \theta_i, \delta_k)$ is the response probability under the IRT model (with an example given in (1)), $g(\theta_i \mid \lambda, x)$ is the density function for θ_i, and $h(\delta_k \mid \tau, x)$ is the density function of δ_k. The latter densities have parameters which are a function of parameters λ and τ, respectively, and both may depend on covariates denoted by x.

Overview

An exhaustive review of all currently used structural IRT models is beyond the scope of this article. Therefore, this article reviews some of the best-known models, as far as they are not treated elsewhere in this encyclopedia. Models for ability parameters, from a simple model to evaluate differences between groups to rather complex multilevel linear models that allow for measurement error in both the dependent and independent variables, are studied, as are models for the item parameters. A distinction is made between fixed effect models (with an application to the evaluation of differential item functioning) and random effect models (with an application to the analysis of responses to item clones). A model for testlets with a random parameter for the interaction between respondents and items is discussed. Finally, references to relevant software are mentioned.

Models for Ability Parameters

Differences in Ability Level between Groups

Suppose respondents are sampled from two populations, say males and females, and the interest is in evaluating the difference in the mean ability level of the two populations. Gender is coded as

$$x_i = \begin{cases} 1 & \text{if } i \text{ is a male} \\ 0 & \text{otherwise,} \end{cases} \tag{3}$$

and gender differences in ability are modeled as

$$\theta_i = \mu + \beta x_i + e_i, \tag{4}$$

where it is assumed that e_i has a normal distribution with mean zero and variance σ^2. Note that μ is the mean ability level of the females, while $\mu + \beta$ is the mean ability level of the males. So β is the effect of being male. In IRT, the assumption that the variance σ^2 is equal over groups is easily generalized to the assumption that groups have unique variances, say σ_g^2.

Maximum marginal likelihood (MML) estimation is the most used technique for parameter estimation in IRT models. In this approach, a distinction is made between structural parameters, which need to be consistently estimated and nuisance parameters, which are not of primary interest. MML estimation derives its name from maximizing a likelihood function that is marginalized with respect to the nuisance parameters. In the present case, the likelihood is marginalized with respect to the ability parameters θ, leading to the marginal likelihood

$$L(\delta, \beta, \mu, \sigma; y, x) = \prod_i^I \int_{-\infty}^{\infty} \prod_k^K p\left(y_{ik} \mid \theta_i, \delta_k\right)^{d_{ik}} \times g(\theta_i \mid \mu, \beta, \sigma, x_i)\, d\theta_i, \tag{5}$$

where $g(\theta_i \mid \mu, \beta, \sigma, x_i)$ stands for the normal density as implied by Eq. (4). The reason for maximizing the marginal rather than the joint likelihood of all parameters simultaneously is that maximizing the latter likelihood does not lead to consistent estimates.

Table III gives a small simulated example of the procedure. The data were generated with the 1PLM. The design consisted of 9 items administered to two groups. Group 1 consisted of 100 simulees who responded to the items 1 to 6. The second group consisted of 400 simulees responding to the items 4 to 9. So the items in the so-called "anchor" were responded to by 500 simulees. The true item parameters b_k are shown in the second column of Table III, the MML parameter estimates $\hat{b}_k$ and their standard errors $se(\hat{b}_k)$ are shown in the third and fourth column, respectively. Note that the standard errors are inversely proportional to the number of simulees responding to the item. The bottom lines of the table give the generating values for β, σ_g $(g = 1, 2)$, their estimates, and their standard errors. In this example, μ has been set equal to zero to identify the scale of θ. The test whether the two groups have the same mean ability

Table III Parameter Values and Estimates

Item	b_k	$\hat{b}_k$	$se(\hat{b}_k)$
1	−1.00	−0.71	0.33
2	0.00	−0.04	0.30
3	1.00	1.18	0.29
4	−1.00	−1.10	0.14

1	1.00	1.13	0.18
2	1.50	1.45	0.10

level, that is, the test of the null hypothesis $\beta = 0$ against the alternative $\beta \neq 0$, can be based on the ratio of the estimate of β with its standard error, that is, $\hat{\beta}/se(\hat{\beta})$. In the present case, the outcome is $1.07/0.22 = 4.864$. Under the null-hypothesis, the statistic has a standard normal distribution, so the null-hypothesis is clearly rejected.

This approach can be generalized in various ways. One could introduce a second variable, say

$$x_{2i} = \begin{cases} 1 & \text{if } i \text{ lives in an urban area} \\ 0 & \text{otherwise,} \end{cases} \tag{6}$$

and consider the model

$$\theta_i = \mu + \beta_1 x_{1i} + \beta_2 x_{2i} + \beta_{12} x_{1i} x_{2i} + e_i. \tag{7}$$

If x_{1i} stands for gender, then β_{12} stands for the interaction of being male and living in an urban area, and, as above, a test of the hypothesis $\beta_{12} = 0$ against the alternative $\beta_{12} \neq 0$ can be based on the parameter estimate relative to its standard error. The next section gives further generalizations of this approach.

Multilevel Regression Models on Ability

In much social research, elementary units are clustered in higher level units. A well-known example is educational research, where pupils are nested within classrooms, classrooms within schools, schools within districts, and so on. Multilevel models (ML models) have been developed to take the resulting hierarchical structure into account, mostly by using regression-type models with random coefficients. However, if variables in these multilevel models contain large measurement errors, the resulting statistical inferences can be very misleading. Measurement error can be modeled in the framework of classical test theory and IRT. In the classical framework, the variance component due to unreliability can either be imputed in the model or it can be estimated within the model, for instance by splitting test scores into subtest scores. The IRT framework is a generalization of the linear model described above. The approach entails the definition of a multilevel linear model where latent variables from IRT measurement models are entered either as dependent or as independent variables. The resulting model is the so-called multilevel IRT model. The general model is defined as follows. The dependent variables are observed item scores y_{ijk}, where the index i $(i = 1, \ldots, n_j)$ signifies the respondents, the index j $(j = 1, \ldots, J)$ signifies the Level 2 clusters, say the schools, and the index k $(k = 1, \ldots, K)$ signifies the items. The first level of the structural multilevel model is formulated as

$$\theta_{ij} = \beta_{0j} + \beta_{1j} x_{1ij} + \cdots + \beta_{q'j} x_{q'ij} + \beta_{(q'+1)j} \xi_{(q'+1)ij} + \cdots + \beta_{Qj} \xi_{Qij} + e_{ij}, \tag{8}$$

where the covariates x_{qij} $(q = 1, \ldots, q')$ are manifest predictors and the covariates ξ_{qij} $(q = q' + 1, \ldots, Q)$ are latent predictors. Finally, e_{ij} are independent and normally distributed error variables with mean zero and variance σ^2. In general, it is assumed that the regression coefficients β_{qj} are random over groups, but they can also be fixed parameters. In that case, $\beta_{qj} = \beta_q$ for all j. The Level 2 model for the random coefficients is given by

$$\beta_{qj} = \gamma_{q0} + \gamma_{q1} z_{1qj} + \cdots + \gamma_{qs'} z_{s'qj} + \gamma_{q(s'+1)} \zeta_{(s'+1)qj} + \cdots + \gamma_{qS} \zeta_{Sqj} + u_{qj}, \tag{9}$$

where z_{sqj} $(s = 1, \ldots, s')$ and ζ_{sqj} $(s = s' + 1, \ldots, S)$ are manifest and latent predictors, respectively. Further, u_{qj} are error variables which are assumed independent over j and have a Q-variate normal distribution with a mean equal to zero and a covariance matrix T.

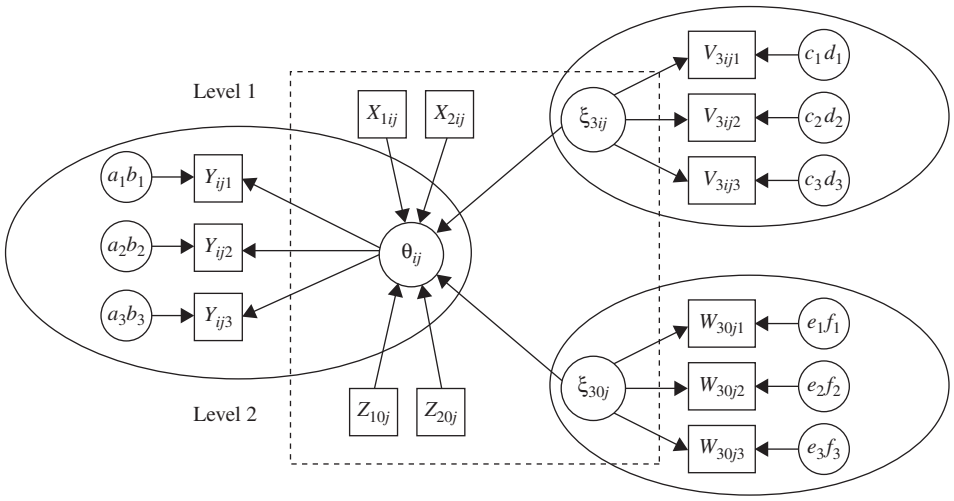

Figure 1 Path diagram of a multilevel IRT model.

An example of a MLIRT model is given in the path diagram in Fig. 1. The structural multilevel part is presented in the big square box in the middle. The structural model has two levels: the upper part of the box gives the first level (a within-schools model), and the lower part of the box gives the second level (a between-schools model). The dependent variable θ_{ij}, say math ability, is measured by three items. The responses to these items are modeled by the 2PLM with item parameters a_k and b_k, $k = 1, \ldots, 3$. Note that the measurement error models are presented by the ellipses. Both levels have three independent variables: two are observed directly, and one is a latent variable with three binary observed variables. For instance, on the first level, X_{1ij} could be gender, X_{2ij} could be age, and ξ_{3ij} could be intelligence as measured by a three item test. On the second level, Z_{10j} could be school size, Z_{20j} could be the school budget and ζ_{30j} could be a school's pedagogical climate, again measured by a three-item test. In order not to complicate the model, it is assumed that only the intercept β_{0j} is random, so the Level 2 predictors are only related to this random intercept and the slopes are fixed.

The parameters in the MLIRT model can be estimated in a Bayesian framework with a version of the Markov chain Monte Carlo (MCMC) estimation procedure: the Gibbs sampler. There are many considerations when choosing between a frequentist framework (such as MML) and Bayesian framework (such as MCMC), but the reason for adopting the Bayesian approach given by Fox and Glas is a practical one: MML involves integration over the nuisance parameters, and in the present case these integrals become quite complex. In the Bayesian approach, the interest is in the posterior distribution of the parameters, say $p(\theta, \delta, \beta, \mu, \sigma \mid y)$. In the MCMC approach samples are drawn from the posterior distribution and in this process nuisance parameters play a role as auxiliary variables. So the problem of complex multiple integrals does not arise here.

To give some idea of the output of the procedure, consider an application reported by Shalabi. The data were a cluster sample of 3384 grade 7 students in 119 schools. At student level the variables were Gender (0 = male, 1 = female), SES (with two indicators: the father's and mother's education, scores ranged from 0 to 8), and IQ (range from 0 to 80). School level variables were Leadership (measured by a scale consisting of 25 five-point Likert items, administered to the school teachers), School Climate (measured by a scale consisting of 23 five-point Likert items), and Mean-IQ (the IQ scores aggregated at school level). The items assessing Leadership and School Climate were dichotomous. The dependent variable was a mathematics achievement test consisting of 50 multiple-choice items. The 2PLM was used to model the responses to the Leadership and School Climate questionnaire and the mathematics test. The parameters were estimated with the Gibbs sampler. For a complete description of all analyses, one is referred to the work of Shalabi, here only the estimates of the final model are given as an example.

Table IV Estimates of the Effects of Leadership, Climate, and Mean IQ

	MLIRT estimates		*ML estimates*	
	Estimates	*C.I.*	*Estimates*	*C.I.*
γ_{00}	–1.096	–2.080––0.211	–0.873	–1.20––0.544
β_1	0.037	0.029–0.044	0.031	0.024–0.037
β_2	0.148	0.078–0.217	0.124	0.061–0.186
β_3	0.023	0.021–0.025	0.021	0.019–0.022
γ_{01}	0.017	0.009–0.043	0.014	0.004–0.023
γ_{02}	0.189	0.059–0.432	0.115	0.019–0.210
γ_{03}	–0.136	–0.383––0.087	–0.116	–0.236–0.004
Variance components				
τ_0^2	0.177	0.120–0.237	0.129	0.099–0.158
σ^2	0.189	0.164–0.214	0.199	0.190–0.210

The model is given by

$$\theta_{ij} = \beta_{0j} + \beta_1 \mathrm{SES}_{ij} + \beta_2 \mathrm{Gender}_{ij} + \beta_3 \mathrm{IQ}_{ij} + e_{ij}, \quad (10)$$

$$\beta_{0j} = \gamma_{00} + \gamma_{01} \mathrm{Mean\text{-}IQ}_j + \gamma_{02} \mathrm{Leadership}_j + \gamma_{03} \mathrm{Climate}_j + u_{0j}. \quad (11)$$

The results are given in Table IV. The estimates of the MLIRT model are compared with a traditional ML analysis where all variables were manifest. The observed Mathematics, Leadership, and School Climate scores were transformed in such a way that their scale was comparable to the scale used in the MLIRT model. Further, the parameters of the ML model were also estimated with a Bayesian approach using the Gibbs sampler.

The columns labeled C.I. give the 90% credibility intervals of the point estimates; they were derived from the posterior standard deviation. It can be seen that the magnitudes of the fixed effects in the MLIRT model were larger than the analogous estimates in the ML model. This finding is in line with the other findings, which indicates that the MLIRT model has more power to detect effects in hierarchical data where some variables are measured with error.

Models for Item Parameters

Fixed Effects Models: Differential Item Functioning

Differential item functioning (DIF) is a difference in item responses between equally proficient members of two or more groups. For instance, a dichotomous item is subject

to DIF if, conditionally on ability level, the probability of a correct response differs between groups. One might think of a test of foreign language comprehension, where items referring to football impede girls. The poor performance of the girls on the football-related items must not be attributed to their low ability level but to their lack of knowledge of football. Since DIF is highly undesirable in fair testing, several techniques for the detection of DIF have been proposed. Most of them are based on evaluation of differences in response probabilities between groups conditional on some measure of ability. The most generally used technique is based on the Mantel–Haenszel statistic, others are based on log-linear models and on IRT models.

In the Mantel–Haenszel (MH) approach, the respondent's number-correct score is used as a proxy for ability and DIF is evaluated by testing whether the response probabilities differ between the score groups. Though the MH test works quite well in practice, its application is based on the assumption that the number-correct score is a sufficient statistic for ability, that is, that the 1PLM holds. In application of the MH test in other cases, such as cases where the data follow the 2PLM or the 3PLM, the number-correct score is no longer the optimal ability measure. In an IRT model, ability is represented by a latent variable θ, and an obvious solution to the problem is to evaluate whether the same item parameters apply in subgroups that are homogeneous with respect to θ.

As an example, DIF can be investigated by introducing a more general alternative to the 3PL model as defined in Eq. (1) given by

$$p(y_{ik} = 1 \mid \theta_i, a_k, b_k, c_k, d_k) = c_k + (1 - c_k)\Psi(a_k(\theta_i - b_k - x_i d_k)), \quad (12)$$

where x_i is the background variable Gender as defined by (3), and d_k is the change in the difficulty level of item k for males. The model defined by (12) pertains to dichotomous items, but the idea of modeling DIF by introducing item parameters depending on background variables also applies to polytomous items.

Tests for DIF are usually item-oriented, that is, items are tested one at a time. In general, a test for DIF can be defined by choosing a no-DIF IRT model (say, the 3PLM) as the null hypothesis and an IRT model for DIF (say, the model given by Eq. (12)) as the alternative. The test can be based on a likelihood ratio statistic or a Wald statistic. Both statistics require maximum likelihood estimates of both the parameters under the null model and the alternative model. Therefore, Glas proposed using the Lagrange multiplier statistic, which only requires estimation of the null-model. The LM test is based on the evaluation of the first-order partial derivatives of the log-likelihood function of the alternative model evaluated using the maximum likelihood estimates of the null model. The magnitudes of these first-order partial derivatives determine the value of the statistics, that is, the closer they are to zero, the better the model fit. The LM statistic is asymptotically chi-square distributed with degrees of freedom equal to the difference in the number of parameters of the two models.

Tables V and VI give a small simulated example of the procedure. The data were generated according to

Table V Parameter Generating Values, Estimates, and the LM Statistic

2	1.50	1.41	0.08		

the same setup as the example of Table III, but with some differences. First, both groups now consist of 400 simulees, and both groups respond to all 9 items. However, to simulate DIF, for the first group the parameter of item 5 was changed from 0.00 to 0.50. Table V gives the generating values of the parameters, the estimates and the standard errors. The last two columns of Table V give the value of the LM statistic and the associated significance probability. In the present case, the LM statistic has an asymptotic chi-square distribution with one degree of freedom. The test is highly significant for item 5.

For the analysis of Table VI, item 5 has been split into two virtual items: item 5 was assumed to be administered to group 1, and item 10 was assumed to be administered to group 2. So the data are now analyzed assuming an incomplete item administration design, where group 1 responded to the items 1 to 9 and group 2 responded to the items 1 to 4, 10, and 6 to 9 (in that order). As a consequence, one group only responded to the virtual items 5 and 10, and the LM test for DIF cannot be performed for these items. It can be seen in Table VI that the values of the LM statistics for the other items are not significant, which gives an indication that the model fit now fits.

Random Effect Models for Variability in Item Parameters

In the previous section, variability of item parameters was treated as a fixed effect, that is, the item parameters were a finite number of unique entities. In the present section, the focus is on item parameters as random effects, that is, the item parameters are seen as exchangeable draws from a distribution. Interest in item sampling is related to the introduction of computer-generated items in educational measurement. Using item-cloning techniques, items can be generated by a computer from a smaller set of "parent items" through the use of transformation rules. An example is the "replacement set procedure," where elements of the parent item (e.g., key terms, relations, numbers, and distractors) are randomly chosen from a well-defined set of alternatives. Because this introduces (slight) random variation between items derived from the same parent, it is possible to model the item parameters as random and shift the interest to the hyper-parameters that describe the distributions of the item parameters within parents.

To define the model, consider a set of item populations $p = 1, \ldots, P$ of size $K_1, \ldots, K_P$, respectively. The items in population p will be labeled $k_p = 1, \ldots, K_p$. The first-level model is the 3PLM which describes the probability of a correct response as $p(y_{ik_p} \mid \theta_i\ a_{k_p},\ b_{k_p},\ c_{k_p})$, as in Eq. (1) but with the subscript changed from k to k_p. In the Level 2 model, the values of the item parameters a_{k_p}, b_{k_p}, c_{k_p} are considered as realizations of a random vector. It is assumed that the item parameters, say ξ_{k_p}, have a 3-variate normal distribution with mean μ_p and a covariance matrix Σ_p. To support the assumption of normality, the item parameters are transformed as $\xi_{k_p} = (a_{k_p},\ b_{k_p},\ \text{logit}\, c_{k_p})$ or as $\xi_{k_p} = (\log a_{k_p},\ b_{k_p},\ \text{logit}\, c_{k_p})$. The logit transformation is a standard way to map a probability, such as c_{k_p}, to the real numbers, and taking the logarithm of a_{k_p} assures that a_{k_p} is positive. The model can be estimated by Bayesian methods based on the MCMC procedure or by MML.

The Testlet Model

A testlet is a subset of items related to some common context. Usually these sets take the form of a number of multiple choice items organized under or within some text. When a test consists of a number of testlets, both the within and between dependence between the items play a role. One approach is to ignore this hierarchical dependence structure and analyze the test as a set of atomistic items. This generally leads to an overestimate of measurement precision and bias in the item parameter estimates. Another approach is to aggregate the item scores within the testlet to a testlet score and analyze the testlet scores using an IRT model for polytomously scored items. This approach discards part of the information in the item responses, which will lead to loss of measurement precision. The rigorous way to solve the problem is to model the within and between dependence explicitly. Wainer, Bradlow, and Du introduce a generalization of the 2PLM given by

$$p(y_{ik} \mid \theta_i, a_k, b_k, c_k, \gamma_{id(k)}) = c_k + (1 - c_k)\Psi(a_k(\theta_i - b_k + \gamma_{id(k)})),$$

where $d(k)$ is the testlet to which item k belongs and $\gamma_{id(k)}$ a person-specific testlet effect. It is assumed that $\gamma_{id(k)}$ has a normal distribution with a mean equal to zero and variance σ^2_γ. Further, it is assumed that θ has a standard normal distribution.

The parameters in the model can be estimated in a Bayesian framework using MCMC or in a frequentist framework using MML. Glas, Wainer, and Bradlow report a number of simulation studies performed to assess the effect of ignoring the testlet structure on the precision of item calibration. Some of their results are reported here. Every simulee responded to 40 items. The item discrimination parameters a_i were drawn from a uniform distribution on the interval $[0.8, \ldots, 1.2]$, the item difficulty parameters b_i were drawn from a uniform distribution on $[-1, \ldots, 1]$, and all item guessing parameters c_i were equal to 0.25. The ability parameters θ were drawn from a standard normal distribution. Fixing the guessing parameter to its true value was sufficient to obtain MML estimates

Table VII Mean Absolute Error of Item Parameter Estimates for 3PLM and Testlet Model

$\gamma_{id(k)}$	*Number of items in testlet*	*Number of testlets*	N	*3PLM*		*Testlet Model*	
				MAE(a)	*MAE(b)*	*MAE(a)*	*MAE(b)*
0.25	10	4	2000	0.083	0.070	0.083	0.071
			5000	0.046	0.046	0.046	0.046
	5	8	2000	0.083	0.068	0.081	0.068
			5000	0.046	0.036	0.048	0.037
1.00	10	4	2000	0.092	0.064	0.072	0.062
			5000	0.025	0.060	0.038	0.035
	5	8	2000	0.112	0.082	0.072	0.066
			5000	0.087	0.075	0.039	0.041

(without priors on the other parameters). In the simulation study, three factors were varied: the number of testlets (4 or 8, and, hence, 10 and 5 items per testlet), the number of simulees (2000 or 5000), and the testlet effect size $\gamma_{id(k)}$ (0.25 or 1.00). Table VII gives results averaged over 10 replications. In the columns labeled *MAE*(*a*) and *MAE*(*b*), the mean absolute errors of the estimates of the discrimination and difficulty parameters are presented, computed ignoring and including the testlet parameters. The difference between the parameter estimates was negligible for the cases where $\gamma_{id(k)} = 0.25$, while moderate effects appear for the more substantial within-persons standard deviation $\gamma_{id(k)} = 1.00$.

Conclusion

A final remark concerns the software for estimation and testing of the models discussed above. First, simple linear models for θ can be directly computed using standard IRT software that can handle multiple groups, such as Bilog, Multilog, Parscale, Testfact (products of Scientific Software International), ConQuest (developed in part to meet the needs of large scale educational surveys as the TIMSS project), or OPLM (developed by Cito, the National Institute for Educational Measurement in the Netherlands). The latter program has an appendix called Saul that can estimate more complex linear models. The MLIRT model can be estimated by the MLIRT program (available via the Web). The testlet model can be estimated using Scoright (a product available through Educational Testing Service).

Structural Models in Anthropology

David B. Kronenfeld
University of California, Riverside, Riverside, California, USA

Glossary

cognitive structure A structure consisting of concepts (and/or categories of concepts) showing a meaningful set of relationships among them. "Concepts" here can refer to knowledge of factual matters, of conceptual relations, of behavioral or emotional concomitants of entities, actions or events, of action consistent with goals or values, and so forth.

collective representations Knowledge—whether abstract or embodied in action—that is constructed and held by the membership of a community, that entails some sort of coordination among community members, and that is ascribed to the community as a whole.

componential structure A semantic structure formed by a set of contrasting terms that share a root defining semantic attribute and that are distinguished from one another by contrasting values on one or more out of a set of intersecting semantic dimensions. "Mother," "father," "sister," etc. are all "blood" kin. "Mother" differs from "father" in sex; "mother differs from "sister" in generation; "father" differs from "sister" in generation and sex; and so forth.

cultural grammar A modeling of relations among form classes for some cultural entity—on the model of a linguistic grammar.

cultural structures The collective representations for some domain of knowledge or activity held by (or ascribed to) members of some community. For example, kinterm systems, ethnobotanical systems, the system of roles in a university, or how to play football.

kinship terminological system The kinship terms of a language (e.g., "father," "mother," "uncle," and "cousin") organized and analyzed as a distinct system.

section system A system of kinship and marriage in which the membership of a society is divided into opposed groups (usually seen as the defined by the intersection of cross-cutting moieties), and in which husbands and wives must come from one set of opposed groups, and in which children and their spouses belong to a contrasting set of opposed groups.

social structure Modeling of interactive relations among groups of people, where group membership is based on (or recognized in terms of) some set of collective representations.

taxonomic structure A tree- or dendrogram-shaped semantic structure formed by a hierarchy of inclusion relations (a dog is a kind of mammal, a mammal is a kind of animal, etc.) and contrast (Boxers, Bassetts, and Collies are contrasting (or opposed) kinds of dog; dogs, cows, and raccoons are contrasting kinds of mammals, etc.).

unilineal descent group Corporate (holding some property in common) kingroup consisting of the descendants of some apical ancestor in either the male line (a patrilineal descent group) or in the female line (a matrilineal descent group). The system is "segmentary" if successively wider groups are defined around a genealogically based "taxonomy" of apical ancestors.

After a discussion of what anthropologists understand by "structural models," the range of such models is described and exemplified. Different kinds of structural models vary in the topics they address, in their degree of formality, in the questions that are asked of them, and in the sources they are based on. Sources include structural linguistics, mathematics (graph theory and algebra), and computer programming. Topics include social structure in Radcliffe-Brownian Structural-Functionalism, social and cognitive structures in Levi-Straussean Structuralism, componential/paradigmatic and taxonomic structures of linguistic anthropology, the structure of marking hierarchies and implicational chains of concepts, the structure of culturally standardized decisions, and the conceptual structure of culture itself.

Meaning of "Structural Model" as Commonly Understood in Anthropology

A model reflects some literal representation (or construction) of some piece or aspect of something else—in anthropology usually some presumed reality. In this usage, a model differs from a theory since the latter is a set of formal propositions about underlying or generating entities and relations (cf. axioms) from which outcomes can be deduced—and represents a stab at an analytic understanding. Model airplanes can be literal replications (to any desired degree of exactitude) of real planes. As such, they may actually fly, and they can be used for experiments relating to many aspects of aircraft design (e.g., air flow, lift, and drag). At the same time, they are not any kind of theory of flight, and, indeed, can be made successfully in the absence of any such theory. As "models," they are simplifications, and, hence, cannot represent the full reality of the modeled aircraft. For instance, our little flight models will not tell us much about metal fatigue nor about when the wings will be too heavy for the plane (or vice versa).

Simplifying can be good when it allows us to see (or examine) things that we would not otherwise see (or be able to look at). Models are helpful to us as simplifications that we can experiment with—adding whatever complexity is necessary to address the issues we choose to address. As models become more closely and effectively tuned to "systems" they do thereby come more closely to approximate instantiations of "theories" of the systems in question. Simplified models can also be used by people to avoid having to think too hard about stuff they cannot readily articulate or do not really believe; thereby, they can serve a variety of ideological roles by artificially justifying extreme actions, making people feel good or important, allaying fears and low self esteem, and so forth.

Structure represents the systematic relationships among the entities that make up a system, that is, the relationships that govern interactions among the entities. Often "structure" is seen as a kind of skeleton on which the meat of actual behavior is mounted. In anthropology, these entities are often grouped into sets that make up the subsystems of "culture" known as a cultural domains (e.g., kinship, politics, ethnobotany). In such a set, the entities represent the effective operative units (whether of people, groups of people, concepts, or whatever) in the domain. The label "structural model" is less widely used (except in certain particular schools of work—see below), but is usually understood as referring to a representation of the structure of a domain. Typically (and perhaps prototypically) this is presented as a diagrammatic model (though algebraic representations sometimes appear). A structural model differs from a simple diagram or picture in that it represents the underlying relations among some sort of parts that are seen to govern behavior in the given domain. However, we should note that neither structure nor structural models has any well-defined and generally shared meaning within anthropology.

Sources and Kinds of Structural Models

Radcliffe-Brownian Structural Functionalism

The initial significant anthropological appeal to structure was in Radcliffe-Brownian (British) Structural Functionalism. The central idea was that a set of institutions (kinship, politics, economics, religion, ecology, etc.) had a structural organization—a system of analytic or systemic units and relations among them—around which social functioning was organized. Structure was constituted by the functionally significant units and relations among them. Social structure, then, referred to the sets of functionally significant groups of people (kin groups, communities, neighborhoods, sodalities, etc.) and the understood regularities in relations among them. These relations could include obligations for mutual assistance, gifts, or support; residential rights and obligations; or competitive access to resources, and they could derive from the nature of the group or from obligations (such as marriage) assumed by group members.

The Radcliffe-Brownian emphasis, however, was on function. There was no general move to pull out anything like what might be called structural models. Illustrative diagrams—of, say, ties among kingroups or of relations among political entities—were often used to show or explicate structural relations Malinowski, while at least as important to the British Structural Functional School and the students who came out of it, was even less concerned with structure, and was even, in some significant ways, opposed to the idea of structure.

In the first student generation, Evans-Pritchard and Fortes did offer something more like explicit models in their discussions of segmentary systems of balanced opposition (linking kinship and politics). For important examples see the work of Evans-Pritchard and Fortes.

For societies with such systems, a genealogy based on unilineal descent relations served as a political framework that defined relative degrees of affiliation among territorial/organizational units and the political and military concomitants of those affiliations. For instance, Evans-Pritchard described the patrilineal Nuer as having a system in which ego, whether male or female, belonged to his or her father's immediate family corporation and to the wider kin groups to which it was affiliated via chains of ancestral males (apical ancestors of various segments).

Inheritance, bridewealth, and homicide payments were among the activities tied to various levels of relationship. That male-line genealogy was continued up to the point at which all Nuer were related via a single genealogy. It was much like the Biblical genealogy of Abraham, Isaac, Jacob/Israel, and the apical ancestors of the various Hebrew tribes. With the genealogy came a feud system in which closer relatives unite against more distant relatives. The genealogy became a political charter via the association of territorial segments (immediate communities and the larger groups which they in turn made up) with the descendants of various apical ancestors—i.e., with segments of the encompassing Nuer genealogy. The military and juridical obligations of community members in any given local conflict were normally defined by the genealogical relations of the lineage segments with which the communities were associated, even though only a minority of any local community actually belonged to the lineage segment with which the community was associated. A system of justice was compounded out of a combination of feud obligations, places of sanctuary, and negotiations for compensatory payments. The successful operation of the system depended on opposed (intra-Nuer) segments (segments associated with the sons of a given ancestral father) being of roughly equal population and power. Such balance was maintained through a system of selective pruning of more distant ancestors from the genealogy (what has sometimes been called "structural amnesia"); the pruning was the unself-conscious effect of the fact that Nuer learned their genealogies only via their participation in activities tied to genealogical units; they only learned the names and positions of ancestors who were relevant to actual events (i.e., structurally relevant). (See Fig. 1.)

Within the Radcliffe-Brownian tradition the conception of social or political "structure" ranged from Evans-Pritchard's mental conception of it to Fortes' behavioral. That is, Evans-Pritchard (in his Nuer books) saw social structure as a mental template in terms of which the somewhat chaotic assemblages of everyday life were recognized, categorized, and understood. Fortes, on the other hand (in his Tallensi books), saw social structure as the actual recurrent groupings of actual people on the ground (a view very similar to the classic Bloomfieldian view of linguistic structure). Thus, in Evans-Pritchard's Nuer ethnography, if two men were on opposite sides of a fight, their presence there would be credited to their own descent group relations, the descent group relations of the local lineages associated with their residences (commonly different from their own lineages), or other social ties—depending on what possibilities were factually available and on how those doing the crediting saw the reason for the fight. In Fortes' Tallensi accounts, worshipping together at certain kinds of shrines was based on shared descent group membership, and a careful mapping of who

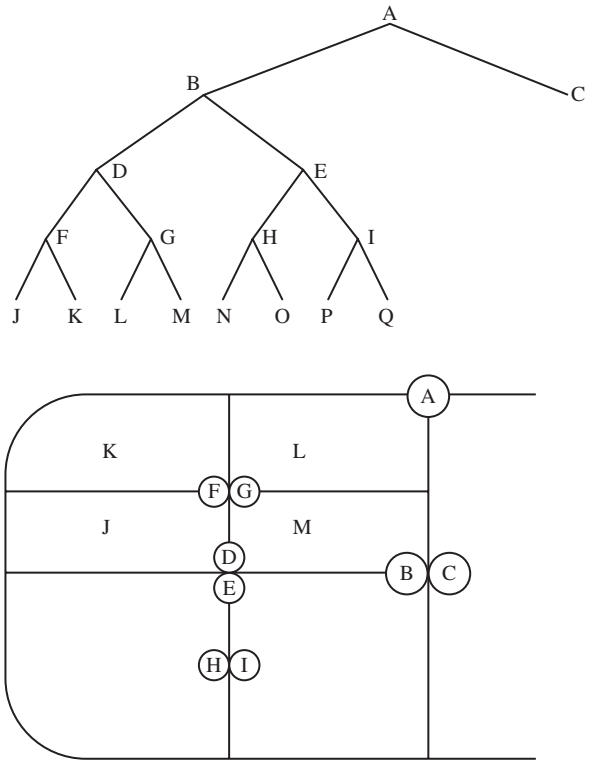

Figure 1 Nuer political structure: Evans-Pritchard's linked genealogical and territorial units (adapted from Evans-Pritchard, 1940). (Top) Geneology: A–Q are ancestors of living people; (bottom) Territory: A–Q are regions or communities associated with the descent groups descended from the given ancestors.

worshipped with whom at such shrines would directly reveal the descent group structure. Changes in such co-worshipping—and in the descent group structures apparently implied—from one year to the next accounts for most of the confusing complexities of Fortes' Tallensi accounts (vs. the great clarity with which he often wrote).

Gregory Bateson, in *Naven*, suggested the existence in different cultures of cognitive (as well as social) structures (which he modeled), even if his conception of them was somewhat abstract and thin by today's standards, and even if his conception never really caught on. Additionally, and importantly, with his brilliant development of "schismogenesis," he pioneered development of the concept of feedback, and our understanding of its role in the change over time of the shared cognitive and behavioral entities that make up culture.

Edmund Leach, before he moved in more Levi-Straussian directions, offered a new and exciting approach to the structural analysis of kinship terminologies. In his 1945 paper on Jinghpaw kinship terms (reprinted in his *Rethinking Anthropology*), he explored what would be the significant set of kinship roles and definitions, given normative rules of lineage affiliation and postmarital residence. Even though it failed to fully account for the regularities of

terminological systems, Leach's effort was a useful contribution. It in some ways prefigured later prototype-extension approaches to terminological categories, and it offered a kind of structural frame in which terminological categories, kinship roles, and kin groups could be brought together in a common treatment.

Section Systems

Another area of kinship in which structural-functionalists associated with Radcliffe-Brown produced early structural models was the "section systems" of aboriginal Australian societies. These were systems of affiliation based on aspects of descent and linked to kinterm categories. These systems constrained marriages and served as the basis of wide regional systems of putative kin (systems by which nonkin or people whose actual kin status was unknown were assimilated into kin categories for various, but not all, social, political, and economic purposes). Four-section systems eventually came to be described as, and are often pictured as, an intersection either of patri- and matri-moieties or of a moiety system with an alternating generation rule. Eight-sections systems were then seen as based on subdivisions of a basic 4 (see Fig. 2).

Structural Linguistics

An important source for contemporary anthropological understandings of structure and structural models has been structural linguistics in its Saussurean roots and in its developed Bloomfieldian/Yale/American and Prague versions.

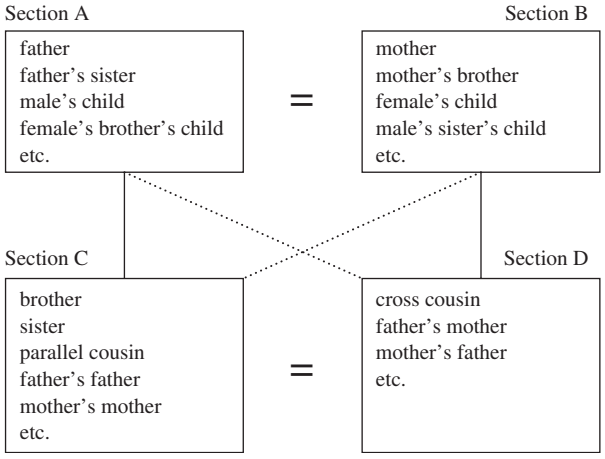

Figure 2 A Four-Section System. Each box is a section and in it are kinds of relatives of an ego (who happens to be in Section C) who fall in that section. Vertical lines between boxes (in either direction) link fathers with their children. Lines of dots between boxes (in either direction) link mothers with their children. An equal sign between boxes indicates a marriage relationship; that is, a person in the one box must take a spouse from the other. (Adapted from Gould, citation in Kronenfeld.)

Saussure's early programmatic version laid out the -analytic concepts, including relations among entities of opposition (and inclusion), a "sign" defined by the joining of a "signifier" (a "sound image," made up of cognized phonological units) to a "signified" (a concept, defined in opposition to other concepts), paradigmatic structures of opposition vs. syntagmatic structures of co-occurrence. These structures were cognitive (i.e., mental) as was his notion of "linguistic value" (function or communicative effect of linguistic entities) which was dependent on structures of opposition. But his only essay in actual model building came much earlier in his analysis of the Proto-Indo-European (PIE) vowel system ("Memoire sur le systeme primitif des voyelles dans les langues indo-europeenes," 1878), where he used an analysis of the various phonological structures of daughter languages to suggest for PIE systematic phonological elements (laryngeals). At the time no known Indo-European language had such phonological elements, but they were later discovered in ancient Hittite.

Structure in American linguistics had to do with systematic and recurring relationships (in speech) among form classes, whether in phonology, morphology, or syntax (e.g., what could be seen as stops vs. fricatives vs. etc., as first person vs. second person vs. etc., as nouns, count nouns, adjectives, noun phrases, etc.). There was some concern with the functions of different structures, but (unlike British structural functional anthropology) the focus was on the accurate and efficient elicitation, description, and presentation of the structures. Structure represented the constant framework of relationships within which variable constructions acquired their interpretability.

In the Prague School version of phonology, structure was more a matter of the formal defining elements of phonemes, their paradigmatic possibilities for opposition, and their syntagmatic possibilities for combination in one or another language. Phonological structure was tightly tied to phonological function. Within the wider range of structural linguistic approaches, the Prague School of Trubetzkoy and Jakobson was relatively heavily concerned with the structural effects of phonetic content (i.e., the physical or phenomenal world) while others such as Hjelmslev's Glossematic School saw structure more as a system of essentially arbitrary combinations or arbitrary entities.

Two major anthropological approaches to cultural structures developed out of structural linguistics, the "structuralism" of Levi-Strauss and those influenced by him and the "ethnoscience" approach (later to become "cognitive anthropology") associated initially with Ward Goodenough, Floyd Lounsbury, Harold Conklin, and Charles Frake.

Levi-Strauss

His early analytic work dealt with kinship (see Kronenfeld and Decker's 1979 article for an overview). He built on British social anthropology, but especially went back to its sources (and the locus of his own training)—Emile Durkheim, Marcel Mauss, and their colleagues. This led Levi-Strauss to a concern for solidarity of various kinds and for the systemic effects of repeated individual decisions. But, in distinction from the Radcliffe-Brownians, Levi-Strauss foregrounded structural relations, showing, or example, the systemic effects of different marriage rule and descent rule combinations and (based on the work of Audrey Richards) the cumulative social effects of different combinations of power and affect relations within a basic kinship unit (comprising a man, his sister, her husband, and the couple's child). Levi-Strauss did bring mathematics, and the idea of mathematical structure, into the picture via Andre Weil's appendix to the French edition of Elementary Structures of Kinship, but he never much followed up on mathematical aspects beyond his use of mathematical appearing formulas.

Levi-Strauss's later work on myth shifts from social anthropology to a Boas-based approach to cultural content, though with much influence from a Jakobsonian version of structural linguistics. The change came after a series of discussions with Boas and Jakobson in New York in 1941 just before Boas's death. Structure here referred to patterns or series of analogous oppositions wherein successive versions were more increasingly contained or contextualized in a way that enabled their apparent transcendence. The oppositions were found in culture content. The structures were not part of the overt surface content, but were analytically revealed as the underlying entities and relations that generated the surface content. The Levi-Straussian approach was a little like Bateson's in looking for cumulative (systemic) effects of repeated instances of a given opposition. In his mythological studies, he often found the structure of myths to be a counterfactual version of normal human events in which the negative myth outcomes were seen a reinforcing (or justifying) the social rules of the society in question.

Levi-Strauss introduced and/or underlined some basic useful distinctions among types of structural models, including that between mechanical and statistical models (of behavior), that between "native" and "anthropological" models, and that between conscious (or explicit) and unconscious (or implicit) models. He also went on to suggest linkages among the former elements vs. the latter of each of the oppositions—linkages that seem more problematic.

In the Structuralism that grew up around Levi-Strauss, structure, taken from linguistics, was taken in much more of a Praguean or Jakobsonian sense than in an American or Bloomfieldian sense. While supposedly based on Saussure, the approach significantly misconstrued the original Saussurean model—particularly in its misunderstanding of the nature of the sign (including the signifier–signified relationship, the role of speech (*parole*), and the relationship between synchrony and diachrony. "Post-structuralist" writers (for example, Bourdieu in Outline of a Theory of Practice) corrected many of the structuralist anthropology excesses, but without recognizing either Structuralism's misconstrual of its Saussurean roots or the modernity and analytic power of those roots.

A different approach to structure was that of the cultural grammar. In part modeled on linguistic grammars, but more directly deriving from Vladimir Propp's 1958 (orig. 1929) *Morphology of the Folktale*, Colby pioneered a computer analysis of Eskimo folktales in 1973, and more recently has followed up with an analytic parsing of Ixil Maya Divination (*The Daykeeper* in 1981). Frake relied more directly on American descriptive linguistic traditions in his *Structural Description of Subanun "Religious Behavior"* which, along with his article on *Notes on Queries in Ethnography*, pioneered the examination and analysis of culturally standardized cognitive structure in terms of native speaker/actor categories. Frake's approach matches well with the simulations of cognitive systems coming out of Cognitive Sciences as seen in Edwin Hutchins 1980 analysis of Trobriand Litigation in *Culture and Inference* and in Schank and Abelson's 1977 simulations of conversations about restaurants in their *Scripts, Plans, Goals and Understanding: An Inquiry into Human Knowledge Structures*.

Kinship Terminologies

The following discussion is based on Kronenfeld's introductory overview of kinship terminology studies, and full citations for the works discussed here can be found in the Special Issue of *Anthropological Theory* (2001). Kinship terminological systems have long been described via idealized genealogical diagrams. Such diagrams focused on an "ego" and traced down from ego through a son and a daughter, and a son and daughter of each to ego's various kinds of grandchildren, then up through ego's parents and grandparents (and maybe higher) and then down through a male and a female child (not on the chain of parents) of each ancestor to the range of collateral descendants of the apical ancestors (usually in ego's grandchildren's generation, but sometimes shallower or deeper). These idealized genealogies were used in anthropology as early as the mid-19th Century, e.g., by Dorsey in 1884, and formed part of the basis of Rivers' classic 1910 article on the "genealogical method." But such diagrams, as also the lists of genealogical positions that Morgan used in his survey schedules and Kroeber's 1909 list of significant analytic features, fell short of the idea of getting at the

underlying shapers of behavior that is implicit in the idea of a "structural model." Tax's 1955 Fox analysis came closer, but did not really contain any model, and Leach's Jinghpaw approach never caught on.

Componential or Paradigmatic Structures

It was with Goodenough and Lounsbury's adaptation in 1956 of "componential analysis" from structuralist phonology that something like genuine or full-fledged structural models were introduced into studies of kinship terminological systems. These were distinctive feature analyses in which the goal was to find the minimal set of features that were necessary and sufficient to distinguish the referents of kinterms in a given system from one another. These were attempts to model the semantic structure of kinship terminologies, and existed within a wider context of concern with analyzing semantic structure in general; the conception of structure and how it related to behavior was taken from structural linguistic analyses of phonological systems (especially Prague, but also see Zellig Harris's work within the Bloomfieldian tradition).

One result of componential work in kinship was the realization that semantics differs from phonology in important ways having to do with the function of the systemic entities, the role of features, and the degree of constraint of the relevant universe. A second result emerged when it was realized that native speaker assignments of relatives to kin categories did not depend on distinctive features (unlike the phonological case where features do govern assignments), but on a relative product "calculus" of the "he's my mother's brother, so that makes him my uncle" sort. The distinctive features found in a componential analysis of kinterms are, in fact, dependent on prior knowledge of how the relatives are related (genealogically, say); that is, they are defined in terms of kinterms, rather than vice versa. But, there exists considerable evidence that people use such distinctive features in sorting kinfolk, behaving toward them, and so forth. There still exists some question concerning the degree to which the distinction in kinship between the means by which entities are defined and the features by which those entities are associated with related thought and behavior is normal for some wider set of semantic systems—or is unique to the special domain via which people receive their basic social locations or identities.

These realizations posed basic questions about the nature of semantic structure and its modeling. Componential analyses of a densely populated and complex domain such as kinship yielded empirically powerful structural models, as shown in the classic studies of Wallace and Atkins in 1962 and Romney and D'Andrade in 1964. But, attempts to describe and formally model the system used by native speakers in their definitions led to very different kinds of structures (see Kronenfeld's 1980 analysis of Fanti for an early version, and the articles by Read and Lehman in Kronenfeld's 2001 edited collection as well as Gould's 2000 *A New System for the Formal Analysis of Kinship*, for sophisticated algebraic versions). These structures have the formal properties of algebraic structures and lend themselves to rigorous and informative graphic representations.

Taxonomic Structures

Work on folk taxonomic systems (see Berlin's 1992 book for one overview) has led to the development of tree or dendrogram models that represent successive subdivisions of a superordinate category by two or more subordinate categories. These structural models are based on the empirical delineation and concatenation of Saussurean relations of contrast and inclusion. The contrast between opposed categories sometimes seems based on contrasting values on distinctive features—making these models a kind of variant on the componential one (which is based on intersecting, cross-cutting, features); but at other times the contrasts seem to be between complex gestalts that cannot be easily represented by features.

Componential (Saussure's paradigmatic) and taxonomic structures represent two ways of building a larger structure out of relations of contrast and inclusion. A problem is that both kinds of structures—at least as developed, consistently held wholes—seem rare; much of cultural semantic classification seems looser and more *ad hoc*: cars contrast with trucks and motor bikes as kinds of motor vehicles, and all of those with bicycles, tricycles, and kids' wagons as nonmotor vehicles, but alternatively we can group our vehicles by number of wheels, by who drives/rides them, by who makes them, by the surfaces on which they are used, and so on. Berlin distinguished a "basic" taxonomy from "special purpose taxonomies (e.g., the set of answers to questions such as "what is that fish" vs. answers to questions like "what fish are caught in nets" or "what fish are most expensive"). Atran, among others, has argued that "natural kinds" (natural entities and their groupings—part of the context of our evolutionary history—such as fish and plants) are classified differently than are our cultural constructions (such as vehicles, occupational roles, and so forth, cf. potential answers to "what is that car?" [a Ford, a sedan, . . . ?]), while Kronenfeld among others has not been so sure of the usefulness or analytic effectiveness of that distinction (as opposed to one having to do with the kinds and frequency of people's interaction with items and categories in the given domain.

Algebraic Structures and Pragmatic Issues

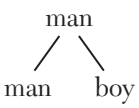
The kinds of complex algebraic structures based on relative products found to generate kinship terminologies so far seem unique to the kinship domain, but all domains seem to exhibit special properties and constraints deriving from the pragmatic natures of their construction, interaction, use, and so forth. One solution seems to be to separate narrowly semantic structures of inclusion and opposition (however they may cumulate into larger structures) from pragmatic models of the worlds to which they pertain. From this perspective, algebraic representations of kin categories pertain not to the terms' semantics but to systematic features of the conceptual world they refer to (and the social and biological worlds variously linked to it)—what categories of people get linked in what ways to what other categories. The comparable information for vehicles perhaps concerns how they are powered, how many wheels they have, what they are used for, where they are used, etc.; these constraints are looser and more flexible than are those of kinship, but certainly there exist technological areas in which the constraints are tight (for instance, rockets to space and fast submarines). In the taxonomic realm, ethnobiological classifications must accommodate both the nature of the biological world (structured as it is by Darwinian evolution) and the commonalities and contrasts associated with people's interaction with that world.

Piaget, among others, considers the ways in which the nature of the pragmatic world constrains and shapes the cognitive structures we form to represent parts of that world, and how our push to get productive mental control over wide classes of situations leads to mathematically tight representations (especially, in Piaget's view, group and lattice structures).

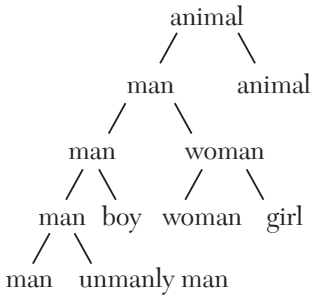
An important issue raised by Piaget's work, and posed in anthropology from a variety of theoretical perspectives, e.g., by Giddens (as "structuration"), is the degree to which structure is interactively constructed and reconstructed in an ongoing manner (vs. more rarely and maybe accidentally constructed), and then mostly more passively received. Fredrik Barth (again, among others), e.g., in his article in A. Kuper's *Conceptualizing Society* has raised the question of the degree to which cultural or social structure (systems of shared and distributed knowledge or the systems of interactions produced by that knowledge) is epiphenomenal (i.e., simply the patterns of activity produced by repeated and similar experiences and feedback experiences of separate individuals) vs. something that has some real cognitive force (an active shaper of behavior). If active, then one has to worry about how it is constructed or transmitted, that is, how it comes to be shared and collective. Constructivist approaches to cognition, such as Piaget's, are important here, but with the general addendum that the push for finding or creating structure applies also to representations of the social world and of putatively collective knowledge in addition to the individual knowledge structures mostly studied by psychologists. The cognitive structure of putative "collective representations" of the sort brought to our attention by Durkheim and Saussure is at issue here, though no good general account or theoretical model of such apparently collectively held structures yet has been proposed.

Marking Structures

The cognitive structures discussed so far all deal with intercategory relations. One insight that has come out of work on kinship, color, and plant classifications is that the relationship of exemplars to categories in ordinary usage (whether we be talking about semantic, pragmatic, or other cultural categories) is that the relationship of specific items (situations, exemplars, actions, or whatever) to the categories that we use to label them, think about them, etc. is often (even usually) not a simple matter of directly fitting the set of defining features that define or structure the intercategory relations. Instead, our cultural and linguistic categories often come with presumed (imagined, understood) prototypic exemplars, and then our recognition of an instance of the category involves assessing the relative similarity of the given instance to the prototypes of possible categories. The similarity assessment takes account of various aspects of context, including the relative plausibilities of competing categories, what is at issue in the choice, the categorizer's goals, and stake, and so forth; different kinds of classification (semantic, behavioral, etc.) will foreground different aspects of context and different kinds of purposes (communicative, instrumental, aesthetic, etc.). In one approach, the prototype represents a default referent or instance of the category; with more contextual information a different referent or instance may become a secondary default, and so forth. In linguistics Trubetzkoy developed and then Greenberg generalized marking theory—in which among a set of alternatives the default value was considered the "unmarked" option as opposed to "marked" options (which were marked by their need for additional specification). The unmarked option could represent either the generic category (ignoring the opposition at issue) or the default value of the opposition. Thus, the word "man" or "men" can be both adult and young men, but the default expectation is adult men vs. the marked alternative, "boy." A structural diagram of this relationship would be the following:



In this example, the term "man" is said to appear at two levels of contrast—one in which "man" (vs., say, "woman") includes "boy" and a more specified one in which "man" contrasts with "boy." Marking relations can be concatenated to form hierarchies, such as



Such structural models have been used by Berlin to illustrate the development of vocabulary, by Randall in his 1977 Ph.D. dissertation *Change and Variation in Samal Fishing: Making Plans to "Make a Living" in the Southern Philippines* to define the structure of activity choices by Samal fisherman, and by myself (in current work) in attempts to specify one kind of interrelation among cultural models based on their degrees of specificity. Hage (see, for example, his 1999 article on "Linguistic Evidence for Primogeniture and Ranking in Proto-Oceanic Society") has used such models to describe the historical development within language families of kinterm categories.

Mathematical Models

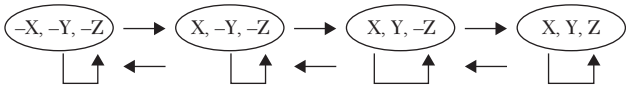
Algebraic models of kinship structures have already been discussed above. In many parts of the world outside of anthropology "structure" or "structural model" refers typically to a mathematically described (though commonly not quantitative) regularities. Mathematical models of structure have played a role in anthropology, even if not yet any really central role. An early example was Weil's previously mentioned 1949 appendix to Levi-Strauss's *Elementary Structures of Kinship* in which he used the theory of permutation groups to construct an algebraic analysis of some types of marriage laws (particularly of the sort related to Australian section systems. Harrison White's *An Anatomy of Kinship: Mathematical Models for Structures of Cumulated Roles* in 1963 dealt with a much wider range of what have been called "prescriptive marriage systems," that is, systems in which a person's spouse is supposed to come from a particular category of kin. These are mostly systems that have been analyzed (especially since Levi-Strauss's work) as being built on marriage alliances among unilineal descent groups—Levi-Strauss's "elementary" structures of kinship. Mathematical models of such structures continue to be a topic of research (see, e.g, Gould's *A New System for the Formal Analysis of Kinship*, and various works of Tjon Sie Fat's, both cited in the introduction to Kronenfeld's 2001 edited collection). There has been no comparably broad interest in mathematically modeling Levi-Strauss's analytic approach to the cultural content of cognitive systems (i.e., his analyses of myth and other symbolic systems), though El Guindi and Read's 1979 article on "Mathematics in Structural Theory" in *Current Anthropology* represents one early attempt at such modeling.

Graph Theory

Graph theory is a branch of mathematics. In both the simple sense of using graphs to represent theoretical or structural relations and in the more sophisticated sense of making use of the axiomatic analytic machinery, graph theory has provided a useful tool for forming, viewing, and analyzing a variety of kinds structural models in anthropology. Hage and Harary's 1996 *Island Networks: Communication, Kinship and Classification Structures in Oceania* provides a particularly useful overview of its anthropological relevance, and Flament's overview of applications remains good. Directed graphs ("digraphs," graphs in which the points are connected with lines that go in only one direction) were used by Greenberg in his work on substantive universals in language to describe the state transitions (e.g., addition or deletion of distinctive features in a phonological system) that were possible, given a set of interrelated implicational universals. An implicational universal was recognized in a large-scale cross-language comparison when the 2 by 2 table formed by the comparison of the presence or absence of X with the presence or absence of Y had a "zero," i.e., empty, cell (given numbers in the other cells adequate for statistical significance). For example

		Y: +	Y: −
X	+	cases	cases
	−	no cases	cases

means that Y can only occur when X occurs, or, in logical terms, $Y \rightarrow X$ (or "the presence of X is a necessary but not sufficient condition for the presence of Y"). A chain of implicational universals among defining features of some linguistic or cultural system—as, e.g., $Z \rightarrow Y \rightarrow X$ could be graphically represented as follows—where the universe is systems of the given sort and the different states are different bundles of defining features.



The arrows represent potential changes from the state "behind the arrow" to the state at the arrow's head; changes can (logically) consist in the addition of a feature, the loss of a feature, or no change. Note that −X,−Y,Z −X,Y,Z X,−Y,Z −X,−Y,Z are all logically possible states, but unreachable under the observed empirical constraints.

Greenberg's linking of zero cells in empirical codistributions to implicational relations and then representing chains of those relations in a directed graph has been taken up by several anthropologists to form structural models of aspects of particular cultures or of intercultural comparisons. Among important examples are the following. Berlin and Kay use the approach in their classic 1964 cross-language study *Basic Color Terms* of the evolution of color terminologies. D'Andrade in 1976 used the technique on data representing the cooccurrence of various attributes in informant characterizations across a variety of illnesses within each of two speech communities. That representation nicely summarized a wide set of diagnostic and disease-development sequences even if it did not speak to the folk theories that underlay them, and the comparison between the diagrams revealed interesting differences between the two communities. Burton, White, and Brudner (in their 1977 *American Ethnologist* article on "A Model of the Sexual Division of Labor") applied the approach in a cross-cultural study of features that shape the sexual division of labor—comparing their findings with earlier ones by Murdock *et al*. using correlational measures. Their implication findings were powerful and provided substantial support for theoretical assumptions relating cognitive economy to extreme case differences in cultures' exposure of men vs. women to risk. Hage (e.g., in his 1998 "Proto-Polynesian Kin Terms and Descent Groups") has applied the approach to the study of historical changes in the defining features of kinterminological systems within a single language family.

Network Structures

Graph theory has provided a particularly powerful and useful way of modeling networks and network related phenomena (see Wasserman and Faust for an overview). White (with Jorion in their 1992 "Representing and Analyzing Kinship: A Network Approach" in *Current Anthropology*, with Houseman in Houseman and White's 1998 "Taking Sides: Marriage Networks and Dravidian Kinship in Lowland South America," and with Denham) has made creative and effective use of network models to investigate and solve some classic problems concerning the empirical fit of marriages to a proposed marriage rule and the empirical interrelationship of descent, marriage, and demographic variables in kinterm categories.

Computational Models

Our categories overlap, and most of the algebraic, implicational, and network models described above have significant computational (in its now common sense of computer implemented) components, as in Read's kinship terminology analysis. In many cases, the computational component allows the model implicit in a body of empirical data to be pulled out inductively via a computer program designed to recognize and cumulate the relevant kinds of regularities, as in White's work on marriage patterns. We have also seen some directly computational structural models of, e.g., the fundamentals of society itself as an emergent system (Kronenfeld and Kaus's 1993 "Starlings and Other Critters: Simulating Society" in the *Journal of Quantitative Anthropology*), of urban produce markets (in Plattner's contribution "Economic Decision Making of Marketplace Merchants: An Ethnographic Model"), kinship and demography (Read's 1998 "Kinship Based Demographic Simulation of Societal Processes" in the on-line *Journal of Artificial Societies and Social Simulation*), and cultural systems for ecological management (Lansing *et al*.'s 1998 "System-Dependent Selection, Ecological Feedback and the Emergence of Functional Structure in Ecosystems" in the *Journal of Theoretical Biology*).

The topic of computational models of structure in anthropology extends considerably beyond sociocultural anthropology to a moderate but significant set of such models in archaeology (particularly regarding the developmental of regional economic, social, and political systems in relation to ecological and demographic conditions) and a rich and large set in biological anthropology (for instance, of patterns of migration, demographic change, and gene flow). A classic overview of models in human population biology is found in the work of Harrison and Boyce, which includes chapters such as "Migration, Exchange, and the Genetic Structure of Populations" by the editors and "Genetic Implications of Population Breeding Structure" by W. J. Schull. More recently, Fix has reviewed population genetics models in relation to human migration and shown how more complex evolutionary models may be constructed and evaluated using computer simulation. In archaeology, one interesting approach is that of Reynolds *et al*.; the Proceedings volume in which it appears contains much else that is relevant to computational models in anthropology and related disciplines.

The increasing use of formal models of structural relations in anthropology (both computer program based and directly mathematical) and the increasing sophistication and empirical relevance of these models suggest a significant and important role for them in the future.

Survey Design

Theodore C. Wagenaar
Miami University, Oxford, Ohio, USA

Glossary

anonymity When a respondent's identity is not known.
case–control designs Designs used to compare two groups, one of which is involved with the issue of interest.
confidentiality When the respondent's identity is known, but the researcher promises not to reveal it.
contingency question A question that is asked only of those who have given a particular response to a prior question.
cross-sectional designs Survey designs that are completed at one point in time.
exhaustive Item responses that provide an appropriate response for every respondent.
generalizability The extent to which survey results can be applied to the larger population from which a sample was taken.
longitudinal designs Survey designs in which data are collected at multiple points in time.
mutually exclusive Item responses that allow respondents to fit in only one response category.
random digit dialing A strategy for doing telephone interviews that involves dialing computer-generated telephone numbers.
reliability The feature a measure has if repeated measures yield the same results.
respondent Someone who responds to a questionnaire or interview.
response set The tendency for respondents to mark the same response to a series of items.
specifications Instructions for interviewers regarding their responses to ambiguous situations.
validity The feature a measure has when it accurately measures what it is intended to measure.

Survey design helps researchers reach large numbers of respondents easily. Variations of survey design enable researchers to use various random sampling designs, which enhance the generalizability of the results. Questionnaires and interviews comprise the two basic approaches, each with its own advantages and disadvantages. Questionnaires tend to be cheaper and easier to complete, whereas interviews require trained interviewers and take longer to complete. Items in surveys can be structured to give respondents specific responses, or they can be unstructured to elicit responses in the respondents' own words. Researchers have developed specific strategies for conducting effective questionnaires and interviews that have been found to enhance the reliability and validity of the results. The various questionnaire and interview designs each have their own advantages and disadvantages. Researchers are increasingly using online surveys to simplify the data-gathering process.

Utility of Survey Design

Survey design has distinct benefits when compared with other designs commonly used by social scientists, such as experimental and observation designs. Surveys enable researchers to use large random samples to gather data on many variables from many respondents. Surveys can be completed in relatively short periods of time. They can be used to describe something in a population, to explore a topic that may be studied in more depth later, and to develop causal models of attitudes and behaviors. Surveys can be used to solicit individuals' responses about themselves, other people, organizations, neighborhoods, and other units of analysis.

Surveys can be cross-sectional or longitudinal. Cross-sectional studies are done at one point in time, whereas longitudinal studies are done at multiple points in time. Both types of designs can be used to describe, explore, or explain concepts of interest. Longitudinal studies are better for establishing causality because the time order of variables is more clear. Longitudinal studies can be

accomplished with three approaches. The trend study simply compares populations at multiple points in time. For example, support for abortion can be compared over time. The cohort study follows a specific group of people over time, although the same individuals are not necessarily studied. For example, a random sample of first-year students can be studied and 1 year later a random sample of sophomores can be studied, with similar designs for juniors and seniors at subsequent time points. Finally, the panel study follows the same individuals over time. This design is superior to the cohort design because the researcher can identify changes, and hence causality, more definitively. The disadvantage of the panel design is panel attrition, which occurs when individuals withdraw from the study over time. The cohort design addresses this weakness by drawing samples of the same size over the 4 years of college, for example. Researchers can approximate longitudinal approaches when using cross-sectional studies by asking retrospective questions. For example, respondents could be asked how often they participated in high school extracurricular activities as well as how many community groups they belong to currently if the goal is to assess a possible causal link between these two variables.

Surveys are particularly useful with case–control designs. Researchers sometimes wish to learn why one group has a particular experience and another does not. For example, a survey could be designed to ask retrospective and other questions to learn why some new mothers experienced postpartum depression while others did not. The case–control design requires that the researcher be able to identify ahead of time those with the experience and those without.

Self-Administered Questionnaires vs Interviews

Both self-administered questionnaires and interviews are used in survey research. Interviews can be conducted in person or with the telephone. Self-administered questionnaires are generally cheaper because interviews typically involve training costs and in-person interviews involve travel time. It also takes longer to execute an interview than it does for a respondent to complete a self-administered questionnaire. Response rates are typically higher with interviews, often approximately 70–80%, whereas self-administered questionnaires often have response rates less than 50%. It is more difficult for respondents to refuse an interview because of the personal attention given to the respondents, whereas it is easy for respondents to discard surveys received in the mail. The presence of an interviewer helps reduce the uncertainty that respondents may experience with some items, thereby increasing the validity of the results. This feature also makes interviews more flexible. An easily misunderstood item, for example, can be reworded before completing additional interviews. After such an item appears in a self-administered questionnaire, it cannot be fixed. Some people argue that telephone interviews yield more honest answers because respondents are less inhibited when they do not have to look directly at an interviewer. Others argue that people are more suspicious of telephone interviewers and may give less honest answers. Interview studies usually involve many interviewers, who may each introduce their own biases into the data-gathering process. Reliability is therefore greater with self-administered questionnaires.

Interviews require more skill because the interviewers must be trained; it takes less skill to stuff questionnaires into envelopes and score the results. Self-administered questionnaires can be sent to hundreds or thousands of people quickly, but interview studies generally involve smaller samples because each respondent must be interviewed. Telephone interviews can reach more people than do in-person interviews, but issues of interviewer and respondent safety often affect response rates. Self-administered questionnaires can be sent easily via the mail, whereas face-to-face interviews limit the geographic area of samples. Anonymity is easily maintained with self-administered questionnaires, but it is more difficult to maintain with interviews. Instead, researchers typically offer respondents confidentiality when doing interviews—a promise that the respondent's identity will not be revealed to others. Interviews can be done in cases in which respondents cannot read or write, such as when interviewing preschoolers. Because self-administered questionnaires require literacy, their use is limited in populations with limited reading ability (approximately one-fifth of the U.S. population is functionally illiterate). The atmosphere is critical when doing interviews. For example, the presence of a spouse may affect a respondent's responses to questions about marital happiness. Such distractions are less intrusive for respondents completing self-administered questionnaires, either by mail or via the Internet.

Structured vs Unstructured Formats

Items in surveys can be structured or unstructured, also known as closed-ended and open-ended formats, respectively. The structured approach includes fixed responses to an item. For example, "woman" and "man" are the fixed responses to the question "What is your gender?" The unstructured approach lacks such fixed responses. "What do you see as the three major

problems facing our country today?" is an example of an unstructured question.

The structured approach has several advantages. It is more standardized and hence easier to execute. The results are easier to analyze. Such items provide a frame of reference. Instead of asking an open-ended question about frequency of church attendance, for example, a closed-ended item provides a framework for responding by providing such responses as "once a year or less" and "several times a year." The structured approach reduces the likelihood that interviewers will introduce their own biases. The structured approach also has several disadvantages. Closed-ended questions sometimes force respondents into stating an opinion when they really have none on a particular issue. Such items may overlook possible responses. An item asking why students dropped a course, for example, may list various common reasons pertaining to the professor or the workload but may overlook the possibility that the student simply switched sections of the course.

The unstructured approach also has advantages and disadvantages. Open-ended items may help the researcher determine if the respondent is telling the truth or knows what he or she is talking about. Such items may be more appropriate when the goal is an intensive study of attitudes. Researchers often employ an unstructured approach in the exploratory phase of a research study to help formulate relevant hypotheses and measures. The unstructured approach can help identify relevant possible response alternatives for a question that may later be used as a structured item. Some researchers follow a grounded theory strategy by letting data emerge for subsequent theoretical analysis; the unstructured approach is central to this strategy. The unstructured approach also has difficulties. Perhaps most salient is the difficulty researchers experience with data analysis. Pages and pages of responses to open-ended questions pose unique analysis difficulties, even with the help of computer programs. This method also requires considerably more time than the structured approach. If using an unstructured self-administered questionnaire, respondents must be able to write.

Effective Self-Administered Questionnaires

Effective self-administered questionnaires are attractive, easy to complete, arranged in a logical manner, and include specific directions. Postage-paid envelopes should be included if a mail survey is used, and specific response instructions should be included if the survey is completed on the Internet. A well-designed cover letter should be included that explains the purpose of the study, reflects human subjects guidelines, and informs the respondent if the results will be confidential or anonymous. One way to maintain anonymity but still keep track of who responds is to include a separate postcard addressed to the researcher indicating that the survey has been completed. A good cover letter also underscores the importance of participation, provides a deadline and instructions for returning the questionnaire, tells respondents that there are no right or wrong answers, and thanks the respondents. Effective cover letters also indicate who is doing the survey and include a general statement about how the respondent was selected. The researcher may wish to offer respondents a summary of the results. Respondents should be encouraged to leave blank those items that they believe they cannot complete, to contact the researcher with questions, and to offer comments if they wish.

In order to improve your questionnaire, show a draft to experts in the field as well as to people who are like those who will receive the survey. The first strategy will help enhance the validity of your measures, and the second strategy will help identify troublesome items. Be sure to ask pretest respondents to comment on the difficulties they see in the survey. Such strategies will help identify the problems with the following type of item: "To which social class do you belong?" This item could be interpreted to mean "Which social class best characterizes you?" as well as "You may not be in it, but in which class do you belong?" Also, avoid double-barreled questions, which combine two (or more) questions into one question, such as "How satisfied are you with your working conditions and wages?" If someone gives a low satisfaction score, you will not know if that person is dissatisfied with working conditions, wages, or both. Develop items that respondents are able to answer. For example, respondents are not likely to remember if their first day at kindergarten was happy or traumatic. Avoid negatives in items to help minimize confusion. For example, the item "I am not satisfied with my working conditions" may inadvertently lead respondents to overlook the word "not" and select "strongly agree" to indicate high satisfaction.

Experts generally recommend that items in a questionnaire do not all reflect a "positive" or "negative" view because this situation can lead to response set, the tendency for respondents to not read items carefully and to mark the same response for a series of items. Consider the following two items: "Women who work, either full-time or part-time, outside the home should have help from their husbands in doing the housework" and "It is more important for a woman to help her husband in his career than to develop her own." A response of "strongly agree" to the first item would generally parallel a response of "strongly disagree" to the second item. The use of items reflecting alternating views of an issue can help identify those respondents who did not take the survey seriously and simply marked the same responses to all items.

Sometimes, one may wish to ask questions only if a particular response is given to a prior question; these are known as contingency questions. For example, one may first ask if the respondent graduated from college. If a "yes" response is given, the respondent can then be directed to additional questions on major, grade point average, and the like.

Avoid biasing items by eliminating words and phrases that may lead the respondent to answer in a particular way. For example, asking "Do you agree with the president that welfare support should be limited?" may bias respondents by associating the issue with the president. Leading questions and phrases should also be avoided, such as "don't you agree with the president that welfare support should be limited?" Emotional words, such as "absurd" or "completely wrong," should be avoided. Where items are placed may affect responses. For example, placing items on how overpopulated the world is before items on birth control usage may affect respondents' feelings about the latter issue. Socially desirable items should be used with caution. Such items generally yield very high levels of agreement or disagreement and, therefore, contribute little to explanatory analyses. Examples include "Are you basically a warm and loving person?" and "A world at peace is desirable."

Item responses should be mutually exclusive and exhaustive. Mutually exclusive responses enable respondents to fit in only one response. For example, responses of "Protestant," "Catholic," "Jewish," "Lutheran," "other," and "none" are not mutually exclusive because someone who is Lutheran could fit in two categories. Exhaustive responses enable all respondents to fit into a response. For example, those with no religion would have no response to select if the response of "none" were missing from the responses in the previous example. Use questions asking for raw numbers sparingly. Respondents are not likely to know the exact response to a question such as "How much did you earn last year?" or "How many movies did you see last year?" Instead, provide responses with ranges, such as "less than $10,000" and "$10,000 through $20,000." Avoid the use of responses such as "rarely," "sometimes," and "often" because respondents will interpret these words differently. If you believe there is a need for a question asking for raw numbers for a response, insert the word "approximately" in the item so that respondents do not feel obligated to remember the exact number.

Follow-ups can increase the response rate notably. Without follow-ups, the typical mail questionnaire will generate a response rate of approximately 40%. The rate increases to approximately 55% with one follow-up and approximately 60% with two follow-ups. It is critical to include new copies of the questionnaire and new postage-paid response envelopes with follow-ups if doing the survey by mail. It is best to send the first follow-up approximately 2 weeks after the deadline noted in the cover letter of the original survey and to send the second follow-up approximately 2 weeks after the deadline noted in the cover letter of the first follow-up survey.

Several factors may affect response rates. Inducements can help increase response rates, although amounts less than $1 seem to have little effect. One sociologist taped two pennies to the top of the cover letter and noted in large letters, "We want your two cents worth, and are willing to pay you for it." The disadvantage of this approach is that respondents may feel insulted because they may think that their time is worth more than 2¢. Other social scientists offer to contribute $1 to one of several charities; the respondent can select the charity. The nature of the respondents may also affect response rates. Generally, higher response rates are obtained from more educated, middle-class populations. Sponsorship is also important; a self-administered questionnaire that has a cover letter on a university letterhead will be seen as more legitimate than one that has a post office box return address. In addition, length is important; self-administered questionnaires with three or fewer pages generate a higher response rate than do longer questionnaires. An effective cover letter helps generate interest. Questionnaires on interesting topics will generate higher response rates than those on more mundane topics, and questionnaires on topics of interest to the respondents will generate even higher response rates.

It may be relevant to compare respondents with nonrespondents to help estimate response bias. This can be done only on factors for which one has prior knowledge. Nonrespondents in a survey of students, for example, could be compared with respondents on residency (on campus or off) and class level but not on how much they study. A response rate graph plotting responses received per day may help estimate any biasing effect of historical events. For example, a campus survey on racial attitudes may be affected by a particular racial incident that occurred on campus. Comparing those who responded before and after the incident will help estimate this effect.

Various mailing options exist for sending out self-administered questionnaires and receiving them back. There is debate about whether to use bulk mail or postage stamps for the outgoing survey. Some believe that a brightly colored commemorative stamp will help distinguish the survey from junk mail sent by bulk mail. On the other hand, it is much cheaper to use bulk mail if the sample size is relatively large. Postage-paid reply envelopes should be used. Respondents may remove and use postage stamps on reply envelopes for personal use. Business-reply mail helps solve this problem and is generally cheaper (even with the postage surcharge) due to survey response rates. When a high response rate for a survey is anticipated, it is less expensive to use first-class

postage, and it is less expensive for low-response surveys to use business-reply mail.

Effective Interviews

Conducting effective interviews requires comprehensive training and practice. The process is more than just reading items on the interview schedule. Interviewers should do several practice interviews, and these should be videotaped. The tapes should then be reviewed with a supervisor to elicit strengths and weaknesses. The researcher can help by providing specifications for the interview, a set of clarifying comments embedded within the instrument to help the interviewer respond to difficult situations. For example, if an item asks, "Has support for the police in your area increased or decreased?" the specifications can make it clear that a volunteered response of "stayed the same" is acceptable.

Interviews should be scheduled. Respondents are more likely to decline the interview if an interviewer shows up at the door or calls without prior notification. It also helps to send a letter on official letterhead informing the prospective respondent of the study, the sampling procedures used, the importance of the respondent's participation, and names of contact persons in case of questions. Interviewers should present appropriate identification from the sponsoring institution and should be coached in how to deal with refusals. Those doing in-person interviews should dress appropriately. Generally, this means that they should be dressed as well as or better than the potential respondents. Research shows that appearance affects credibility. When interviewing strangers, well-dressed interviewers enhance the likelihood that respondents will agree to the interview.

Interviewers should be very familiar with the instrument so that they can do the introduction and the first few questions almost from memory. This practice will also enhance rapport and credibility, and it will enable interviewers to respond quickly and effectively to questions that the respondents may ask. This practice will also help interviewers skip inappropriate questions for particular respondents. Interviews must be administered in a consistent fashion. This is particularly important because multiple interviewers may otherwise each introduce their own biases into the process. Consistent interviews also yield greater accuracy of results.

Interviewers should be trained to look and listen for nonverbal cues. Such cues can help assess the honesty of responses and can indicate the need for item clarification. Probing skills can help generate more accurate and thorough responses. Various probing techniques can be used. A brief assertion of understanding and interest will make respondents feel more comfortable. Sometimes, simply waiting a moment for the respondent to formulate a response is necessary, particularly for open-ended questions. Allowing insufficient time to respond is a common mistake made by new interviewers, and they should be reminded to not let silence bother them. Occasionally, it helps to repeat the question, which gives the respondent more time to respond and reminds the respondent of the question (many respondents are reluctant to ask that items be repeated). Another probe is to simply repeat the respondent's words, particularly if the response was very brief. Doing so encourages the respondent to expand on the response. Finally, the interviewer can simply ask for clarification when needed. It is important to record responses exactly and to not simply assume that one understands a particular response. For example, the response, "All politicians are crooked," may carry different meanings, and the interviewer should clarify if this means that politicians are bribed, do not represent their constituency adequately, or something else.

The police should be informed when doing in-person interviews. This practice may help reduce the likelihood of being interrogated when an interviewer is sitting in a car jotting down notes on an interview. It may also help convince a respondent to participate in the survey. I once helped conduct a market interview on banking institutions and knocked on the door of a bank vice president. He assumed that I was gathering competitive information, so I encouraged him to call the police department to verify my identity. He did, and the interview was completed. In-person interviews should be done only during daylight hours because respondents are less likely to participate after dark.

Interviewers should remain neutral so that responses are not biased. Interviewers should be reminded that respondents may respond according to the image that they perceive that the interviewer has of the respondent. Hence, neutrality is important. Interviewers should retain the upper hand and not provide advice, act judgmentally, or become emotionally involved. Respondents will occasionally ask interviewers about their own views on the survey items. It is best if interviewers not do so, but if they believe that they must to facilitate the interview, the interviewers' opinions should not be shared until the interview has been completed. Social scientists may feel a need to be helpful when conducting interviews, particularly if the topic under study is a sensitive one. One sociologist who interviewed gay men in-depth felt the need to offer some form of reciprocity and compiled a list of gay-friendly professionals in various fields to offer respondents.

Respondents should be isolated from others, which may be difficult with telephone interviews. The presence of others may influence responses. With telephone interviews, the interviewer may ask if another time would be better. With in-person interviews, perhaps another room could be used that would minimize interference.

Respondents should be assured at the outset that the survey has no right or wrong answers, that the results will be held confidential, and that they are free to omit items or to withdraw from the interview at any time. It may be helpful to engage in a few icebreakers as a transition to the interview, but one should avoid anything that may bias the survey responses.

Comparison of Survey Approaches

Surveys can be completed using mailed or hand-distributed questionnaires, telephone interviews, face-to-face interviews, or online. Data collection for mailed questionnaires requires approximately 10 weeks, whereas telephone interviews can be completed in a relatively short period of time if enough interviewers are used. Because of travel time, in-person interviews take longer and limit the geographical coverage. Mailed questionnaires and telephone interviews theoretically have no geographic boundaries, an advantage when considering generalizability. People seem more willing to respond to longer surveys when administered as an interview. Mailed surveys should generally be simple in design, whereas interviews can be more complex. Question ordering is highly constrained in questionnaires, whereas interviews allow for more variability in question order. Open-ended questions generally receive more complete responses when used in interviews. The greater rapport afforded by in-person interviews yields opportunities for more extensive questioning.

One advantage of mailed questionnaires is that respondents can take the time to consult their personal records. For example, a questionnaire may ask about the cost of property taxes or whether children have been vaccinated. Questionnaires may also be better for asking about sensitive or embarrassing topics, such as trouble with the law. The lower response rates to questionnaires generate greater response biases, such that those surveyed are less representative of the population, whereas in-person interviews generate higher response rates and lower response biases. In-person interviews allow the researcher to present charts listing alternative responses that are less easily communicated in telephone interviews. Both types of interviews have the distinct advantage of application to less literate populations.

Online surveys pose several advantages and disadvantages. Perhaps the strongest advantage over the questionnaire design is that the survey can be tailored to each respondent. If a respondent indicates that he or she has no children, for example, the online survey will simply skip subsequent questions about children. A questionnaire, on the other hand, will take up space with questions about children and ask the respondent to skip them. The skip patterns embedded in online surveys can also be much more complicated than those employed by a human interviewer. Perhaps the weakest aspect of online surveys is limited generalizability. Many people do not have online access, and those who do tend to be more educated and of a higher social class than those who do not.

The choice of survey method is largely dictated by the nature of the population to be sampled and the nature of the research instrument. Time and resources available are also factors. For example, random digit dialing may be employed to survey a specific population without the need to consult a telephone directory. This procedure employs computers to dial randomly selected phone numbers, including both listed and unlisted numbers.

Conclusion

Survey design lies at the heart of social science research. It has been used successfully for decades in such notable studies as the General Social Survey. Survey research yields the broadest reach in terms of sampling and generalizability, particularly when compared to experimental and observational research. Methodologists have made considerable headway in operationalizing concepts, and the survey design has contributed to this progress. Survey research affords comprehensive and efficient measurement of many concepts and has laid the groundwork for the well-developed multivariate causal analyses so popular in the past few decades. Survey research has also been the basis for numerous policy decisions, ranging from the organizational to the national level.

Survey Questionnaire Construction

Elizabeth Martin
U.S. Census Bureau, Washington, DC, USA

Glossary

closed question A survey question that offers response categories.
context effects The effects that prior questions have on subsequent responses.
open question A survey question that does not offer response categories.
recency effect Overreporting events in the most recent portion of a reference period, or a tendency to select the last presented response alternative in a list.
reference period The period of time for which a respondent is asked to report.
response effects The effects of variations in question wording, order, instructions, format, etc. on responses.
retention interval The time between an event to be remembered and a recall attempt.
screening questions Questions designed to identify specific conditions or events.
split sample An experimental method in which a sample is divided into random subsamples and a different version of a questionnaire is assigned to each.
standardized questionnaire The wording and order of questions and response choices are scripted in advance and administered as worded by interviewers.

Questionnaires are used in sample surveys or censuses to elicit reports of facts, attitudes, and other subjective states. Questionnaires may be administered by interviewers in person or by telephone, or they may be self-administered on paper or another medium, such as audiocassette or the Internet. Respondents may be asked to report about themselves, others in their household, or other entities, such as businesses. This article focuses on construction of standardized survey questionnaires.

The utility of asking the same questions across a broad group of people in order to obtain comparable information from them has been appreciated at least since 1086, when William the Conqueror surveyed the wealth and landholdings of England using a standard set of inquiries and compiled the results in the "Domesday Book." Sophistication about survey techniques has increased vastly since then, but fundamental insights about questionnaires advanced less during the millennium than might have been hoped. For the most part, questionnaire construction has remained more an art than a science. In recent decades, there have been infusions of theory from relevant disciplines (such as cognitive psychology and linguistic pragmatics), testing and evaluation techniques have grown more comprehensive and informative, and knowledge about questionnaire design effects and their causes has cumulated. These developments are beginning to transform survey questionnaire construction from an art to a science.

Theoretical Perspectives on Asking and Answering Questions

Three theoretical perspectives point toward different issues that must be considered in constructing a questionnaire.

The Model of the Standardized Survey Interview

From this perspective, the questionnaire consists of standardized questions that operationalize the measurement constructs. The goal is to present a uniform stimulus to respondents so that their responses are comparable. Research showing that small changes in question wording or order can substantially affect responses has reinforced the assumption that questions must be asked

exactly as worded, and in the same order, to produce comparable data.

Question Answering as a Sequence of Cognitive Tasks

A second theoretical perspective was stimulated by efforts to apply cognitive psychology to understand and perhaps solve recall and reporting errors in surveys of health and crime. A respondent must perform a series of cognitive tasks in order to answer a survey question. He or she must comprehend and interpret the question, retrieve relevant information from memory, integrate the information, and respond in the terms of the question. At each stage, errors may be introduced. Dividing the response process into components has provided a framework for exploring response effects, and it has led to new strategies for questioning. However, there has been little research demonstrating that respondents actually engage in the hypothesized sequence of cognitive operations when they answer questions, and the problems of retrieval that stimulated the application of cognitive psychology to survey methodology remain nearly as difficult as ever.

The Interview as Conversation

Respondents do not necessarily respond to the literal meaning of a question but rather to what they infer to be its intended meaning. A survey questionnaire serves as a script performed as part of an interaction between respondent and interviewer. The interaction affects how the script is enacted and interpreted. Thus, the construction of meaning is a social process, and it is not carried by question wording alone. Participants in a conversation assume it has a purpose, and they rely on implicit rules in a cooperative effort to understand and achieve it. They take common knowledge for granted and assume that each participant will make his or her contribution relevant and as informative as required, but no more informative than necessary. (These conversational maxims were developed by Paul Grice, a philosopher.) The resulting implications for the interview process are as follows:

1. Asking a question communicates that a respondent should be able to answer it.
2. Respondents interpret questions to make them relevant to the perceived intent.
3. Respondents interpret questions in ways that are relevant to their own situations.
4. Respondents answer the question they think an interviewer intended to ask.
5. Respondents do not report what they believe an interviewer already knows.
6. Respondents avoid providing redundant information.
7. If response categories are provided, at least one is true.

These implications help us understand a number of well-established questionnaire phenomena. Consistent with item 1, many people will answer survey questions about unfamiliar objects using the question wording and context to construct a plausible meaning. As implied by items 2 and 3, interpretations of questions vary greatly among respondents. Consistent with item 4, postinterview studies show that respondents do not believe the interviewer "really" wants to know everything that might be reported, even when a question asks for complete reports. Consistent with items 5 and 6, respondents reinterpret questions to avoid redundancy. As implied by item 7, respondents are unlikely to volunteer a response that is not offered in a closed question.

The conversational perspective has been the source of an important critique of standardization, which is seen as interfering with the conversational resources that participants would ordinarily employ to reach a common understanding, and it has led some researchers to advocate flexible rather than standardized questioning. A conversational perspective naturally leads to a consideration of the influences that one question may have on interpretations of subsequent ones and also the influence of the interview context—what respondents are told and what they infer about the purposes for asking the questions—on their interpretations and responses.

Constructing Questionnaires

Constructing a questionnaire involves many decisions about the wording and ordering of questions, selection and wording of response categories, formatting and mode of administration of the questionnaire, and introducing and explaining the survey. Although designing a questionnaire remains an art, there is increasing knowledge available to inform these decisions.

Question Wording

Although respondents often seem to pay scant attention to survey questions or instructions, they are often exquisitely sensitive to subtle changes in words and syntax. Question wording effects speak to the power and complexity of language processing, even when respondents are only half paying attention.

A famous experiment illustrates the powerful effect that changing just one word can have in rare cases. In a national sample, respondents were randomly assigned to

be asked one of two questions:

1. "Do you think the United States should allow public speeches against democracy?"
2. "Do you think the United States should forbid public speeches against democracy?"

Support for free speech is greater—by more than 20 percentage points—if respondents answer question 2 rather than question 1. That is, more people answer "no" to question 2 than answer "yes" to question 1; "not allowing" speeches is not the same as "forbidding" them, even though it might seem to be the same. The effect was first found by Rugg in 1941 and later replicated by Schuman and Presser in the United States and by Schwarz in Germany, so it replicates in two languages and has endured more than 50 years—even as support for freedom of speech has increased, according to both versions.

Terminology

"Avoid ambiguity" is a truism of questionnaire design. However, language is inherently ambiguous, and seemingly simple words may have multiple meanings. Research by Belson and others demonstrates that ordinary words and phrases, such as "you," "children," and "work," are interpreted very differently by different respondents.

Complexity and Ambiguity

Both cognitive and linguistic factors may impede respondents' ability to understand a question at all, as well as give rise to variable or erroneous interpretations. Questionnaire designers often intend a survey question to be interpreted literally. For example,

"During the past 12 months, since January 1, 1987, how many times have you seen or talked with a doctor or assistant about your health? Do not count any times you might have seen a doctor while you were a patient in a hospital, but count all other times you actually saw or talked to a medical doctor of any kind about your health."

Such questions challenge respondents, who must parse the question, interpret its key referents (i.e., "doctor or assistant" and "medical doctor of any kind"), infer the events to be included (i.e., visits to discuss respondent's health in person or by telephone during the past 12 months) and excluded (i.e., visits while in a hospital), and keep in mind all these elements while formulating an answer. Apart from a formidable task of recall, parsing such a complex question may overwhelm available mental resources so that a respondent does not understand the question fully or at all. Processing demands are increased by embedded clauses or sentences (e.g., "while you were a patient in a hospital") and by syntactic ambiguity. An example of syntactic ambiguity appears in an instruction on a U.S. census questionnaire to include "People living here most of the time while working, even if they have another place to live." The scope of the quantifier "most" is ambiguous and consistent with two possible interpretations: (i) "... [most of the time] [while working] ..." and (ii) "... [most of the [time while working]]...."

Ambiguity also can arise from contradictory grammatical and semantic elements. For example, it is unclear whether the following question asks respondents to report just one race: "I am going to read you a list of race categories. Please choose one or more categories that best indicate your race." "One or more" is contradicted by the singular reference to "race" and by "best indicate," which is interpretable as a request to select one.

Cognitive overload due to complexity or ambiguity may result in portions of a question being lost, leading to partial or variable interpretations and misinterpretations. Although the negative effects of excessive burden on working memory are generally acknowledged, the practical limits for survey questions have not been determined, nor is there much research on the linguistic determinants of survey question comprehension.

Presupposition

A presupposition is true regardless of whether the statement is true or false; that is, it is constant under negation. (For example, the sentences "I am proud of my career as a survey methodologist" and "I am not proud of my career as a survey methodologist" both presuppose I have a career as a survey methodologist.) A question generally shares the presuppositions of its assertions. "What are your usual hours of work?" presupposes that a respondent works, and that his or her hours of work are regular. Answering a question implies accepting its presuppositions, and a respondent may be led to provide an answer even if its presuppositions are false. Consider an experiment by Loftus in which subjects who viewed accident films were asked, "Did you see *a* broken headlight?" or "Did you see *the* broken headlight?" Use of the definite article triggers the presupposition that there was a broken headlight, and people asked the latter question were more likely to say "yes," irrespective of whether the film showed a broken headlight.

As described by Levinson, linguists have isolated a number of words and sentence constructions that trigger presuppositions, such as change of state verbs (e.g., "Have you *stopped* attending church?") and factive verbs (e.g., "regret," "realize," and "know"). (For example, "If you knew that the AMA is opposed to Measure H, would you change your opinion from *for* Measure H to *against* it?" presupposes the AMA is opposed to Measure H.) Forced choice questions such as "Are you a Republican or a Democrat?" presuppose that one of the alternatives is true.

Fortunately for questionnaire designers, presuppositions may be cancelled. "What are your usual hours of

work?" might be reworded to ask, "What are your usual hours of work, or do you not have usual hours?" Filter questions [e.g., "Do you work?" and (if yes) "Do you work regular hours?"] can be used to test and thereby avoid unwarranted presuppositions.

Question Context and Order

Question order changes the context in which a particular question is asked. Prior questions can influence answers to subsequent questions through several mechanisms. First, the semantic content of a question can influence interpretations of subsequent questions, especially when the subsequent questions are ambiguous. For example, an obscure "monetary control bill" was more likely to be supported when a question about it appeared after questions on inflation, which presumably led respondents to infer that the bill was an anti-inflation measure.

Second, the thoughts or feelings brought to mind while answering a question may influence answers to subsequent questions. This is especially likely when an answer to a question creates expectations for how a subsequent one should be answered. A famous experiment manipulated the order of a pair of questions:

"Do you think the United States should let Communist newspaper reporters from other countries come in here and send back to their papers the news as they see it?"

"Do you think a Communist country like Russia should let American newspaper reporters come in and send back to America the news as they see it?"

Respondents were much more likely to think Communist reporters should be allowed in the United States if they answered that question second. Respondents apparently answered whichever question was asked first in terms of pro-American or anti-Communist sentiments. The second question activated a norm of reciprocity. Since many respondents felt constrained to treat reporters from both countries equally, they gave an answer to the second question that was consistent with the first.

Third, following conversational maxims, respondents may interpret questions so they are not redundant with prior questions. When a specific question precedes a general question, respondents "subtract" their answer to the specific question from their answer to the general one in certain circumstances. Respondents asked questions about marital satisfaction and general life satisfaction reinterpret the general question to exclude the specific one: "Aside from your marriage, which you already told us about, how satisfied are you with other aspects of your life?"

This type of context effect, called a part–whole effect by Schuman and Presser, can occur for factual as well as attitudinal questions. For example, race and Hispanic origin items on the U.S. census form are perceived as redundant by many respondents, although they are officially defined as different. When race (the more general item) appears first, many Hispanic respondents fail to find a race category with which they identify, so they check "other" and write in "Hispanic." When Hispanic origin is placed first so that such respondents first have a chance to report their Hispanic identity, they are less likely to report their Hispanic origin in the race item. Thus, when the specific item comes first, many respondents reinterpret race to exclude the category Hispanic. In this case, manipulating the context leads to reporting that is more consistent with measurement objectives.

One might wonder why a prior question about marital satisfaction would lead respondents to exclude, rather than include, their feelings about their marriages in their answers to a general life satisfaction question. Accounts of when information primed by a prior question will be subtracted rather than assimilated into later answers or interpretations have been offered by Schwarz and colleagues and by Tourangeau *et al.*

The argument is that when people are asked to form a judgment they must retrieve some cognitive representation of the target stimulus, and they must also determine a standard of comparison to evaluate it. Some of what they call to mind is influenced by preceding questions and answers, and this temporarily accessible information may lead to context effects. It may be added to (or subtracted from) the representation of the target stimulus. The questionnaire format and the content of prior questions may provide cues or instructions that favor inclusion or exclusion. For example, Schwarz and colleagues induced either an assimilation or a contrast effect in German respondents' evaluations of the Christian Democratic party by manipulating a prior knowledge question about a highly respected member (X) of the party. By asking "Do you happen to know which party X has been a member of for more than 20 years?" respondents were led to add their feelings about X to their evaluation of the party in a subsequent question, resulting in an assimilation effect. Asking "Do you happen to know which office X holds, setting him aside from party politics?" led them to exclude X from their evaluation of the party, resulting in a contrast effect.

Alternatively, the information brought to mind may influence the standard of comparison used to judge the target stimulus and result in more general context effects on a set of items, not just the target. For example, including Mother Teresa in a list of public figures whose moral qualities were to be evaluated would probably lower the ratings for everyone else on the list. Respondents anchor a scale to accommodate the range of stimuli presented to them, and an extreme (and relevant) example in effect

shifts the meaning of the scale. This argues for explicitly anchoring the scale to incorporate the full range of values in order to reduce such contextual influences.

Response Categories and Scales

The choice and design of response categories are among the most critical decisions about a questionnaire. As noted, a question that offers a choice among alternatives presupposes that one of them is true. This means that respondents are unlikely to volunteer a response option that is not offered, even if it might seem an obvious choice.

Open versus Closed Questions

An experiment by Schuman and Presser compared open and closed versions of the question, "What do you think is the most important problem facing this country at present?" The closed alternatives were developed using responses to the open-ended version from an earlier survey. Just as the survey went in the field, a prolonged cold spell raised public fears of energy shortages. The open version registered the event: "food and energy shortages" responses were given as the most important problem by one in five respondents. The closed question did not register the energy crisis because the category was not offered in the closed question, and only one respondent volunteered it.

This example illustrates an advantage of open questions: their ability to capture answers unanticipated by questionnaire designers. They can provide detailed responses in respondents' own words, which may be a rich source of data. They avoid tipping off respondents as to what response is normative, so they may obtain more complete reports of socially undesirable behaviors. On the other hand, responses to open questions are often too vague or general to meet question objectives. Closed questions are easier to code and analyze and compare across surveys.

Types of Closed-Response Formats

The previous example illustrates that response alternatives must be meaningful and capture the intended range of responses. When respondents are asked to select only one response, response alternatives must also be mutually exclusive.

The following are common response formats:

Agree–disagree: Many survey questions do not specify response alternatives but invite a "yes" or "no" response. Often, respondents are offered an assertion to which they are asked to respond; for example, "Do you agree or disagree?—Money is the most important thing in life." Possibly because they state only one side of an issue, such items encourage acquiescence, or a tendency to agree regardless of content, especially among less educated respondents.

Forced choice: In order to avoid the effects of acquiescence, some methodologists advocate explicitly mentioning the alternative responses. In a stronger form, this also involves providing substantive counterarguments for an opposing view:

"If there is a serious fuel shortage this winter, do you think there should be a law requiring people to lower the heat in their homes, or do you oppose such a law?"

"If there is a serious fuel shortage this winter, do you think there should be a law requiring people to lower the heat in their homes, or do you oppose such a law because it would be too difficult to enforce?"

Formal balance, as in the first question, does not appear to affect response distributions, but providing counterarguments does consistently move responses in the direction of the counterarguments, according to Schuman and Presser's experiments. Devising response options with counterarguments may not be feasible if there are many plausible reasons for opposition, since the counterargument can usually only capture one.

Ordered response categories or scales: Respondents may be asked to report in terms of absolute frequencies (e.g., "Up to $\frac{1}{2}$ hour, $\frac{1}{2}$ to 1 hour, 1 to $1\frac{1}{2}$ hours, $1\frac{1}{2}$ to 2 hours, 2 to $2\frac{1}{2}$ hours, more than $2\frac{1}{2}$ hours"), relative frequencies (e.g., "All of the time, most of the time, a good bit of the time, some of the time, a little bit of the time, none of the time"), evaluative ratings (e.g., "Excellent, pretty good, only fair, or poor"), and numerical scales (e.g., "1 to 10" and "−5 to +5").

Response scales provide a frame of reference that may be used by respondents to infer a normative response. For example, Schwarz and colleagues compared the absolute frequencies scale presented in the previous paragraph with another that ranged from "Up to $2\frac{1}{2}$ hours" to "More than $4\frac{1}{2}$ hours" in a question asking how many hours a day the respondent watched television. The higher scale led to much higher frequency reports, presumably because many respondents were influenced by what they perceived to be the normative or average (middle) response in the scale. If there is a strong normative expectation, an open-ended question may avoid this source of bias. Frequently, ordered categories are intended to measure where a respondent belongs on an underlying dimension (scale points may be further assumed to be equidistant). Careful grouping and labeling of categories is required to ensure they discriminate. Statistical tools are available to evaluate how well response categories perform. For example, an analysis by Reeve and Mâsse (see Presser *et al.*) applied item response theory to show that "a good bit of the time" in the relative frequencies scale presented previously was not discriminating or informative in a mental health scale.

Rating scales are more reliable when all points are labeled and when a branching structure is used, with an initial question (e.g., "Do you agree or disagree . . . ?")

followed up by a question inviting finer distinctions ("Do you strongly agree/disagree, or somewhat agree/disagree?"), according to research by Krosnick and colleagues and others. The recommended number of categories in a scale is 7, plus or minus 2. Numbers assigned to scale points may influence responses, apart from the verbal labels. Response order may influence responses, although the basis for primacy effects (i.e., selecting the first category) or recency effects (i.e., selecting the last category) is not fully understood. Primacy effects are more likely with response options presented visually (in a self-administered questionnaire or by use of a show card) and recency effects with aural presentation (as in telephone surveys).

Offering an Explicit "Don't Know" Response Option

Should "don't know" be offered as an explicit response option? On the one hand, this has been advocated as a way of filtering out respondents who do not have an opinion and whose responses might therefore be meaningless. On the other hand, it increases the number of respondents who say "don't know," resulting in loss of data. Schuman and Presser find that the relative proportions choosing the substantive categories are unaffected by the presence of a "don't know" category, and research by Krosnick and others suggests that offering "don't know" does not improve data quality or reliability. Apparently, many respondents who take the easy out by saying "don't know" when given the opportunity are capable of providing meaningful and valid responses to opinion questions. Thus, "don't know" responses are best discouraged.

Communicating Response Categories and the Response Task

Visual aids, such as show cards, are useful for communicating response categories to respondents in personal interviews. In self-administered questionnaires, the categories are printed on the questionnaire. In either mode, the respondent does not have to remember the categories while formulating a response but can refer to a printed list. Telephone interviews, on the other hand, place more serious constraints on the number of response categories; an overload on working memory probably contributes to the recency effects that can result from auditory presentation of response options. Redesigning questions to branch, so each part involves a smaller number of options, reduces the difficulty. Different formats for presenting response alternatives in different modes may cause mode biases; on the other hand, the identical question may result in different response biases (e.g., recency or primacy effects) in different modes. Research is needed on this issue, especially as it affects mixed mode surveys.

The same general point applies to communicating the response task. For example, in developmental work conducted for implementation of a new census race question that allowed reports of more than one race, it proved difficult to get respondents to notice the "one or more" option. One design solution was to introduce redundancy so respondents had more than one chance to absorb it.

Addressing Problems of Recall and Retrieval

Psychological theory and evidence support several core principles about memory that are relevant to survey questionnaire construction:

1. Autobiographical memory is reconstructive and associative.
2. Autobiographical memory is organized hierarchically. (Studies of free recall suggest the organization is chronological, with memories for specific events embedded in higher order event sequences or periods of life.)
3. Events that were never encoded (i.e., noticed, comprehended, and stored in memory) cannot be recalled.
4. Cues that reinstate the context in which an event was encoded aid memory retrieval.
5. Retrieval is effortful and takes time.
6. Forgetting increases with the passage of time due to decay of memory traces and to interference from new, similar events.
7. The characteristics of events influence their memorability: Salient, consequential events are more likely to be recalled than inconsequential or trivial ones.
8. Over time, memories become less idiosyncratic and detailed and more schematic and less distinguishable from memories for other similar events.
9. The date an event occurred is usually one of its least accurately recalled features.

Principle 6 is consistent with evidence of an increase in failure to report events, such as hospitalizations or consumer purchases, as the time between the event and the interview—the retention interval—increases. Hospitalizations of short duration are more likely to be forgotten than those of long duration, illustrating principle 7. A second cause of error is telescoping. A respondent who recalls that an event occurred may not recall when. On balance, events tend to be recalled as happening more recently than they actually did—that is, there is forward telescoping, or events are brought forward in time. Forward telescoping is more common for serious or consequential events (e.g., major purchases and crimes that were reported to police). Backward telescoping, or recalling events as having happened longer ago than they did, also occurs. The aggregate effect of telescoping and forgetting is a pronounced recency bias, or piling up of reported events in the most recent portion of a reference

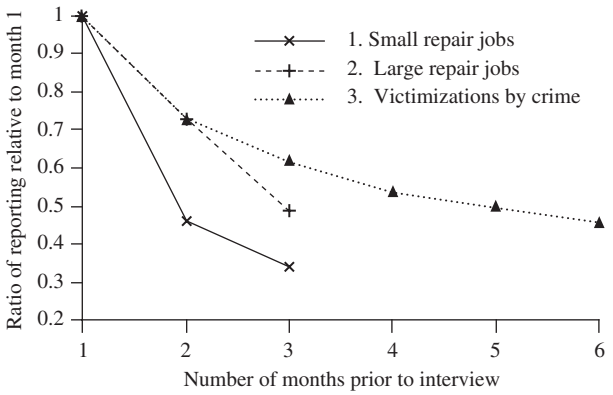

Figure 1 Recency bias for two surveys. *Sources:* Neter, J., and Waxberg, J. (1964). A study of response errors in expenditures data from household interviews. *J. Am. Stat. Assoc.* **59**, 18–55; and Biderman, A. D., and Lynch, J. P. (1981). Recency bias in data on self-reported victimization. *Proc. Social Stat. Section (Am. Stat. Assoc.)*, 31–40.

period. Figure 1 illustrates the effect for two surveys. The rate for the month prior to the interview is taken as a base, and the rates for other months are calculated relative to it. Line 3 shows that monthly victimization rates decline monotonically each month of a 6-month reference period. Lines 1 and 2 show the same for household repairs over a 3-month reference period; note the steeper decline for minor repairs. Recent theories explain telescoping in terms of an increase in uncertainty about the timing of older events. Uncertainty only partially explains telescoping, however, since it predicts more telescoping of minor events than of major ones, but in fact the opposite occurs.

Because of the serious distortions introduced by failure to recall and by telescoping, survey methodologists are generally wary of "Have you ever . . . ?"-type questions that ask respondents to recall experiences over a lifetime. Instead, they have developed various questioning strategies to try to improve respondents' recall.

Strategies to Improve Temporal Accuracy

In order to improve recall accuracy, questions are usually framed to ask respondents to recall events that occurred during a reference period of definite duration. Another procedure is to bound an interview with a prior interview in order to prevent respondents from telescoping in events that happened before the reference period. Results of the bounding interview are not included in survey estimates. Another method attempts to make the boundary of the reference period more vivid by associating it with personal or historical landmark events. This can reduce telescoping, especially if the landmark is relevant to the types of events a respondent is asked to recall. A more elaborate procedure, the event history calendar, attempts to structure flexible questions in a way that reflects the organization of memory, and it has proved promising in research by Belli and associates.

For many survey questions, respondents may rely on a combination of memory and judgment to come up with answers. When the number of events exceeds 10, very few respondents actually attempt to recall and enumerate each one. Instead, they employ other strategies, such as recalling a few events and extrapolating a rate over the reference period, retrieving information about a benchmark or standard rate and adjusting upward or downward, or guessing. By shortening the reference period, giving respondents more time, or decomposing a question into more specific questions, questionnaire designers can encourage respondents to enumerate episodes if that is the goal.

Aided and Unaided Recall

In general, unaided (or free) recall produces less complete reporting than aided recall. It may also produce fewer erroneous reports. Cues and reminders serve to define the scope of eligible events and stimulate recall of relevant instances. A cuing approach was employed to improve victimization reporting in a 1980s redesign of the U.S. crime victimization survey. Redesigned screening questions were structured around multiple frames of reference (acts, locales, activities, weapons, and things stolen) and included numerous cues to stimulate recall, including recall for underreported, sensitive, and nonstereotypical crimes. The result was much higher rates of reporting.

Although cuing improves recall, it can also introduce error because it leads to an increase in reporting of ineligible incidents as well as eligible ones. In addition, the specific cues can influence the kinds of events that are reported. The crime survey redesign again is illustrative. Several crime screener formats were tested experimentally. The cues in different screeners emphasized different domains of experience, with one including more reminders of street crimes and another placing more emphasis on activities around the home. Although the screeners produced the same overall rates of victimization, there were large differences in the characteristics of crime incidents reported. More street crimes and many more incidents involving strangers as offenders were elicited by the first screener.

Dramatic cuing effects such as this may result from the effects of two kinds of retrieval interference. Part-set cuing occurs when specific cues interfere with recall of noncued items in the same category. For example, giving "knife" as a weapons cue would make respondents less likely to think of "poison" or "bomb" and (by inference) less likely to recall incidents in which these noncued items were used as weapons. The effect would be doubly biasing if (as is true in experimental studies of learning) retrieval

in surveys is enhanced for cued items and depressed for noncued items.

A second type of interference is a retrieval block that occurs when cues remind respondents of details of events already mentioned rather than triggering recall of new events. Recalling one incident may block retrieval of others because a respondent in effect keeps recalling the same incident. Retrieval blocks imply underreporting of multiple incidents. Early cues influence which event is recalled first, and once an event is recalled, it inhibits recall for additional events. Therefore, screen questions or cues asked first may unduly influence the character of events reported in a survey.

Another illustration of cuing or example effects comes from the ancestry question in the U.S. census. "English" appeared first in the list of examples following the ancestry question in 1980 but was dropped in 1990. There was a corresponding decrease from 1980 to 1990 of approximately 17 million persons reporting English ancestry. There were also large increases in the numbers reporting German, Acadian/Cajun, or French-Canadian ancestry, apparently due to the listing of these ancestries as examples in 1990 but not 1980, or their greater prominence in the 1990 list. These effects of examples, and their order, may occur because respondents write in the first ancestry listed that applies to them. In a related question, examples did not have the same effect. Providing examples in the Hispanic origin item increased reporting of specific Hispanic origin groups, both of example groups and of groups not listed as examples, apparently because examples helped communicate the intent of the question.

Tools for Pretesting and Evaluating Questions

It has always been considered good survey practice to pretest survey questions to ensure they can be administered by interviewers and understood and answered by respondents. Historically, such pretests involved interviewers completing a small number of interviews and being debriefed. Problems were identified based on interview results, such as a large number of "don't know" responses, or on interviewers' reports of their own or respondents' difficulties with the questions. This type of pretest is still valuable and likely to reveal unanticipated problems. (For automated instruments, it is also essential to test the instrument programming.) However, survey researchers have come to appreciate that many questionnaire problems are likely to go undetected in a conventional pretest, and in recent decades the number and sophistication of pretesting methods have expanded. The new methods have led to greater awareness that survey questions are neither asked nor understood in a uniform way, and revisions based on pretest results appear to lead to improvements. However, questions remain about the validity and reliability of the methods and also the relationship between the problems they identify and measurement errors in surveys. Because the methods appear better able to identify problems than solutions, an iterative approach involving pretesting, revision, and further pretesting is advisable. (A largely unmet need concerns pretesting of translated questionnaires. For cross-national surveys, and increasingly for intranational ones, it is critical to establish that a questionnaire works and produces comparable responses in multiple languages.)

Expert Appraisal and Review

Review of a questionnaire by experts in questionnaire design, cognitive psychology, and/or the relevant subject matter is relatively cost-effective and productive in terms of problems identified. Nonexpert coders may also conduct a systematic review using the questionnaire appraisal scheme devised by Lessler and Forsyth (see Schwarz and Sudman) to identify and code cognitive problems of comprehension, retrieval, judgment, and response generation. Automated approaches advanced by Graesser and colleagues apply computational linguistics and artificial intelligence to build computer programs that identify interpretive problems with survey questions (see Schwarz and Sudman).

Think-Aloud or Cognitive Interviews

This method was introduced to survey researchers from cognitive psychology, where it was used by Herbert Simon and colleagues to study the cognitive processes involved in problem solving. The procedure as applied in surveys is to ask laboratory subjects to verbalize their thoughts—to think out loud—as they answer survey questions (or, if the task involves filling out a self-administered questionnaire, to think aloud as they work their way through the questionnaire). Targeted probes may also be administered (e.g., "What period of time are you thinking of here?"). Tapes, transcripts, or summaries of respondents' verbal reports are reviewed to reveal both general strategies for answering survey questions and difficulties with particular questions. Cognitive interviews may be concurrent or retrospective, depending on whether respondents are asked to report their thoughts and respond to probes while they answer a question, or after an interview is concluded. Practitioners vary considerably in how they conduct, summarize, and analyze cognitive interviews, and the effects of such procedural differences are being explored. The verbal reports elicited in cognitive interviews are veridical if they represent information available in working memory at the time a report is verbalized, if the respondent is not asked to explain and interpret his or her own thought processes, and if the

social interaction between cognitive interviewer and subject does not alter a respondent's thought process, according to Willis (see Presser *et al.*). Cognitive interviewing has proved to be a highly useful tool for identifying problems with questions, although research is needed to assess the extent to which problems it identifies translate into difficulties in the field and errors in data.

Behavior Coding

This method was originally introduced by Cannell and colleagues to evaluate interviewer performance, but it has come to be used more frequently to pretest questionnaires. Interviews are monitored (and usually tape recorded), and interviewer behaviors (e.g., "Reads question exactly as worded" and "Reads with major change in question wording, or did not complete question reading") and respondent behaviors (e.g., "Requests clarification" and "Provides inadequate answer") are coded and tabulated for each question. Questions with a rate of problem behaviors above a threshold are regarded as needing revision. Behavior coding is more systematic and reveals many problems missed in conventional pretests. The method does not necessarily reveal the source of a problem, which often requires additional information to diagnose. Nor does it reveal problems that are not manifested in behavior. If respondents and interviewers are both unaware that respondents misinterpret a question, it is unlikely to be identified by behavior coding. Importantly, behavior coding is the only method that permits systematic evaluation of the assumption that interviewers administer questions exactly as worded.

Respondent Debriefing or Special Probes

Respondents may be asked directly how they answered or interpreted specific questions or reacted to other aspects of the interview. Survey participants in effect are asked to assume the role of informant, rather than respondent. Probes to test interpretations of terminology or question intent are the most common form of debriefing question, and their usefulness for detecting misunderstandings is well documented by Belson, Cannell, and others. For example, the following probes were asked following the previously discussed question about doctor visits: "We're interested in who people include as doctors or assistants. When you think of a doctor or assistant, would you include a dentist or not? Would you include a laboratory or X-ray technician or not?... Did you see any of those kinds of people during the last year?" Specific probes targeted to suspected misunderstandings have proved more fruitful than general probes or questions about respondents' confidence in their answers. (Respondents tend to be overconfident, and there is no consistent evidence of a correlation between confidence and accuracy.) Debriefing questions or special probes have also proved useful for assessing question sensitivity ("Were there any questions in this interview that you felt uncomfortable answering?"), other subjective reactions ("Did you feel bored or impatient?"), question comprehension ("Could you tell me in your own words what that question means to you?"), and unreported or misreported information ("Was there an incident you thought of that you didn't mention during the interview? I don't need details."). Their particular strength is that they reveal misunderstandings and misinterpretations of which both respondents and interviewers are unaware.

Vignettes

Vignettes are brief scenarios that describe hypothetical characters or situations. Because they portray hypothetical situations, they offer a less threatening way to explore sensitive subjects. Instead of asking respondents to report directly how they understand a word or complex concept ("What does the term *crime* mean to you?"), which has not proved to be generally productive, vignettes pose situations that respondents are asked to judge. For instance,

"I'll describe several incidents that could have happened. We would like to know for each, whether you think it is the kind of crime we are interested in, in this survey. ... Jean and her husband got into an argument. He slapped her hard across the face and chipped her tooth. Do you think we would want Jean to mention this incident to us when we asked her about crimes that happened to her?"

The results reveal how respondents interpret the scope of survey concepts (such as crime) as well as the factors influencing their judgments. Research suggests that vignettes provide robust measures of context and question wording effects on respondents' interpretations.

Split-Sample Experiments

Ultimately, the only way to evaluate the effects of variations in question wording, context, etc. on responses is to conduct an experiment in which samples are randomly assigned to receive the different versions. It is essential to ensure that all versions are administered under comparable conditions, and that data are coded and processed in the same way, so that differences between treatments can be unambiguously attributed to the effects of questionnaire variations. Comparison of univariate response distributions shows gross effects, whereas analysis of subgroups reveals conditional or interaction effects. Field experiments can be designed factorially to evaluate the effects of a large number of questionnaire variables

on responses, either for research purposes or to select those that produce the best measurements. When a survey is part of a time series and data must be comparable from one survey to the next, this technique can be used to calibrate a new questionnaire to the old.

Conclusion

Survey questionnaire designers aim to develop standardized questions and response options that are understood as intended by respondents and that produce comparable and meaningful responses. In the past, the extent to which these goals were met in practice was rarely assessed. In recent decades, better tools for providing feedback on how well survey questions perform have been introduced or refined, including expert appraisal, cognitive interviewing, behavior coding, respondent debriefing, vignettes, and split-sample experiments. Another advance is new theoretical perspectives that help make sense of the effects of question wording and context. One perspective examines the cognitive tasks in which a respondent must engage to answer a survey question. Another examines the pragmatics of communication in a survey interview. Both have shed light on the response process, although difficult problems remain unsolved. In addition, both perspectives suggest limits on the ability to fully achieve standardization in surveys. New theory and pretesting tools provide a scientific basis for decisions about construction of survey questionnaires.

Glossary

anchor points Values that serve as bases for judgments. They are usually a consideration in response formats.
bounded recall A technique used in panel surveys whereby respondents are reminded of their responses from the previous wave. It is used to combat seam effects.
clustered sampling A sampling strategy that requires the selection of a sample of higher order groups within which desired elements are organized in order to survey the desired elements; for example, selecting a sample of schools in order to survey the children attending those schools.
cognitive pretesting A method of pretesting survey questions that considers respondents' understanding of the question, their ability to recall information, the way they arrive at judgments, and the accuracy with which they report information.
estimation strategies Systematic methods that survey respondents use to make reasonable guesses about behavioral frequency information of which they are unsure.
interrogatives, space of uncertainty, and propositions Linguistic terms describing the question asking and answering process. An interrogative is a question statement. The space of uncertainty is the set of possible answers. Propositions are suggestions made by the question wording that may lead respondents to a conclusion, either intended or unintended.
narrative chains The idea that events are linked in memory as narratives, or stories, rather than by topic.
non-sampling error The difference between the population estimate and the true population value due to factors not related to the sample design, such as undercoverage, nonresponse, and reporting inaccuracies.
panel survey A survey in which a sample of respondents is interviewed more than once.
population estimate A statistic derived from a sample that is used as a proxy for the population value.
repeated cross section A series of cross-sectional surveys—that is, surveys in which individual samples are selected at different points in time—in which the same questions are repeated.
sample frame List of elements (units to be studied in a survey) in a population from which a sample will be drawn. In many surveys, elements are individuals. The sample frame sometimes has to be constructed from multiple sources and may contain duplicate or missing elements.
sampling error The difference between the population estimate, derived from the sample, and the true population value. The difference is due to the fact that not all elements in the population are selected into the sample.
seam effect Bias in reporting that occurs in panel surveys in which the respondent reports about several months during each wave of the panel. More change in status is noted across the seam of any two waves—that is, from the most recent reporting month of the last wave to the most remote reporting month of the subsequent wave—than between any months within waves.
stratified sampling Organizing the sample frame by mutually exclusive and exhaustive categories (e.g., region, sex, race, and age) and selecting samples within each of the categories, sometimes using different sampling rates for each category.
telescoping The tendency of respondents to recall events as happening earlier than they actually occurred (forward telescoping) or, less frequently, later than they actually occurred (backward telescoping).
time line An aid used in surveys to help respondents recall events that happened in the past.

Surveys are powerful research tools used by social scientists to study social phenomena. The process of conducting a survey includes defining a population, selecting a sample, developing and administering a questionnaire, and collecting and analyzing data. Survey sampling permits the researcher to make inferences from

samples to populations. Questionnaire design has been advanced by studies of the psychology of survey responding, primarily examining the role of cognition in the survey response process. Advances in questionnaire design have also emerged from attention to the conversational nature of a survey interview and linguistic aspects of survey questions. Survey researchers have always taken advantage of new methodologies and they continue to do so. They exploit new technologies as opportunities for collecting better data, and they conduct methodological research to overcome obstacles posed by the new technologies.

Introduction

Survey research is a popular and powerful means by which to study people and organizations in society. It consists of a rich set of techniques used to obtain information about individual attitudes, values, behaviors, opinions, knowledge, and circumstances. Surveys are also used to study organizations and institutions, for example, assessing their culture, policies, and finances. This article discusses both of these uses of surveys but emphasizes surveys conducted on individuals. The goal of this article is to inform the consumer of survey information about survey techniques and their impact on the interpretation of results. Most of the discussion about individual-level surveys applies to interpretation of surveys about organizations.

A social survey is a standardized and systematic method for obtaining information about a population by using a questionnaire to measure elements sampled from that population. Standardization and systemization facilitate replication, which is a hallmark of the scientific method. Thus, surveys are an important tool in advancing social science. The sampling component—that is, the ability to study a sample and make projections to a population—makes the sample survey an efficient tool for studying the characteristics of populations. The questionnaire is the main method for extracting information, and careful questionnaire construction is important in order to obtain high-quality data. Social, cognitive, and linguistic elements are at play in questionnaire construction. The means for administering the questionnaire encompasses both the training of interviewers, who are the information collection agents, and the selection of a modality of the interview. Modalities include face-to-face administration, administration by telephone, mail and computerized self-administered questionnaires, and, recently, surveys via the Internet and the World Wide Web.

Most surveys involve the following steps, although not necessarily in the order presented. First, a population one wishes to study is determined and a list of the population elements, called a sample frame, is obtained. Second, a topic or topics of interest are determined. The first and second steps combined may be thought of as defining a research question (or set of questions). For example, studying the employment patterns of high school dropouts necessitates both selecting topics relevant to employment and obtaining a sample of high school dropouts. The third step in the survey process is designing a method for sampling elements from the population. The fourth step is designing a questionnaire that reflects the topical areas of interest. The fifth step is deciding on a modality of administration. The fourth and fifth steps are important to consider together because the mode of administration will affect the design of the questionnaire. The sixth step consists of training interviewers in the administration of the questionnaire (which is sometimes, but not always, necessary for self-administered surveys), and the seventh step involves devising a method for compiling and aggregating the survey information. The analysis of the information is the eighth step. This article focuses on the first six steps.

Before the steps are discussed in detail, it is worthwhile to examine the types of surveys. There are three general types of surveys. A cross-sectional survey represents a population at a given point in time. A well-known example of a national cross-sectional survey is the General Social Survey (GSS) conducted by the National Opinion Research Center at the University of Chicago. In the GSS, which has been conducted nearly every year on independent samples of Americans for the past 30 years, some questions appear in only 1 year, whereas others are repeated year after year. Repeating questions in cross-sectional surveys is useful for assessing trends in opinions, attitudes, values, knowledge, or behavior. When cross-sectional samples include the same items year after year, the entire set of surveys is called a repeated cross-section design. Trend data for repeated cross-section designs over an extended period represent a combination of change (or stability) in responses to the questions and in the population demographics.

A second type of survey is the longitudinal survey. In this type of survey, the same respondents are interviewed repeatedly over time. Some longitudinal surveys are of an age cohort; the age group is followed over time, sometimes for as long as 20 years. For example, the National Longitudinal Survey of Youth consists of a sample of the senior class of 1978. This group has been reinterviewed nearly every year since that time. Another type of longitudinal survey is the panel survey. An example of this is the Panel Study of Income Dynamics (PSID) conducted by the Institute for Survey Research at the University of Michigan. In this type of survey, a sample is selected and interviewed. Sample members are then reinterviewed, sometimes at fixed intervals and other times to track the effects of some important social event. The sample is not an age cohort but a cross section of the population at the time the panel was created. Some panel surveys consist of only two rounds of interviews. Others, like the

PSID, have many rounds. More complicated designs include combinations of cross sections and panels.

Populations and Sampling

As mentioned previously, defining a population is one of the early steps in the survey process. A population is a total set of elements. It may be small, such as the total number of cars in a given parking lot, or large, such as the total number of households in the United States. Typically, surveys are concerned with collecting information from large populations. One way of collecting information about populations is to survey all the elements. This is called a census. A very famous example of a census done on a large population is that conducted in the United States every 10 years. More typically, surveys use scientific sampling methods and collect information about a subset of the total elements. If this is done properly, estimates about the characteristics of the entire population can be derived. The goal of a sample survey is to obtain unbiased estimates of population information without having to collect information from all the elements of the population. At this point, it is worthwhile to examine properties of information obtained from sample surveys compared to the information as it exists in the population. Because sample surveys collect information from only a portion of a population, statistics derived from the information obtained from a sample survey will not likely match exactly the statistics in the populations. For example, a scientifically designed sample survey of the household income of residents in a city may indicate that the median income is $35,500. If household incomes from all the households in that city were obtained, the true value might be $36,200. The survey value and the population value do not match.

However, if the sample is constructed according to scientific principles it is possible to determine a range within which the true population household income probably lies. This range will be centered around the population statistic. The range is called the margin of error; it is expressed as the estimate plus or minus a value. That value is a function of two factors, the standard deviation of the estimate and the sample size. Figure 1 shows sample sizes needed for margins of error of different magnitudes for a variable with standard deviation 0.5 and for another one with standard deviation 0.26. These numbers are the standard deviations of sample proportions of 0.5 and 0.93, respectively. To make these numbers more concrete, they can be thought of in terms of the proportion of a sample engaging in some behavior, for example, saying they will vote for candidate Jones in the upcoming mayoral election. If 50% of the sample say they will vote for Jones, the sample proportion voting for Jones is 0.5 and the standard variance of that proportion is $(0.5^* (1 - 0.5))^{0.5}$, or 0.5. On the other hand, if 93% of the sample say they will vote for Jones, the sample proportion is 0.93 and the standard deviation is $(0.93^* (1 - 0.93))^{0.5}$, or approximately 0.26.

A standard benchmark is to be 95% certain that the true value lies within the range determined by the margin of error, and the sample sizes in Fig. 1 were constructed using this benchmark. According to Fig. 1, if 50% of the sample say they will vote for Jones, and the survey was conducted using responses from 246 scientifically selected voters in the city for which Jones is running for mayor, then one can be 95% certain that the proportion of the population saying they will vote for Jones is

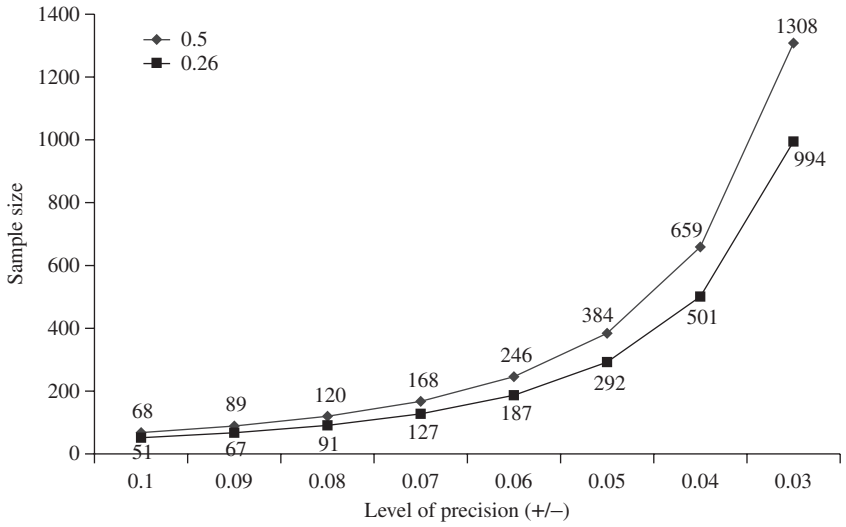

Figure 1 Approximate sample sizes needed for different levels of precision in a simple random sample survey assuming variances of 0.5 and 0.26.

between 44 and 56%. Figure 1 illustrates three points. First, for the same standard deviation, as the sample size increases the margin of error becomes smaller. Second, the relationship is not linear. To obtain increasingly smaller margins of error, the sample size begins to double or triple. When the standard deviation is 0.5, to go from a margin of error of ± 0.04 to one of ± 0.03 the sample size has to be doubled. To go from 0.03 to 0.02, the sample size has to almost be tripled. Although it is not shown in the figure, the survey would need to have a sample size of more than 16,000 cases in order to go from a margin of error of 0.02 to one of 0.01. The third point illustrated in the figure is that for variables with smaller standard deviations the sample size needed to obtain a given margin of error is less and the increase in sample size to obtain smaller standard errors is also less. Of course, it makes no sense to talk about a ± 0.1 margin of error for a sample proportion of 0.93 because $0.93 + 0.1$ gives a proportion greater than 1, which is clearly impossible. When proportions are very close to 0 or very close to 1, special statistical considerations have to be made for estimating some of the standard errors. The example here was used for illustration of the three points made previously, which hold despite this anomaly. Although this example used a sample proportion as the statistic, the same principles apply to other statistics, such as averages or totals. Of course, the standard deviations are calculated differently than for the proportion.

An additional point about sample sizes is that when dealing with populations of 10,000 or more, the size of the population does not affect the margin of error appreciably. Therefore, a sample size of 1000 will give roughly the same margin of error for a population of 10,000 as it will for a population of 100,000 or 184 million, the current estimate of the number of people in the United States. If a population is small such that it is practical to draw a sample of 10% or more, then a factor called the finite population correction can be used to reduce the standard deviation of an estimate and thus reduce the sample size needed for a given margin of error. The factor is calculated as $((N-n)/N))^{0.5}$, where N is the size of the population, and n is the size of the sample.

Sample Designs

Reference has been made to scientifically designed samples. Some basic elements of such samples are now discussed. A scientifically designed sample, at a minimum, specifies a method for choosing elements from a population with known selection probability. A simple random sample is the most elementary form of a scientifically designed sample. More complex designs (discussed later) use principles of the simple random sample as their basis. An example will illustrate a number of features of a simple random sample. Imagine that there are 5423 businesses with annual revenue of less than $50,000 in a certain geographic region and that the Internal Revenue Service wants to conduct an audit using a sample survey. Also imagine that you own one of these businesses. Using a simple random sample design, each business would be assigned an equal probability of selection, which would be 1/5423. In a sample of size 1, your business would have a 1/5423 or 0.000184% chance of being selected. If 10 businesses were selected simultaneously at random, then your business would have a 10/5423 chance of being in the sample. The larger the sample, the greater the probability that your business would be selected into it, but in each case the selection probability is known. For any population, the probability of any element within that population to be selected into a sample is the sample size divided by the population size.

Simple random sampling may work in certain, limited situations, but surveys usually call for more complicated designs. One level of complexity is stratification. In a stratified design, elements in the sample frame are grouped according to one or more characteristics and a simple random sample is selected from each stratum. Sometimes, elements are selected at different rates from each stratum. It is important to note that statistics derived from the sample must take into account the sampling rate in each stratum or erroneous population estimates will be calculated.

Another level of complexity is called clustering. Sometimes, it is impossible or impractical to obtain a good sample frame of the elements one wishes to study. If these elements are grouped into higher order elements, as is, for example, the population of eighth graders in public schools in a given county, then one can start with a list of all the public schools with eighth grades within the county and work down. This is done by selecting a sample of public schools from the list of schools and either surveying all the eighth graders in the sampled schools or selecting a sample of the eighth graders in each of the sampled schools. The higher order elements (schools) are called primary sampling units, and the elements contained within the primary units (students) are called secondary sampling units. The full-sample, or complex, probability of selection of a secondary element into the sample is the product of two selection probabilities. The first is the probability of the selection of the primary sampling unit, and the second is the probability of selection of the secondary sampling unit.

To make this concrete, suppose a researcher was interested in studying the characteristics of eighth graders in public schools within your county. Also suppose that there were 150 such schools and the researcher randomly selected a sample of 15. The selection probability for any given school would be 15/150 or 0.1. Now suppose that in 1 sampled school there were 100 eight graders and the

researcher sampled 30 of them using simple random sampling. The within-class selection probability for each student in the sample for that class would be 30/100 or 0.33. The full survey or complex selection probability for each sampled student from that class would be the selection probability for the school (0.1) multiplied by the selection probability of the student within the class in the school (0.33) or 0.033.

In a survey design, clustering can be extended to three levels (e.g., counties sampled within a region, schools sampled within counties, and students sampled within schools) or more. In addition, stratification and clustering can be combined to create complex survey designs. For example, the country could be divided into mutually exclusive quadrants of approximately the same geographic size. An equal number of schools could be selected within each quadrant, ensuring that the sample is not dominated by areas of the country that are heavily populated. This is useful especially if it is desirable to make comparisons between schools in densely populated areas and schools in sparsely populated areas. The calculation of the margin of error for stratified and clustered designs requires the use of specialized techniques. Making the assumption that these complex designs are like simple random samples, and analyzing them accordingly, is likely to result in the overestimation of the margin of error (making it too large) with a stratified design and the underestimation (making it too small) in a clustered design. The ratio of the sample design-based standard error to the standard error based on the assumption that the design was a simple random sample is called the sample's design effect, and it is a useful statistic to compare the efficiency of different sample designs.

Two other types of survey designs that are worth mentioning are convenience sampling and quota sampling. These are not scientific designs because there is no way of knowing the selection probability of each case in the sample. Although they can be useful under certain limited conditions, margins of error cannot be calculated. Convenience sampling involves collecting information from respondents who are available. If the population is small (e.g., the number of people who work in a small office building) and the convenience sample is large (e.g., 90% of the workers complete the survey), it is not unreasonable to assume that the results of the convenience sample represent results for the population.

However, convenience samples of large populations may be grossly misleading. Consider, for example, surveys that popular magazines regularly conduct. Their readership may be in the hundreds of thousands and 10,000 readers may mail in a completed questionnaire on a particular topic. However, it is likely that only those respondents who were interested in the topic chose to participate in it, causing a large amount of selection bias in the sample. Also, there is no way to determine whether a single respondent completed two or more surveys. Although information from these respondents may provide entertainment value, it should not be considered representative of any population because the sample of respondents was not selected in a scientific manner.

A second type of nonprobability sampling is quota sampling. If one knows something about the distribution of a population on key demographic characteristics, one can construct a convenience sample that reflects that distribution. Consider the following example. A certain town is known to have a population that consists of 30% African Americans, 20% Hispanics, and 50% whites. Furthermore, it is known that males and females are distributed evenly across the race/ethnicity groups. A quota sampling strategy would be to construct a convenience sample of town residents that consisted of 15% African American males, 15% African American females, 10% Hispanic males, 10% Hispanic females, 25% white males, and 25% white females. Quota sampling was frequently used by survey researchers into the early 1970s, and it is used occasionally today. There are cost advantages to this method, but, strictly speaking, margins of error cannot be determined because selection probabilities are not known.

Error and Bias in Surveys

Probability samples are the mainstay of modern survey research because they allow the researcher to control the margin of error. Probability samples, perfectly constructed and implemented, all other things being equal, produce unbiased estimates. However, rarely is it the case that construction and implementation are perfect, and when they are not the potential for bias arises. Bias is the difference between the population value that is supposed to be estimated and the population value that is actually estimated. There are two common sources of bias that are usually discussed with regard to sampling. One common source of bias emerges from the use of a sample frame that does not fully cover the units in the population (the undercoverage problem). The second common source is produced from the failure to obtain data from each of the selected elements in the sample (the nonresponse problem).

Samples are typically selected from lists of units that encompass the entire population (or by using an approximation technique if no such list is available). This list is called a sample frame, and it often only imperfectly represents the population. In part, this is because populations are dynamic, whereas sample frames are static. For example, a list of all the small businesses in the country that one might construct today could be out of date tomorrow if a new business started or an existing one ended. There are methods to update sample frames, but even in

the best circumstances a sample frame is unlikely to be a complete listing of all the elements in a population. To the extent that a sample frame covers the population completely or nearly completely, there is hope for obtaining unbiased estimates of population values from a properly designed sample. To the extent that there is substantial undercoverage—that is, a substantial number of elements of the population are missing in the sample frame—there may be bias in the survey estimates.

One example of sample frame undercoverage is seen in telephone survey sampling. Techniques are available to obtain a good approximation of all the possible telephone numbers in a geographical area or even in the entire country. However, if telephone numbers are to be used as a sample frame, households without telephones will have no chance of being represented in a sample selected from that sample frame. The survey estimates will be of the population of households that have telephones. To the extent that this population differs from the population of households without telephones, the estimate will be biased. Undercoverage is a potential source of bias in survey estimates but it need not be a serious source. If the undercoverage is small, for example, in a medium to large community in which 98% of households have telephones, the amount of bias in information is likely to be small. If only 50% of households in an area have telephones, the bias in information collected from a telephone survey has the potential to be large, and telephone survey methodology would not be recommended. If it is the case that elements are not represented in the sample frame for random reasons, then undercoverage is unlikely to produce bias; however, this is usually not the case.

Another common failing leading to bias is the inability to collect information from some of the selected units. For example, in a confidential survey conducted in a corporation some employees selected into the sample may choose not to participate. The failure to collect information from units selected into the survey is expressed as the rate of nonresponse. The nonresponse rate is the number of individuals (or schools or other organizations) who refused to participate in the survey (or could not be located) divided by the total number of individuals (or schools/organizations) selected into the sample. The response rate is the number of completed surveys divided by the total number in the sample. High nonresponse rates can lead to significant bias in survey estimates. Therefore, it is important to know the response rate of the survey when evaluating the quality of its results.

Questionnaire Design

The sample design determines who will be measured. Questionnaire design determines what is being measured. Social surveys use questionnaires to obtain many different types of information—values, attitudes, opinions, knowledge, behaviors, characteristics, and circumstances. Questionnaire design is a multifaceted activity. It involves first deciding what information is desired and then crafting a questionnaire that is likely to elicit accurate responses. Attention has to be paid to instructions, question format (close-ended or open-ended), question wording, response categories, question order, and the mode of administration. Each one of these characteristics of a questionnaire can affect results. Poor question construction or poor questionnaire design can result in nonsampling error, which is the technical term for error or bias due to respondent reports.

Elements of Good Questionnaire Design

The prototypical survey question has a stem and response format. The stem is the question. For example, a stem for a question about educational attainment might read as follows: "What is the highest level of education you have completed?" The response format may consist of a list of typical education levels. The choice of words in the question stem is important, particularly for attitude and opinion questions. A question that consists of words indicating extreme positions may elicit more disagreement than a question that is semantically equivalent but uses less strong language. In a classic example from the 1940s, fewer respondents agreed that the United States should "forbid" reporters from a communist country to come into this country to report the news back home than agreed that the United States should "not allow" the foreign reporters. A recent study showed that far fewer respondents endorsed spending more government money on "welfare" than on "assistance to the poor." The general recommendation is to avoid asking questions with strong or "loaded" wording.

Questions should be limited to one topic. A question that has a conditional phrase may be "double-barreled"; that is, it may be asking about two things. For example, the question, "Do you think that Congress should increase the income tax to support increased civil defense?" asks about tax increases and increased civil defense. A respondent who favors increasing civil defense but who thinks taxes are high enough already may have difficulty answering this question. Similarly, an analyst may have difficulty interpreting the results. A better strategy would be to ask if the respondent favors increasing civil defense in one question and then ask whether it should be done through tax increases (or perhaps through other means) in a second question.

Questions may be close-ended or open-ended. A close-ended question contains a stem and a set of preselected response categories. An open-ended question has the stem but no response categories; verbatim responses are recorded. There is an intermediate type, the semi-structured question, which has a number of response options but allows the respondent to offer a response that is not one of the options. Most survey questions are of the close-ended type because these types of questions do not require the expensive categorization and coding of responses that completely open-ended questions require. However, in close-ended questions, response selections are limited to those generated by the researcher and may not reflect those that are important to respondents. Either format is legitimate, but when interpreting the results, it is important to know which format was used; results from the same question asked in different formats may not be comparable.

One area in which open-ended questions are particularly useful is in the assessment of behavioral frequency. For example, a question may ask, "How many hours of television do you watch during an average week?" or "How many alcoholic drinks did you have last week?" It is common practice to include frequency ranges, such as "none, one to five, six to ten, eleven to fifteen, more than fifteen," as response categories. However, research has shown that the range of response categories can influence the category that is selected. Thus, estimates of frequencies will differ depending on how the categories are constructed.

The placement of questions in the questionnaire is important to consider. For attitude or opinion questions, related prior questions can affect responses to questions about obscure topics or to questions about which the respondent has mixed feelings or no strong opinion. For example, responses to a question about whether the United States should invade Iraq, a topic over which there was public debate and uncertainty, may be swayed in a positive direction if it is preceded by questions about the largely successful U.S. military activities in Afghanistan or in a negative way if it is preceded by a question about the flagging U.S. economy. These effects are not limited to attitude questions. A question asking respondents how often they go to the dentist followed by a vaguely worded question such as "Does your employer provide insurance benefits?" will almost certainly have respondents thinking about dental insurance. If the researcher is interested in health insurance, the data obtained will be very inaccurate.

Whether a question includes an explicit "don't know" option or not may affect responses to topics that are obscure. With the absence of an explicit "don't know" option, and motivated by a desire to please the interviewer or by the fear of appearing uninformed, respondents will sometimes give opinions when they know very little about a topic. If the survey context suggests an interpretation, then biased responses may be given. Providing an explicit "don't know" category as a response option will mitigate the tendency for uninformed respondents to give substantive responses. Another technique to eliminate asking questions to respondents who know nothing about an issue is to provide a screening question asking whether the respondent has heard about the issue and only eliciting opinions from those who answer affirmatively.

For sensitive topics respondents may use an explicit "don't know" category as a way to avoid giving an answer. This can lead to response bias. For example, if a question that asks smokers how many cigarettes they smoke in a day has an explicit "don't know" option and enough heavy smokers choose this option rather than admitting that they smoke two packs of cigarettes a day, an underestimate of the number of cigarettes smoked will be obtained. A screening question before a sensitive question may also give respondents an easy way to avoid answering the question by simply saying no to the screener. Asking respondents whether they smoke and then asking only those who say yes how much they smoke may lead to an underestimate of smokers compared to a single question that asks how many cigarettes a respondent usually smokes in a day. Those who do not smoke will simply say "none" or "I don't smoke cigarettes." If a topic is sensitive, it may be better to assume that the behavior occurs and allow the respondent to offer a "never" response rather than explicitly providing that option.

Questionnaire Design and Human Cognition

The design of questionnaires has been improved by paying attention to the cognitive processes of the respondent. From the 1940s through the mid-1980s, research on different techniques of asking questions suggested that the way questions were asked affected responses. Research on survey response effects (i.e., finding that different response formats result in different patterns of response), question wording effects (i.e., finding that apparently synonymous terms in the question stem result in very different responses), and question order effects (i.e., finding that response patterns differ depending on preceding questions) suggested that survey questions were interacting with psychological processes of the respondent. However, with few exceptions, very little attention was given to systematically exploring the psychology of the survey respondent. A breakthrough conference in the mid-1980s, the Conference on Cognitive Aspects of Survey Methodology, changed this to a large extent and became a catalyst for research on cognition and survey responding that continues today.

A popular framework that describes the tasks that the survey respondent confronts emerged from this conference. The framework suggests that respondents engage in question interpretation, retrieval of information from memory, judgment formation, and editing for social desirability when they give their answer to a survey question. Consideration of these tasks has been useful in providing a greater understanding of the influence of question type, question wording, response format, and question order on responding. The first three tasks—interpretation, retrieval, and judgment—are, by and large, performed unconsciously. The fourth task, editing, is thought to be strategic, driven for the most part by respondents' tendencies to wish to avoid presenting themselves in an unfavorable way. One of the more enduring fruits of this framework has been a technique for pretesting survey questions called cognitive pretesting in which test respondents are administered carefully developed probe questions. This technique has helped survey researchers create questions that minimize bias introduced by the elements of questionnaire construction discussed previously.

As mentioned previously, questions can be close-ended or open-ended. Attention to cognitive processes reveals that each type of question involves a different cognitive task. The open-ended format clearly involves a recall task. For some types of questions, such as the standard questions used to measure occupation and industry (e.g., "What kind of work do you?" and "What business is it in?") in which the respondent is largely asked to report factual information, recall is straightforward. Other types of open-ended questions require more complicated cognitive processing.

For example, the question, "What is the most important issue facing the country today?" requires respondents first to search memory for candidate issues and then to judge the importance of each issue. The thoroughness of this search and evaluate process may depend on the respondent's motivation or the amount of distraction in the interview setting. A nonthoughtful response may be generated based on some superficial source, such as what he or she had read in the newspaper that morning or had seen on the news the previous night. A completely thoughtful response might require an amount of time that neither the respondent nor the interviewer care to spend. If the question is presented in close-ended format in which a list of response options is provided, the task for respondents is simplified to that of judgment and the respondents can put more effort into it. Studies have shown that very different patterns can be produced under the two question types, even when pretesting has been conducted to try to include in the close-ended format the range of responses that are likely to emerge from an open-ended format. Perhaps the differences are due to the types of cognitive tasks that respondents have to perform under the different formats.

It was previously mentioned that open-ended questions about behavioral frequency are preferable to those that are close-ended because of the influence of the response ranges on the response. Studies have shown that the range of response options may affect the respondent's interpretation of the question. For example, if a set of response options has a range of frequencies that indicate experiences are high in number and the question is "How often have you been criticized in the last month?" a respondent may interpret criticism as involving small incidents. The range of response options may also provide respondents with one or more anchor points from which to estimate their own behavioral frequency. Also, if the question topic is sensitive (e.g., asking how many sexual partners a respondent had in the pastyear) or if there is a social desirability component (e.g., asking how many hours per week one exercises), a respondent may view the middle category as a normative response and choose that to appear neither over nor under the norm.

It was previously mentioned that the use of strong words may bias the respondent into choosing a "lenient" response, for example, agreeing to "not allow" foreign reporters from a hostile nation into the United States but not agreeing to "forbid" them. There are other examples of question wording effects in which similar wording may indicate completely different concepts, perhaps depending on characteristics of the respondent. One study demonstrated a remarkably strong reaction against supporting "welfare" compared to supporting "assistance to the poor." Although these words appear to refer to the same phenomenon, the term welfare may have brought to mind government welfare programs that were unpopular with the public not because they provided assistance to the poor but because they were associated with wasteful bureaucracies and popular notions that they are often abused. Other studies have shown similar results in the area of crime fighting and dealing with the problem of illegal drugs. Sometimes, the effects interact with individual differences, such as political orientation, suggesting that different groups read different things into these sometimes controversial social issues. These results justify the injunction made earlier of keeping the wording of survey questions as neutral and objective as possible.

Studies have shown that prior questions can affect responses to target questions by influencing the retrieval process—that is, the material from memory that respondents bring to mind when answering the target questions. For example, in a public opinion survey administered during a time when the United States was considering military involvement in Nicaragua, questions about the Vietnam War that preceded questions about U.S. military involvement in Nicaragua resulted in more opposition to

U.S. involvement in Nicaragua and in more mentions of the Vietnam War as a reason for the response in a probe question that followed the Nicaragua question. The example about how prior questions about dental care may affect the interpretation of subsequent questions about insurance indicates that the interpretative and retrieval effects of prior questions are not limited to attitude questions.

Memory and Survey Reporting

Many surveys ask respondents to report on life events, such as what activities they have done or products they have consumed, when they have done them, and how frequently. A wide variety of activities are assessed. Recreation surveys might be interested in frequency and dates for visiting a national park or a museum. Surveys of consumer behavior ask about types of products purchased, when they were purchased, and in what quantity. Other surveys ask about life course questions, such as changes in residence, education level, and employment. Health surveys ask respondents to report on health care utilization, expenditures on health care, and courses of illness. Because all these questions rely heavily on the respondent's memory, much attention has been paid to the role of memory in survey responding and to recall or estimation strategies. The goal of this attention is to construct survey questions that help the respondent give accurate and complete reports.

One of the fundamental principles of memory is that accuracy of recall fades with the passage of time. Therefore, if respondents are asked to report on events that occurred a long time ago, it behooves the survey researcher to provide a structure to aid recall or run the risk of obtaining grossly inaccurate information. A number of structures have been developed around the idea of providing a time line. With a time line, respondents are given a physical representation of the recall period, month by month, and are asked to place salient markers such as their high school graduation, when they got married, birth dates of their children, or any relevant personal or public event that they can place accurately in time. Respondents are then asked to use these events as cues to prompt recall of events of interest to the researcher, such as periods of illness, changes in insurance status, changes in employment, and even personal events such as the number of sexual partners during a 5-year period. The literature is not clear as to whether it is better to begin with the present and work backward, begin with the most remote period and work forward, or let the respondent chose the direction.

Accurately placing events in time is difficult for respondents. Events that were salient or memorable seem to have occurred more recently and events that are more difficult to recall may seem to have happened longer ago than was actually the case. The difficulty of placing events in time poses a particular problem for longitudinal surveys. A phenomenon seen in panel surveys in which respondents are asked to report quarterly on changes in status in areas such as marital status, employment, earnings, and welfare payments is that, across the sample, the change in status is greater across the most recent month of the last reporting period and the furthest month of the current reporting period than across any two adjacent months. Since these two months represent the areas where the two waves of the panel survey join, the phenomenon is called the seam effect.

Imagine a situation in which respondents were interviewed in January, April, July, and October for a given year (i.e., once every quarter). During each interview, they were asked to report their total household income. Across respondents, the percentage reporting a change in income from month to month can be calculated within reporting periods (i.e., nonseam months such as January to February, February to March, April to May, and May to June) and across the seam months (in this case, March to April, June to July, and September to October). On average, the calculated change in income across the nonseam months might be 4 or 5%. However, the calculated income across the seam months may be as much as 9 or 10%.

Although the reasons for the seam effect are not well understood, a remedy called bounded recall has been developed. The bounded recall technique involves collecting information for the first reporting period and using the values about the last month of the first period as a bound for respondents. At the beginning of the second wave of interviews, and for all subsequent interviews, respondents are reminded of their answers from the prior interview and are asked to verify the answer. They are then asked to report on their current status. Information collected during the first wave serves only as a bound and is not used in analysis. This technique has proven effective in reducing reporting bias due to the seam effect.

The study of how respondents answer questions requiring event dating and behavioral frequency has led to insights about human cognitive functioning. One phenomenon noted long ago was that respondents tended to date events that happened outside of a recall period as happening within the period. This phenomenon, called telescoping, seemed to increase as the recall period extended. Therefore, respondents were more likely to engage in telescoping if asked to report on events that happened 1 year ago than if asked to report on those happening within the past 4 months. Early attempts to explain this phenomenon used the notion of forgetting curves derived from psychology.

Table I Example of Telescoping Due to Use of Prototypical Values in Estimating Elapsed Time

Event occurred (days)	*Event reported*	*Midpoint col. 1*	*Event occurred (days)*	*Net bias*
	7		8	−1
9–10	10	(8.5)	11–12	−1
13–14	14	(12)	15–17	−2
18–21	21	(17.5)	22–25	−1
26–30	30	(25.5)	31–44	−10
45–60	60	(45)	61–74	1
75–90	90	(75)	91–104	1
105–180	180	(135)	181–364	−109

Another explanation is provided by a fascinating study of reporting bias by Huttenlocher *et al.*, who explain the phenomenon in part by the way we structure time. Table I provides an illustration about how this affects reporting and can account for telescoping. The first and third columns represent the number of days ago an event occurred. The second column indicates when the event is likely to be reported to have occurred. Note that the entries in the second column are prototypical reporting periods: 1 week, 10 days, 2 weeks, 3 weeks, 1 month, 2 months, and 3 months. When making estimates, we tend to use these prototypical values. The numbers in parentheses in the second column are the midpoints between two adjacent reporting dates. The fourth column shows the net bias—that is, the difference between when the event occurred and when it was reported to have occurred. The negative numbers indicate that because we tend to round to prototypical values, events are reported, on average, sooner than they occurred.

To understand how this works, assume that events that occurred between 1 and 7 days ago are reported accurately, but that events that occur more than 1 week ago tend to be rounded to one of the prototypical values. Values in the first column in Table I will be reported at the prototypical value to the right because they are at or greater than the midpoint between that prototypical value and the preceding one. Values in the third column will be reported as prototypical values to the left because they are between that prototypical value and the midpoint for that prototypical value and the following one. Therefore, if an event occurred 8 days ago it is likely to be reported as occurring 1 week ago. Assuming events that occurred between 1 and 7 days ago are reported accurately, the result is a net bias of −1 days for reporting of events occurring between 1 and 8 days ago. An event that occurred 9 or 10 days ago is likely to be reported as occurring 10 days ago (because 10 is another prototypical number in our culture), producing a positive bias that will be no greater than 10−9 or 1 day. However, events occurring 11 and 12 days ago are also reported as occurring 10 days ago, giving a negative bias of no less than 10−12 or −2 days. So far, events occurring between 1 and 12 days ago have a cumulative negative bias of −3 days. If one does the exercise through all the categories in the chart, it is easy to see how telescoping can be explained at least in part by the use of prototypical values when respondents do not remember exact dates.

Survey respondents are asked to report on a wide variety of events, purchases, and behaviors. Since it is highly unlikely that we carry around counts of all these events in our heads, our responses are often based on the use of estimation strategies. A number of estimation strategies have been identified. On a survey of dental behavior, respondents who do not use dental floss regularly may make a wild guess when they are asked to report on the number of times they have flossed in the past month. Respondents who floss with some regularity still may not know exactly how many times they have flossed in the past month, but they may calculate a rate and then extrapolate across the reporting period. For example, a respondent asked to report on the number of fruits and vegetables consumed during a 2-week period might approach the task by reasoning that he or she usually eats five servings a day. Multiplying that by 14 days, the estimated total number of servings might be reported as 70. Another type of estimation strategy begins with a rate and multiplication, as in the previous case, but then employs addition or subtraction for exceptions. Using this strategy, the respondent may begin with an estimate of 70 but realize that she was out of town one weekend visiting friends and did not eat her usual 5 servings on those days. The respondent would make an allowance by subtracting the number of servings (or an estimate of the number of servings) less than 5 that she had on the days that she was out of town. The researcher, knowing that this is an estimated rather than an actual number, can take this into account when judging the quality of the data. In addition, if it is likely that most respondents will estimate their answers, survey instructions can be included to help them estimate more realistically. For the example, asking the respondent to consider whether eating habits on the weekend are the same as during the week might help the respondent adjust the answer to one that more closely matches the true value.

Modes of Data Collection

Social surveys are conducted face to face, by telephone, or by use of a self-administered questionnaire. Many surveys today use multiple modes in order to obtain high response rates and honest reporting of sensitive topics. The social survey began as a face-to-face interview conducted in a respondent's home, and this modality still plays an important role in contemporary survey research. There are many advantages to this modality. Typically, higher response rates are possible with face-to-face interviews. In addition, it is possible for the interviewer to pick up on nonverbal cues from the respondent indicating confusion about the question. Face-to-face interviews allow the interviewer to use visual aids, such as show cards with response categories, time lines (also called event-history calendars) to aid recall, and pictures or other props necessary to enhance respondent understanding. The interviewer is better able to control the pace of the interview and may be able to help the respondent to minimize distractions.

Nonetheless, face-to-face interviews are expensive. When telephone coverage became nearly universal in the United States, telephone surveys became increasingly more popular. They have proliferated at an astounding rate but, although providing great opportunities for researchers, have opened the door to abuse by sales promotions or political campaign solicitations that pretend to be surveys. In general, this has made the public somewhat distrustful of telephone surveys. Telephone survey response rates have been declining slowly but steadily during the past two decades.

Still, telephone surveys can offer an inexpensive alternative to a face-to-face interview survey and can provide useful data when conducted carefully. To increase response rates, many attempts must be made to call sampled households during different times of the day and days of the week. When possible, letters explaining the importance of the survey should be sent to the household in advance of the interview. In questionnaire construction, attention must be paid to the fact that there is no visual contact between the interviewer and that the respondent must process all information sequentially. Certain survey tasks, such as rank-ordering long lists of items, cannot be accomplished readily in a telephone survey because of the limitations imposed by the inability to use visual displays.

Typically, telephone survey questionnaires should not be longer than 30 minutes, whereas face-to-face interviews as long as 3 hours have been conducted. Undercoverage is greater among population members with low incomes, and technologies such as answering machines, caller-ID, and call blocking have made it more difficult and expensive to obtain high response rates. Sometimes, the anonymity associated with a telephone survey in which the respondent is aware that his or her household was selected completely at random can lead to candor on topics that are not highly sensitive but might have a social desirability component leading to a biased response if asked in a face-to-face format. However, telephone survey respondents can more easily misrepresent characteristics of themselves because of the interviewer's inability to directly observe them or their surroundings. Nonetheless, telephone surveys, and short telephone polls, continue to represent a viable data collection methodology.

Self-administration has been employed in three ways in survey research and a fourth method of self-administration is rapidly gaining popularity. First, a substantial amount of survey research of individuals and institutions is conducted by mail, in which a targeted respondent or household is sent a self-administered questionnaire. There are established techniques for obtaining high response rates in mail surveys, and high-quality data can be collected inexpensively if one follows the procedures, but mail surveys have limitations. One limitation is that it is difficult to know whether the targeted respondent actually completed the survey. Another limitation is that it is easy for respondents to leave questions unanswered and they may, deliberately or inadvertently, skip entire pages or sections of the questionnaire. Carelessly conducted mail surveys can result in very low response rates (as can carelessly conducted telephone surveys), so it is important to have information about response rates when assessing the quality of information from mail surveys. However, great success has been obtained with mail surveys using attractive envelopes and carefully laid-out and short questionnaires and by using a carefully crafted introduction, endorsement, and appeal letters sent at carefully determined intervals.

Self-administered questionnaires have been used to good effect when surveys are administered in group settings. A number of national surveys of elementary and secondary school students have been conducted in this way. If the students are well supervised by trained interviewers, the method can yield high-quality data. The interviewer can check questionnaires to determine if students have omitted critical questions and can ask them to give an answer (even if that answer is a "refused" response). Self-administered questionnaires have also been used in surveys in the workplace. Social norms, incentives, and the promise of anonymity can result in high response rates and high-quality data, provided that the questionnaire is crafted properly.

Self-administered questionnaires are used in the collection of sensitive information, but this topic is discussed in the next section. The most recent innovation in self-administered surveys involves the Internet. Internet and Web-based surveys have proliferated during the past

few years. Using the Internet to collect survey data has exciting possibilities. Short, simple questionnaires in the text of electronic mail, or attached as a document, can be distributed quickly and cheaply to a sample or an entire population of a group with universal electronic mail coverage, such as the faculty on all of the campuses of a large state university or employees of a large multinational corporation. Follow-up reminders to nonrespondents can also be done quickly and cheaply. Responses still have to be coded and compiled, but the potential for quickly collecting information of high quality on important but nonsensitive topics is great.

Surveys conducted via the World Wide Web (WWW) also offer exciting possibilities. As with Internet surveys, coverage is important. Unbiased sample estimates from populations with near universal access to the WWW are possible if good lists of unique Internet addresses are available. Techniques can be used to make it likely that the targeted respondent is the one actually completing the survey and that the responses are confidential and secure. For both Internet and Web-based surveys, coverage is important. Conducting such surveys on a general population, where access to the Internet is not universal, is likely to lead to biased estimates. Web-based surveys offer all of the advantages of computer-assisted surveys. Skip patterns are easily built-in so that the questionnaire can accommodate some level of complexity. Respondents can be prevented from answering questions out of sequence and from skipping a question without providing at least a "don't know" or "refused" response. Visual stimuli, such as pictures and even film clips, can be utilized and the time it takes respondents to answer a question (known as response latency) can be surreptitiously collected along with the responses.

Sensitive Questions

Sometimes it is necessary to obtain information about sensitive topics in surveys. For example, one result of the AIDS epidemic of the 1980s is that today it is not uncommon for surveys to contain explicit questions about sexual behavior. Surveys on topics such as smoking, drinking, and consuming illegal drugs are also common. One can imagine a whole host of behaviors to ask of the general population or of subpopulations that would be sensitive because they are embarrassing to talk about (e.g., sexual practices or problems, health problems, and gambling behavior) or illegal (e.g., owning a handgun that is unregistered, cheating on income tax, and employing illegal immigrants), yet it may be important, for policy reasons, to have accurate estimates of the numbers of people who engage in the behavior.

Special survey procedures have been developed to reduce the underreporting of sensitive behaviors that may result from fear of embarrassment or fear of self-incrimination. One early procedure, which is still in use, is called the randomized response technique. This method was designed to obtain aggregate estimates of sensitive behaviors while maintaining respondent privacy by combining responses to questions about sensitive behaviors for which rates are not known with questions about events for which rates are known. This is illustrated in the following example. The respondent is shown a card with two questions. Question A is the sensitive question for which the population proportion is not known (e.g., "Have you watched a pornographic movie in the past month?"). Question B is a nonsensitive question for which the population proportion is known (e.g., "Does your birthday fall in the month of July?"). Next, the respondent is asked to select a bead from a box containing 50 beads while the interviewer looks away. Seventy-percent of the beads (35 beads) are red and 30% (15 beads) are blue. The respondent is told to give a truthful answer to Question A if a red bead is selected and a truthful answer to Question B if the blue bead is selected. Because the interviewer does not know the color of the bead, he or she does not know which question the interviewer answered truthfully.

Assuming respondents do as they are instructed, the proportion engaging in the sensitive behavior can be estimated using simple algebra. In this example, the estimate of the percentage admitting to having rented a pornographic movie in the past month is $100 \times [(P(\text{Yes}) - (30/12))/70]$. Say 20% of the sample gave a yes response across the two questions. If we assume that birthdays are distributed evenly across months, then we expect that the 1/12 (2.5%) of the 30% who received the birthday question were born in July. The percentage that said yes to the pornography question is estimated by first subtracting 2.5% from 20%, giving 17.5%. This percentage is divided by the percentage that received the pornography question (i.e., 70%), and the result is multiplied by 100. The final result is the estimate that 25% of the population from which the sample was drawn viewed a pornographic movie in the past month. It should be noted that this technique will work best with large samples of 1000 or more because it is only in large samples that the distribution of birthdays and beads across respondents will conform to the expected values. An elegant simplification of this method, with examples of how to use it to study the rate of illegal immigration, has been developed by the Government Accounting Office.

A drawback of this technique is its inability to link the sensitive information to individual respondent characteristics. Thus, although it has utility in providing aggregate estimates of sensitive behaviors, it is of limited use in modeling the sensitive behaviors. Other methods for eliciting truthful responses to sensitive behaviors that do increase the likelihood of reporting and also permit

modeling behavior at the individual level have been developed. A popular, and obvious, method is to introduce privacy into the interview through the use of a self-administrated questionnaire. For example, in a household survey in which an interviewer is reading questions to a respondent in the respondent's home, the survey may be designed so that the part of the survey with the sensitive questions is completed using a self-administered questionnaire. The respondent can then put the questionnaire in a sealed envelope and either return it to the interviewer or, in some cases, mail it. This gives the respondent both privacy in responding and, if the questionnaire is mailed, the assurance that the interviewer will not "peek" at the responses after the interview.

Currently, most large sample household surveys use a computerized questionnaire. In the case in which it is desirable to ask about sensitive topics, a computerized self-administered section of the interview can be utilized. Research has indicated that respondents are more likely to report sensitive behaviors on a self-administered questionnaire than directly to an interviewer, and they are even more likely to report sensitive behaviors when the self-administered questionnaire is computerized. With current technology, it is possible to add an audio component to the computerized self-administered questionnaire. The respondent sits at the keyboard, sees the questions on the screen, and also hears a recording of each question through a headset. The addition of the audio component appears to elicit the most sensitive behavior. Why this is so is not well understood.

Telephone surveys are common because they are less expensive to conduct than household surveys. Traditionally, the telephone survey has not been a good medium for asking sensitive questions in part because of the difficulty of allowing the respondent to answer questions privately. However, promising new technology may change this. Devices that allow respondents to key in their answer using the telephone touch pad (e.g. "Have you ever smoked a marijuana cigarette? Press 1 for yes and 2 for no") are being developed for surveys. These telephone data entry devices can input the response directly into the respondent data file without the interviewer, or someone who happens to be eavesdropping on a second line, knowing how the respondent answered. In addition, completely automated surveys, in which a recorded voice asks the question and the respondent enters a response on the telephone touch pad, are being explored.

Conversational Aspects of Surveys

Although survey practitioners have always acknowledged the human side of survey research—that it consists of two people engaged in a conversation of sorts—the traditional approach has been to standardize the context in which the conversation occurs to minimize the influence that interviewers have on the response. Interviewers were (and are still, for the most part) trained to read questions exactly as they are written; to avoid getting into extended dialogue with the respondent about the meaning of terms; and, to the extent that explanations are necessary, to rely on those presented by the researchers in advance of the interview. Recently, a flaw in this practice has been noted. Although the purpose of the standardization is to improve the data, the rigidity of the conversation may lead to misunderstanding. This is because in most human encounters, meaning is conveyed through discourse. As a consequence, some survey researchers are attempting to understand the survey question-and-answer process from the standpoint of natural language. At the theoretical level, a survey question is an interrogative statement that communicates a space of uncertainty from which responses can be drawn. If the uncertainty space conveyed by the question does not match a space for which a respondent has propositions, then no meaningful answer can be obtained. This might be the case when a question asks a respondent about issues for which the respondent has no knowledge, or when a question contains obscure terminology. This may also be the case when a question asks the respondent to engage in a virtually impossible recall task, such as listing every item the respondent bought from a store during the past week.

Questions also have presuppositions, which are descriptive statements that indicate what the question is about. For example, the question, "What time do you usually leave for work in the morning?" presupposes that the respondent has a job and that it is a daytime job. Presuppositions restrict the uncertainty space. In the preceding question, the uncertainty space has been restricted to information about daytime jobs. If a respondent does not have a job or does not have a daytime job, then the uncertainty space is so restricted for that respondent that he or she cannot answer the question.

Presuppositions have another feature. They can serve as cues to answers and can result in leading the respondent to answer in a certain way. For example, research in cognitive psychology has shown that people who viewed a videotape of a car accident and were asked how fast the cars were traveling when they "crashed" gave higher speed estimates than people who were asked how fast the cars were traveling when they "hit." The presupposition provided by the descriptor crash was that the cars were going fast. This same principle may underlie the finding that a question asking whether something should be "forbidden" is less likely to receive agreement than a question asking whether that same thing should be "not allowed." Although the phrases have the same meaning, the presupposition provided by the word forbidden

seems to indicate much more finality or strictness than that provided by the phrase not allowed.

The attention to natural language in surveys is leading to methods that show promise in eliciting accurate responses to questions involving long-term recall of events. Sometimes it is useful to have information about the history of different events in a respondent's life. For example, a researcher may want to know about all of the places a person has lived during his or her life, how many times he or she has changed jobs and when the changes were made, the types of insurance coverage people have had, the number and type of cars that they have owned, their incomes in different phases of life, or whether their children received all the necessary medical examinations and inoculations prior to starting school. Traditional methods focus separately on each type of event and ask the respondent to start from a point in the past and report forward in time or to start at the present and report backward in time. New methods are being developed that take into account the idea that people may store events not as discrete entities in memories but as parts of narrative chains. Encouraging respondents to engage in these narratives when they are answering questions about their past, for example, allowing them to pick any time point within the range and to begin to tell a story about their circumstances at that time, has been shown to improve recall for target events.

Conclusion

This article is intended to provide an overview of social surveys with an emphasis on instructing the reader in basic concepts, discussing new thinking on questionnaire design, and illustrating how different sampling and questionnaire design issues affect the quality of the data. These and other important topics are covered in more detail in the books and articles listed in Further Reading. The interested reader should consult these and, to keep up with new developments, read journals such as *Public Opinion Quarterly* and *Survey Methodology*, as well as journals in the area of market research.

Survey research in the United States began in earnest in the mid-1930s. Since that time, survey researchers have taken advantage of new methodologies as they emerged to improve upon the information they gather. Early surveys were conducted using quota techniques until advances in sampling theory demonstrated how more accurate results could be obtained through the scientific sampling of survey respondents. For a long time, in-person household surveys were the norm, and they still play an important role in the collection of high-quality survey data. However, as telephones became more common in households throughout the United States, telephone survey methods were developed. Using telephone survey methodology, useful information could be obtained at far lower costs than in-person household surveys. Similarly, the mail survey technique has been highly developed, and it provides a cost-effective method for obtaining useful survey data. Household, telephone, and mail surveys each have their uses, strengths, and limitations. Survey researchers were also quick to take advantage of the development of personal computers, and personal data assistants offer more possibilities, as do portable scanning devices and touch-tone data entry from telephones.

The development of the WWW has also presented opportunities for survey researchers. Web-based surveys are becoming more common, and creative survey researchers are finding ways to use the Web to good advantage while overcoming the challenges Web surveys impose. This is the latest frontier of survey research, and it shows much promise. Based on past experience, it is likely that Web-based surveys will not completely replace the other survey modalities but will add an option to the survey researcher's tool chest that is appropriate in certain situations but not in others. Together, these methodologies give social scientists flexible, powerful, and efficient methods to study important social issues.

Glossary

compliance costs The costs incurred by individual firms or taxpayers in administering their tax affairs.
tax avoidance Tax legally avoided by taxpayers via the exploitation of loopholes in the law.
tax effort A measure of the effort a country makes in levying taxes, generally measured as a ratio (for example, of gross domestic product).
tax evasion Tax illegally evaded by taxpayers.
tax handles The means that facilitate the ability of governments to raise tax revenue.

Initially, perhaps, it would appear that taxation is one concept with which there should be few measurement problems. Tax rates and threshold points are clearly defined in virtually all, if not all, countries; using existing tax regulations, it is relatively easy to determine what a person with a given income and set of socioeconomic characteristics should pay in taxes. The relevant characteristics vary from country to country, but tax codes commonly relate to marital status and number of children or other dependents in the family and to what extent money is earned by work, is a transfer payment from government, and is accumulated from savings or investment in the stock market. However, even at this basic level, there are problems: direct taxation—the taxation of individual incomes—is only a part, and possibly a declining part, of total taxation. Alternative forms of taxation include indirect taxation (taxation on expenditures), taxation on firms, taxation on imports, and even taxation on exports. In addition, taxes can be levied, within the context of the United States, at the local, state, and national levels; within Europe, there is the possibility that taxes may at some point in the future be levied at the supranational level. In reality, the problem is much more complex than may appear at first sight. Among the many complexities, the focus here is primarily on three issues: (1) measuring the tax effort and other comparative measures of tax performance, (2) estimating the compliance costs of taxation, and (3) estimating the extent of tax evasion. In addition, a brief analysis is offered of some of the wider literature that focuses more on measuring, or estimating, the impact of taxation.

Tax Performance

In practice three concepts, tax ratio, tax effort, and taxable capacity, have been used to measure tax performance; sometimes these concepts are used interchangeably. The tax ratio is simply the ratio of tax revenue to some tax base, often gross national product (GNP) or gross domestic product (GDP). The tax effort appears to be widely used in policy circles. For example, two, of many, recent documents from the International Monetary Fund (IMF) have tax effort as a central feature of their dialogue with individual countries, including Pakistan and Paraguay. These documents mention the need to increase tax effort by strengthening tax collection and other measures, and on occasion provide specific targets for total tax revenue as a percentage of GDP.

It may be argued that tax ratios are rather simplistic as a measure of tax capacity, because capacity is also affected by, among other factors, the size of the population, the

availability of "tax handles," and the degree of monetarization. Taxable capacity is a concept that has been interpreted in a number of different ways; some define it as the amount of tax that could be justly or fairly imposed on an individual, or as the ability of people to pay tax and the ability of governments to collect. Others define it as the amount of revenue a country could have raised if it had applied the average effective rates (AERs) to its bases (i.e., if it had made an "average" effort).

Individual Tax Ratios

Tax ratios have not been limited to simplistic definitions; rather, their development has related to specific taxes. These more complex relationships still suffer from problems associated with taxable capacity, but allow a finer analysis of where tax effort is being made and also a comparison of trends over time and differences between countries. The starting point for analysis lies with the difficulties associated with measuring marginal effective tax rates; these problems have led a number of researchers to suggest relating actual tax revenues to certain macroeconomic aggregates. The resulting tax ratios are collectively known as "average effective tax ratios" (AETRs), or implicit tax ratios. This concept was operationalized in the 1990s in an approach subsequently updated by Carey and Tchilinguirian. In taking this approach, a number of assumptions need to be made. With respect to the AETR for capital (Ω_k), the following formula is used:

$$\Omega_k = \frac{\{\Omega_h \cdot (Y_{UB} + R) + T_Y + T_P + T_{FT}\}}{S_O}, \qquad (1)$$

where Y_{UB} is unincorporated business net income; R is interest dividends and investment receipts; T_Y is taxes on income, profit, and capital gains of businesses; T_P is recurrent taxes in immovable property; T_{FT} is taxes on financial and capital transactions, and S_O is operating surplus. The AETR on household income, Ω_h, is

$$\Omega_h = \frac{T_Y}{Y_{UB} + R + W}. \qquad (2)$$

In Eq. (1), $\Omega_h \cdot (Y_{UB}+R)$ represents estimated taxes paid by households on unearned income linked to business activity. In this estimation, it is assumed that the same rate of tax applies to earned and unearned income, an assumption clearly violated in many countries. The need to make such assumptions makes such measurements less than perfect. The other terms in the numerator, $T_Y+T_P+T_{FT}$, then represent the remaining business taxes. The changed assumptions made by Carey and Tchilinguirian vary from tax to tax and indeed from country to country. Thus with respect to Eq. (2) they take account additional taxes, such as wealth taxes and estate, inheritance and gift taxes which the original approach had ignored.

The results of doing these calculations for various taxes are shown in Table I. The figures are informative for several reasons. First, they illustrate the importance of assumptions. It can be seen, for example, that the revised calculations are substantially different from those using the original methodology, particularly with respect to capital taxation, whereby the estimates are substantially higher than previously. The importance of choice of methodology is also apparent with respect to the choice of base. When, for example, gross operating surplus is used, much smaller figures are derived compared to using net figures. This in itself is not surprising, but the impression created, of exceptionally high taxation, disappears when gross figures are used (for example, with respect to Japan when using net figures with the revised methodology). But the figures are also informative in terms of what they tell us about (1) taxation and trends in taxation and (2) the extent to which they confirm the predictions of economic theory. Thus, it can be seen that the United States and Japan have substantially lower AETRs on labor, compared to the European Union (EU) countries, but that within the EU, the United Kingdom is more closely aligned with non-EU countries. Using these figures, economists and commentators have argued that the majority of the EU countries are less competitive with respect to labor and labor costs compared to their competitors in international markets, and this may help to explain job losses in the EU at the end of the 1990s. It also apparent that there is a considerably greater degree of harmonization, as reflected by smaller standard errors, of tax rates within the EU than within the Organization for Economic Cooperation and Development (OECD) as a whole. This is what would be expected, because the close economic union of these countries is forcing harmonization via both legislation and the mobility of the factors of production and consumption. This is less obvious for labor than for consumption and capital, but if the United Kingdom (which, as already noted, is something of an outlier in the EU) is excluded, then it is also true for labor.

The Behavioral Approach

Perhaps the most satisfactory way of measuring tax effort is what is known as "the behavioral approach," where the tax ratio (T/Y) is regressed on a vector of variables ($\mathbf{X}$) that serve as proxies for a country's tax handles:

$$T/Y = f(\mathbf{X}) + e, \qquad (3)$$

where e is a stochastic error term and $f(\mathbf{X})$ then forms the predicted tax ratio against which the actual tax ratio is compared, so that a tax effort index is computed as the ratio of the actual to predicted tax ratio. Variables that have been included within $\mathbf{X}$ include income per capita,

openness of the economy to trade (as measured, for example, by the ratio of imports or exports to GDP), a measure of industrialization (such as the share of agricultural income in GDP), and population density. The latter affects the efficiency of the tax collection system. Differences in the level of tax revenue have also been linked to the impact of government legitimacy, efficiency, and credibility on taxpayers' compliance. Such political and cultural factors clearly affect the taxable capacity of a country. But is it reasonable to link this with tax effort? To an extent, this is a semantic discussion, but, clearly, if a democracy has greater legitimacy than a dictatorship, and because of this tax compliance is greater, then in a real sense tax effort is greater in the democracy.

This approach has recently been extended to include, as well as the usual variables included in **X**, a measure of tax evasion. This is found by a variation on the cash balances method (see later). The impact of tax evasion on the ratio of tax to GDP is ambiguous in that theoretically, tax evasion can reduce both the numerator (tax revenue) and the denominator (GDP) in Eq. (3). Normally, the former would be expected to decline more than the latter, because parts of GDP are effectively free of, or pay little, tax (low earners). However, if the government is able to compensate for the tax shortfall by higher tax rates and more extensive taxes, then GDP will fall by more than tax revenue and tax evasion will have a positive impact on tax ratios. For individual taxes, the effect will depend on whether that tax is sensitive to evasion (see Table II). All of these approaches are static approaches that measure tax potential at a given point in time. It is also important in determining tax effort to look at changes over time. For example, a country with a low tax effort may nonetheless have been making considerable efforts in recent years to increase taxes, and hence the poor performance is a measure of the impact of past policies rather than current ones. This leads some scholars to argue for comparing the income elasticity of taxes. This can be estimated by regressing the log of tax revenue (T) on a constant and the log of income for a country over time:

$$\ln(T_t) = \alpha + \beta \ln(Y_t) + e. \quad (4)$$

The coefficient β gives the estimate of the income elasticity, i.e., the percentage change in tax revenue divided by the percentage change in income.

[a] Original calculations by J. M. Teera.

Measuring Compliance Costs of Taxation

Compliance costs may be defined as those costs that are associated with complying with the requirements of a tax system, over and above any distortion costs inherent in the tax. They do not include the administrative costs of taxation, which are borne by the tax authorities. The quantitative information on compliance costs is largely derived from responses to large-scale questionnaires, i.e., by directly asking taxpayers what are the costs they incur in paying such taxes. This important concept is linked to Adam Smith's fourth "canon of taxation." Government departments are increasingly concerned with minimizing compliance costs, but corrective policy requires an understanding of the causes of such costs, and this can be obtained only from regression analysis. One such study, with respect to the British income tax system, whereby firms deduct tax from employees at source and then transfer this money to the government, found significant economies of scale that put small firms at a considerable disadvantage to larger firms. Further unpublished work on this database for the Inland Revenue, the government department in the United Kingdom that is responsible for collecting income tax (the counterpart to which is the Internal Revenue Service in the United States), suggests that approximately 40% of compliance costs is due to inefficiencies. This is not surprising; especially for small firms, their expertise lies, e.g., in metal manufacture, not in being tax collectors. The chief problem in this area is collecting the data. In the study of the British income tax system, the data were obtained by a large-scale postal questionnaire using a stratified random sample of 5195 employers' payrolls. Stratification was based on the number of taxpayer records in each band. Respondents were chosen so as to ensure roughly equal sizes across bands. To ensure that the questionnaire was received by the appropriate person, initial telephone contact was made with all 5195 employers. The final response rate was 30.2%. Estimates of compliance costs were based on a "bottom up" approach, whereby respondents were asked detailed information on time taken and the

estimated hourly wage of the person engaged on this task. This information was then added to associated costs relating to computer hardware/software, tax advisors' fees, payroll bureau charges, and miscellaneous costs such as telephone, stationary, heating, etc. The data suggest that compliance costs amount to 1.3% of revenue raised. Similar figures for other taxes have been found in other studies.

Compliance costs are rarely less than 2%, and in the case of some taxes in The Netherlands and Australia, they are well above 10%. These costs are not insignificant and in some cases are relatively high, probably indicating an inefficient tax. In addition, such costs can have a significant impact on businesses and individuals. Estimates in one study put the compliance costs associated with corporation income taxes in the United States at over $2 billion. Such data have frequently led governments to seek ways to reduce compliance costs, as has specifically happened in the United Kingdom.

Measuring Tax Evasion

Tax evasion represents a potentially serious loss of revenue to governments, resulting in the possible underfunding of public service and an "unfair" burden falling on honest taxpayers. In the United States, it has been estimated that over 25% of all taxpayers underpaid their taxes by $1500 or more in 1988. In developed countries, tax evasion is frequently estimated to be at about the 20% level of tax revenue. The estimated loss in revenue in the United States in 1992 through underpaid federal income taxes was $95.3 billion. In developing countries, the problem may be worse; the loss in the Philippines, for example, has been estimated to be as much as 50% of income tax revenues.

Empirical work has also focused on the link between tax evasion and socioeconomic characteristics. There would appear to be considerable evidence that evasion declines with taxpayer age, and is more common among men and in households in which the head of the household is married. Measurement of the size of socioeconomic effects and the deterrent effects of audit probability, fines, or penalties necessitates the use of multiple regression analysis. The evidence that is available suggests that both penalties and audit probabilities have significant deterrent impacts on evasion, although the extent of the impact is not clear. In addition, it seems possible that the probability of detection is more important than the fine in deterrence.

Much of the empirical work on tax evasion is centered on the United States and is based on audit data or tax amnesty data. Both types of data suffer from an element of bias, the former because auditors are generally unable to detect all evasion, the latter because only those evaders who respond to the amnesty will be included in the data set. Survey data can be used to circumvent this problem, although self-reporting of actual evasion imports bias, even with confidential surveys. An alternative approach is to use survey responses to hypothetical questions. One group of researchers looked at a question related to hypothetical situations involving collusion with a builder; the builder would offer the individual a lower price to do a job if the individual would pay in cash, hence obviating the need for the builder to declare the income to the tax authorities. A further question relating to the evasion of income tax was also asked. In both cases, in excess of 50% of the population indicated that they would indeed engage in such behavior, a tendency that was greater for the young than for the old. This use of hypothetical questions to analyze real-world problems may have potential value in other areas.

Measuring the Extent of Tax Evasion

There are inherent and obvious difficulties in measuring the extent of tax evasion. Surveys are clearly inappropriate and hence recourse has to be made to indirect methods. Tax evasion is synonymous with the hidden or shadow economy that relates to unrecorded economic activity, generally for reasons of avoiding tax. The first attempt at estimating unrecorded national income was done by Nicholas Kaldor in 1956. Over the years, the methodology has steadily become more sophisticated. A methodology employed in the 1990s assumes that an economic activity M (frequently narrow measures of the money supply) is required in all k sectors/regions or industries of an economy; the level of activity M is determined by the income and other variables (Z_{jt}) related to the k sectors. The assumption is then made that

$$M_{jt} = f_j(Y_{jt}, Y_{\mathrm{H}jt}, \mathbf{Z}_{jt}). \tag{5}$$

In general, the jth sectoral/regional observations on M are unavailable and hence an estimate is made using multiple regression techniques:

$$M_t = \sum_{j=1}^{k} f_j(Y_{jt}, Y_{\mathrm{H}jt}, \mathbf{Z}_{jt}), \tag{6}$$

where Y_{jt} is legitimate (measured) income and $Y_{\mathrm{H}jt}$, hidden income. Of course, $Y_{\mathrm{H}jt}$ is unobservable and various proxies are used. These proxies, together with their estimated coefficients, allow construction of estimates of the size of the hidden economy. This approach does have its weaknesses (for example, in frequently ignoring the possibility that money demand, or whatever proxy is used, may be changing for reasons unrelated to the size of the hidden economy.

A variation on this theme is to estimate the size of the hidden economy on the assumption that the difference between the growth rates of measured GDP and electricity

Table III Estimates of Size of Shadow Economy as Percentage of Gross Domestic Product[a]

	Percentage	
Country	*1994–1995*	*1996–1997*
Australia	13.8	13.9
Canada	14.8	14.9
Germany	13.5	14.8
Italy	26.0	27.2
Sweden	18.6	19.5
Switzerland	6.7	7.8
United States	9.2	8.8

[a] Data from Schneider and Enste (2000); estimates derived using the currency demand approach.

consumption can be attributed to the growth in the shadow economy. All such approaches are based on simplifying assumptions; the electricity based approach, for example, is subject to the criticisms that (1) not all shadow economy activities require a considerable amount of electricity and other energy sources can be used and (2) that shadow economy activities do not take place solely in the household sector. An alternative approach pioneered in the 1980s used the multiple indicators, multiple causes (MIMIC) methodology. Essentially, this treats the size of the underground economy as an unobservable "latent variable." The latter is linked on one hand to a set of observed "causal variables," which are believed to be key determinants of the hidden economy. MIMIC methodology can use the following determinants of the hidden economy: direct tax share, indirect tax share, share of social security contributions, increase in direct tax share, share of public officials, tax immorality, rate of unemployment, and per capita disposable income. The "indicator variables," all of which are assumed to be partly constituted by the latent variable (the hidden economy), may be the male participation rate, hours worked, and the growth of real GDP. Of course, the effectiveness of this approach is determined by the appropriateness of the indicator and determinant variables.

Table III shows that the shadow economy in most countries is estimated to be of the order of 15%, but it is much higher for Italy and much lower for Switzerland. Again, these results are typical, as are the much higher figures that are obtained for developing or transition economies. Clearly, in this case, the data point to a considerable problem facing governments seeking to raise revenue to finance public expenditure.

Measuring the Impact and Incidence of Taxation

There is a considerable volume of literature that seeks to estimate the impact of taxation on individual behavior. There is a specific focus on the effects of taxes on labor supply with respect to individuals and the impact of tax on organizational form, investment decisions, merger and acquisition and dividend polices, accounting choices, and compensation decisions with respect to firms. Much of the literature spotlights the distortionary impacts of taxes that are viewed as undesirable. However, there is also a significant literature on the use of taxes to steer individual decision making in a beneficial fashion. Carbon taxes and taxes on tobacco and alcohol are common examples. An applied general equilibrium model was used to look at the impact of the carbon tax introduced in Norway in 1991. The conclusion was that, despite considerable tax increases, the impact was modest, amounting to just a 2% reduction. The majority of the empirical literature looking at the impact of taxes on behavior is based on simple linear reduced form regressions and it is questionable to what extent they can capture the relevant and complex linkages. However, an alternative that has also been used to analyze individual responses to taxes is to make use of an applied general equilibrium model. These models effectively mimic an economy in equilibrium. Individuals and firms are divided according to differing characteristics. For example, a model of the Dutch economy has focused on wage formation, labor supply and demand, and the process of job matching between vacancies and the unemployed. By including elements of wage bargaining and costly job matching, the model describes equilibrium unemployment in terms of the structure of the tax and social security system. The conclusion is that a more progressive tax system, by narrowing the gap between high- and low-paid workers, reduces labor supply. The bulk of this literature, as does implicitly that on AETRs discussed earlier, tends to assume that the agent on whom the tax falls effectively pays the tax. There is, however, a literature on tax incidence, which explores who effectively pays the tax. For example, when a tax is levied on a specific product, e.g., cigarettes, to what extent can the firm pass this price increase on to the consumer and hence to what extent does the firm pay the tax and to what extent does the consumer pay? The analysis also extends to analyzing the impact of hypothetical tax changes. For example, one study analyzed the incidence of a basic income/flat tax proposal using a simple theoretical general equilibrium model.

Conclusion

Different aspects of measurement problems may be assessed with respect to taxation. The solutions vary from the making of simplifying assumptions with available but incomplete data, to the painstaking collection of new data, to the use of sophisticated econometric techniques to estimate unobservable variables from observable behavior. Regression analysis and applied general

equilibrium analysis are also important in measuring individuals' responses to a change in the policy environment. With respect to overall tax effort, the problem is one of deciding on whether the simple tax ratio is a satisfactory measure of tax effort, and if not, then transforming it in such a way that it becomes more satisfactory. With respect to individual tax rates, the problem lies with the fact that the available data do not sufficiently match the theoretical counterparts. In such cases, simplifying assumptions need to be taken to allow us to derive suitable measures. With respect to compliance costs, the data can be collected only by painstaking sample surveys and then, of course, may quickly become dated. Finally, with respect to tax evasion, there is a need to deduce the level of tax evasion from behavior in legitimate areas of activity and by asking hypothetical questions.

Data can be used to validate the predictions of economic theory, to highlight economic problems, and to inform policymakers as they attempt to deal with these problems. Thus, there has been an increasing degree of harmonization with the EU, a harmonization with which the United Kingdom is slightly out of step. The measurement of compliance costs has led to an increasing awareness by governments of this problem and the introduction of measures to deal with it. Finally, the work on tax evasion has highlighted a considerable problem for governments and has provided the data allowing empirical analysis to suggest the effectiveness of possible solutions, such as higher penalties. However, in all these cases, assumptions are required, and hence there is the probability that the measures will in some way be biased as estimates of the real state of affairs. This then raises the question as to whether such data are still useful. The probable answer, depending on the error variance, is yes; some data are better than none as a background for making decisions, provided the potential inaccuracies are borne in mind by the decision maker, other commentators, and users of the data.

Telephone Surveys

Don A. Dillman
Washington State University, Pullman, Washington, USA

Glossary

aural communication Transmission of information through the sense of hearing.
coverage error Survey error that results from all members or units of a population not having a known, nonzero, chance of being sampled for data collection.
measurement error Inaccuracies in answers to survey questions that result from poor question wording, inadequate interviewing, and/or the respondent behavior.
nonresponse error Survey error that results from respondents to a survey being different than nonrespondents on characteristics relevant to the survey objectives.
random digit dialing A way of generating samples of households that depends on calling randomly selected telephone numbers.
sampling error Survey error that results from only a subset of the entire population or sample frame being selected for participation in the survey.

Telephone surveys are a means of collecting information from individuals, households, or other units of interest whereby potential respondents answer questions asked by an interviewer over the telephone. Perhaps its most common application occurs through the calling of randomly selected samples of households with telephones where the interest of the sponsor is in being able to determine through careful statistical inference from a relatively small number (hundreds or a few thousand) of interviews the occurrence of opinions or attributes in a large, carefully defined population from which the sample was drawn. For example, during election campaigns many organizations call national samples of households to interview likely voters for purposes of identifying voter preferences in order to predict who will win an upcoming election. Thousands of such telephone surveys, or polls as they are typically described, occur prior to major elections in the United States to ascertain voter opinions on candidates for national, state, and local races. Telephone surveys are also used regularly for marketing research. In addition, important national government-sponsored surveys on such topics as employment rates, health status, and educational behavior are done for use in formulating public policy.

Introduction

Origins

Prior to the 1970s, most important surveys were conducted by face-to-face interviews. However, as summarized by Nathan, the conduct of occasional surveys by telephone was reported in the literature prior to that time by marketing researchers, agricultural economists, and health researchers.

In the early 1970s, many organizations began testing use of the telephone for sample survey data collection. In rapid succession, three books were published that described the promise of telephone surveying for conducting a wide array of such surveys. The first of these, by Blankenship, described the use of telephone survey methods for doing marketing research. The second book, by Dillman, provided step-by-step instructions for designing and conducting telephone surveys. The third, by Groves and Kahn, reported a detailed comparison of the telephone and face-to-face interviews for conducting national surveys. Together, they showed that valid information could be collected over the telephone.

In the next few years an enormous amount of research was undertaken as researchers in many countries sought to understand the multiple issues—from sampling to

overcoming refusals—involved in conducting quality surveys by telephone. In 1988, the first comprehensive book on telephone survey methodology was published, the result of a national conference devoted solely to this mode of data collection. In only a decade, the telephone survey had moved from being an idea with promise to becoming the likely replacement for most face-to-face surveys.

Medium-sized survey organizations in the United States that had relied on face-to-face surveys rapidly shifted to use of the telephone, thus enhancing their ability to do larger surveys of more geographically dispersed populations. Small locality-oriented organizations that had relied mostly on mail survey methods also gained the ability to conduct regional and national surveys of much greater significance.

Reasons for the Growth of Telephone Surveying

Random Digit Dialing and Related Developments

The rapid expansion of telephone surveying in the 1970s and 1980s was the result of numerous developments that helped reduce survey errors and improve efficiency. For example, the evolution of telephone numbers to a standard 10-digit structure (area code plus 3-digit exchange plus final 4 digits) allowed the development of random sampling methods so that all telephone numbers could be assigned a known chance of being selected in samples. In addition, the fact that approximately 90–95% of households in the United States and other developed countries had telephones meant that most households had a chance of being selected for inclusion in survey samples.

The use of random digit dialing on a national basis was greatly facilitated when American Telephone and Telegraph files that showed all area code/prefix combinations became available to survey organizations. These developments, combined with the marketing innovation of WATTS (Wide Area Telephone Transmission Service) (i.e., long-distance calling service to interested customers at wholesale rates), provided the key ingredients that encouraged the creation of centralized telephone survey laboratories.

Minimal Measurement Differences

Research also revealed only minor differences between the results of telephone and face-to-face interview surveys. Thus, the fear that unseen interviewers asking questions of respondents over the telephone would adversely affect measurement began to dissipate. Also, the fact that response rates were relatively high, often approximately the same as those that could be obtained using face-to-face interviews, but without costly callback efforts reduced concern about nonresponse as a source of error.

Cost and Timeliness Concerns

Increased use of the telephone for surveying was also fueled by cost concerns. Face-to-face interview costs had risen rapidly as the number of callbacks required to obtain high response rates increased significantly. These higher costs resulted in part from the fact that in more households both adult males and females were employed. A related problem was the greater difficulty in hiring interviewers as more women, the typical interviewers, moved from part-time interview work to full-time employment.

Telephone interviewers could make repeated callbacks in much less time and without travel costs. The development of centralized telephone laboratories, with close supervision, allowed interviewers to become productive with less training investment and widened the pool for interviewer selection because the willingness to drive long distances was not a requirement. A corresponding decline in long-distance rates provided increasing cost advantages to surveying by telephone.

Surveys could also be done far more quickly by telephone than in person. The combination of time and cost savings made use of the telephone especially attractive to market researchers and pollsters who often needed quick assessments of people's behaviors and attitudes.

Methodological Dominance

By the early 1990s, telephone surveying had become the dominant survey methodology for marketing researchers and pollsters. Even surveys that could not tolerate omission of households without telephone numbers (e.g., the Current Population Survey, which establishes the United States unemployment rate each month) had come to rely on telephones for reinterviews of respondents in those households that had telephones.

How Telephone Sample Surveys Work

In order to conduct valid telephone surveys that allow one to generalize results from a few hundred or thousand completed interviews to an entire population of thousands (e.g., the student body of a university) or millions (e.g., households in a state or country), four sources of error—coverage, sampling, measurement, and nonresponse—described by Groves must be overcome. A well-done telephone survey must take into account all these sources of error when making efforts to generalize results to the total population from which the sample was drawn.

Coverage Error

This type of error is minimized by giving every survey unit in a population a known nonzero opportunity of being selected for the survey. For some survey populations (e.g., members of a professional organization or previous participants in a face-to-face survey), lists of everyone's telephone number may exist, so coverage is not a problem. However, for unlisted populations such as the general public, achieving acceptable coverage may be difficult.

Telephone directories are inadequate sample sources because many telephone subscribers, approximately 30–35% nationally, opt for their number not to be listed in directories. Random digit dialing, which in theory allows all telephone numbers to have a known chance of being selected, provided a means of overcoming this coverage problem. Because in some telephone exchanges many potential numbers (the last four digits) are not used, it was important that more efficient methods be developed for calling working numbers.

One procedure for allowing fewer nonworking numbers to be called was based on an unpublished memorandum by Mitofsky that was elaborated by Waksberg and became known as the Mitofsky–Waksberg method. Their procedure was based on the tendency for telephone companies to assign series of numbers for the last four digits rather than doing so randomly within each exchange. By generating the last two digits of telephone numbers randomly, and then attempting to call other combinations of numbers in this series of 100, only in the event that the first number contacted was a residential phone, an equal probability sample of all residential telephone households, could be obtained. Nathan has summarized numerous efforts to improve the efficiency of telephone sampling methods through the use of lists as well as efforts to improve coverage through combining telephone interviewing with the collection of a portion of the data by means of face-to-face interviews.

In household surveys in which the usual interest is making estimates for the adult population of a city or country, random respondent selection within each household is required so that the interviewees represent the entire U.S. adult population. Several procedures have been developed for accomplishing that objective, including a procedure proposed by Kish for face-to-face interviewing that requires listing all household members by age and gender and following a strict protocol for selecting the interviewee. A simplified method, developed by Trodahl and Carter in 1964, asked only the number of people of each gender living in a household. In 1983, Salmon and Nichols proposed selecting individuals on the basis of which adult has had the last (or next) birthday. Tests have shown that the results from the use of these methods are not always equivalent.

Sampling Error

A second source of survey error that must be reduced is sampling. It occurs because only some members of the entire population are selected for interviews. In general, reduction of sampling error is achieved by increasing the number of randomly selected population members who are surveyed. In simple random samples, approximately 100 completed interviews provide results with a precision of $\pm 10\%$, whereas samples of approximately 400 give a precision of $\pm 5\%$. Samples of approximately 1150 are capable of providing a precision of $\pm 3\%$. The latter is the approximate sample size often used for national election polls. The actual precision of results, from a sampling error perspective, depends on the desired degree of confidence in the sample estimates, how the sample was drawn, and related issues described by Lohr.

One of the achievements associated with telephone interviewing was to make possible simpler sample designs and, therefore, smaller samples to obtain the same levels of precision for the resulting sample estimates as those achievable in comparable national interviews done by face-to-face interviews. The latter method required multistage cluster sampling in which areas, segments, and smaller units within them were typically selected before several households were chosen to interview. This clustering was done to keep interviewing costs at acceptable levels. In national telephone surveys, there is generally little or no savings associated with interviewing respondents by telephone from households in the same neighborhood, as there is for in-person interviews.

Measurement Error

Measurement error may result from poorly worded questions that bias respondent answers, poor interviewing practices, and/or the withholding of accurate information by the person being interviewed. Such errors may occur when some interviewers do not read questions accurately or decide to read them out of order, with the result that different answers are given than would have otherwise been the case. Questions may be answered differently because of the order in which they are asked or even the order in which response categories are presented. In addition, sensitive or threatening questions may not be candidly answered.

Use of the telephone also introduced new perspectives in measurement. The complete dependence on aural communication introduced a trend towards question simplification. Because it was necessary for respondents to remember all aspects of a question (show cards were typically used as a visual aid in personal interviews), survey measurement evolved toward the use of fewer categories and fewer word labels (e.g., the use of polar-point

labeled scales, such as "where 1 means strongly agree and 5 means strongly disagree and you can also use any number in between").

In general, telephone interviews have been found to produce answers that are quite similar to those produced by face-to-face interviews. However, compared to self-administered surveys, telephone respondents are less likely to respond accurately to sensitive questions such as those about sexual or drinking behavior. This tendency to provide socially desirable answers (i.e., answers consistent with cultural norms) is only one of the ways in which telephone answers have been found to differ from responses to self-administered surveys. Others include a recency bias (i.e., choosing the last answers provided on a list) and a tendency to choose more extreme categories. These latter concerns may be a result of cognitive processing that stems from the complete dependence on aural communication and the way in which verbal information is retained and recalled by respondents.

Nonresponse Error

It is rare that all survey units sampled for inclusion in a survey are successfully interviewed. If those who do respond to the survey differ from those who do not respond in a way relevant to the survey (e.g., they have different opinions on a topic asked about in the survey), then nonresponse error is said to occur. Nonresponse error is therefore different than response rate (i.e., the percentage of sampled units that complete an interview). However, the mathematical potential that nonresponse error exists decreases as response rates increase.

Response rates to telephone surveys appear to have declined significantly during the 1980s and 1990s. Nathan described this phenomenon as partly the result of ambiguity associated with the increased technological use of household phones, such as fax machines, computers, and screening technologies (e.g., caller identification and answering machines) in people's homes. It also appears to result from frustration associated with receiving many unsolicited and unwanted marketing calls.

Many techniques have been used to improve response rates, including increasing the length of the calling period and the number of call attempts for each number, refusal conversion, token financial incentives sent with a prior letter informing the recipient of an impending call, and leaving messages on answering machines in anticipation of later call attempts.

Another response improvement strategy that has generated much interest in recent years is training interviewers to provide tailored responses to individuals' objections to being surveyed, a strategy detailed by Groves and Couper based on their analyses of personal interview data. In this strategy, when a respondent indicates that he or she does not have time, the interviewer would be expected to respond to this concern by indicating that was okay and he or she would call back at a more convenient time.

Although it is known that respondents to telephone surveys often differ significantly from nonrespondents, it is not clear whether special efforts to improve response rates will lower nonresponse error. A study by Keeter *et al*. did not show significant changes in respondent answers when they increased response rates from 36.0 to 60.6% through the combined use of advance letters and incentives for listed numbers, repeated callbacks, and refusal conversions over an extended time. This is a topic on which substantial research is now being done.

Technology and Its Consequences

Computer-Assisted Telephone Interviewing

Although early telephone interviews were conducted using regular paper questionnaires, this situation changed. Software was developed for mainframe computers that allowed questions to be displayed on computer screens. Early attempts to do this in the 1970s were plagued by limited question structure capabilities (e.g., not allowing answers to early questions to be incorporated into later questions), long lapses between the time an interviewer clicked an answer and the computer responded, and unpredictable computer downtime when no interviews could be conducted. However, this situation changed significantly during the 1980s as computer-assisted telephone interviewing (CATI) shifted from mainframe to dedicated minicomputers and later to networked personal computers. In addition, software was developed that automated important functions, such as creating random samples of numbers to be called, assigning new numbers as well as those to be called back to interview, and the rapid compilation of results. During this time of rapid development in information technologies, more of its advantages accrued to telephone interviewing than to any other form of survey data collection. A primary impact of these developments was that it became possible to conduct telephone surveys faster. Overnight surveying became popular on many topics so that in some cases less than a day elapsed between the time a survey was designed and the time the results were reported.

Questionnaire designers were able to take advantage of CATI developments to resolve potential measurement problems in surveys. For example, answer categories could be systematically rotated in order to eliminate potential effects of presentation order on respondent answers. It also became possible to automatically insert prior answers

into subsequent questions and branch respondents automatically to the next appropriate question.

Technological Developments That Inhibit the Conduct of Telephone Surveys

Technological developments have also influenced the conduct of telephone surveys in negative ways with respect to the potential for error. Today, most U.S. households have answering machines. Calls are monitored in some households and not answered until recipients of the calls know who is calling. In addition, caller-ID devices are used in many households with the result that calls from unknown numbers, or from those who choose to block display of their numbers, go unanswered. Call-blocking technology also makes it possible to prevent calls from ringing in from numbers that the owner chooses to avoid. In addition, technology allows telephone calls to be automatically forwarded to other numbers that may or may not be located in the same geographic or survey area. The effect of these technologies on nonresponse is to make it more difficult to reach some household telephones than in the past, but whether this results in dramatically lower response rates remains to be determined.

In addition, telephones in homes are connected to other household devices, such as computers, faxes, and security systems. Some telephones serve multiple purposes. This situation increases the likelihood of calling telephone numbers that are not answered by the household occupants and contributes to lower survey response rates.

However, the most profound technological change affecting telephone surveys is the increased use of cellular telephones and the tendency for individual household members to have their own phones. In some cases, households have eliminated traditional land-line phones and use cellular phones only, thus reducing the coverage of traditional phone numbers as a sample frame. There are formidable obstacles to including cellular telephone numbers in random digit sample frames. Some individuals pay by the minute for inbound calls and therefore pay for any calls made to them by others. Risks also exist with respect to calling individuals while in the midst of other activities such as driving a vehicle on a busy street.

Significant differences exist among countries with regard to ownership of cellular telephones and norms that govern their use. In some countries, cellular telephones are the dominant means of telephone communication, leading to substantial decreases in use of land-lines. In other countries, particularly those with poor land-line telephone infrastructures, cellular telephone technology has provided a means of offering telephone service where none previously existed. Cellular telephone numbers appear in directories in some countries but not in others. In addition, interrupting people in midactivity to conduct a survey does not seem to be a problem in some countries, but in others it is viewed as unacceptable. It remains to be seen how these concerns will be resolved.

Interactive Voice Response Surveys

A recent development in telephone surveying is the use of touchtone data entry, whereby respondents listen to prerecorded questions and instructions and use the touchtone numbers on telephones to enter their answers. In its more advanced form, interactive voice response, respondents can state their answers verbally. This technology is used for specialized surveys of employees and customers. It has also been used as a means of cutting costs for regular telephone surveys by having interviewers introduce the survey and then transfer respondents to the automated system.

The Future

It is striking that in a slightly more than 30 years, telephone surveys have moved from being viewed with skepticism as a potential survey methodology to becoming the dominant survey mode in the United States. Now, they are once again being viewed with skepticism.

The technological developments that made its extensive use as a survey methodology possible have been paralleled by other developments that threaten its use. However, it would be a mistake to think of these threats to coverage and response as only technological in nature. Advanced societies have undergone an enormous cultural change in how telephones are owned and used. When surveying began in earnest in the 1970s, telephones were limited to voice communication. Most households had only one telephone and answering machines did not exist, so a ringing telephone demanded to be answered. Telephones are now used for multiple functions in addition to voice conversations and have become a personally owned device with an automatic answering machine. In only three decades, the telephone has changed from controlling people to being controlled by them.

Nonetheless, it seems likely that the telephone will continue to be used for many surveys. Alternative survey methodologies (e.g., mail and the rapidly growing Internet) also suffer from significant coverage problems for household and many other types of surveys. It seems likely that future surveying will emphasize different modes—face-to-face, telephone, mail, or the Internet—for different situations. In addition, it seems likely that more surveys will use multiple modes in an effort to maintain response rates and overcome coverage problems associated with individual modes. Expecting an end to telephone surveying is as unthinkable as expecting

a continuation of telephone surveying only as it has been done in the past.

Terman, Lewis

Henry L. Minton
University of Windsor, Windsor, Ontario, Canada

Glossary

achievement Knowledge acquired through learning.
gender identity The extent to which a person chooses to internalize the cultural norms of the masculine or feminine gender.
intelligence The ability to learn or understand from experience.
intelligence quotient (IQ) A quantified measure of tested intelligence, calculated on the Binet scales by dividing mental age by chronological age.
marital adjustment The degree to which married couples are satisfied with their relationship.
mental age On the Binet intelligence scales, the average score of the chronological ages of the standardization group.
mental test Any measure that assesses an individual's ability to learn.
nature–nurture debate Controversy over the extent to which intelligence is influenced by genetic or environmental factors.

Lewis M. Terman (1877–1956) played a central role in the development and establishment of psychological tests that assessed individual and group differences. He was committed to applying the technology of psychological measurement to fit the needs of the dynamically changing American society of the early 20th century. To meet the demands of a growing industrialized and urbanized nation, he sought to demonstrate that measures of intellectual and personality differences could be used to sort individuals into the social roles they were most qualified to fulfill. According to Terman, those individuals who excelled intellectually and motivationally had the potential to achieve the highest positions of responsibility and leadership. As a result of such a meritocratic structure, both individual and social efficiency would be maximized. In this article, Terman's accomplishments in pioneering psychological testing and achieving his social objectives are considered by reviewing and evaluating his career.

Early Life and Professional Training

Terman was born and raised on a farm in central Indiana, the 12th of 14 children. He attended a one-room school, completing the eighth grade when he was 12 years old. Determined to further his education and with the financial help of his parents, Terman left the family farm at age 15 to attend Central Normal College in Danville, Indiana. During a 6-year period, he earned three undergraduate degrees at Normal College. At age 17, with basic teacher preparation achieved, he obtained his first teaching position, and 2 years later he became a high school principal. While at Normal College, he met fellow student Anna Belle Minton (no relation to the author), whom he married in 1899.

With aspirations beyond school teaching, Terman enrolled at Indiana University in 1901, earning a master's degree in psychology in 2 years. With the encouragement of his Indiana mentor, Ernest H. Lindley, he went on to Clark University in 1903 for doctoral studies with G. Stanley Hall, one of the early leaders in American psychology. For his dissertation, Terman undertook an experimental investigation of mental tests in which he compared a "bright" and a "dull" group of 10- to 13-year-old boys. Since Hall did not approve of mental tests, Edmund C. Sanford became his dissertation adviser, and he received his Ph.D. in 1905. Hall, however, influenced Terman's thinking about the nature of intelligence. Consistent with Hall's evolutionary perspective

on individual and group differences, Terman believed that mental tests measured native ability.

During his tenure at Clark, Terman contracted tuberculosis. Although he made a successful recovery, he decided that when he completed his studies it would be desirable to work in a warm climate. He therefore accepted a position as a high school principal in San Bernardino, California. A year later, he was able to obtain a more intellectually stimulating assignment, teaching child study and pedagogy at the Los Angeles State Normal School. In 1910, his academic career was enhanced with an appointment at Stanford University's education department. He spent the remainder of his career at Stanford, becoming the head of the psychology department in 1922, a position he held until his retirement in 1942.

Pioneering the Measurement of Intelligence

The move to Stanford in 1910 coincided with Terman's physical ability to take on a more active academic workload. He thus resumed his research interests in mental testing and began to work with Alfred Binet's 1908 scale, the first widely accepted measure of intelligence. Henry H. Goddard had published translations of Binet's original 1905 scale and the subsequent 1908 revision. Terman's earliest revision of the Binet appeared in 1912, and with the assistance of a team of graduate students, the finished product—the Stanford–Binet—was published in 1916. An innovative feature of the Stanford–Binet was the inclusion of the "intelligence quotient" (IQ), a concept advanced by William Stern but not previously used in mental tests. In competition with a number of other American versions of the Binet, Terman's Stanford revision made use of the largest standardization sample and by the 1920s became the most widely used individually administered intelligence test.

As a result of the published Stanford–Binet, Terman became a highly visible figure in the mental testing movement. Attesting to his reputation, in 1917 he was invited to become a member of a committee that had been assembled at the Vineland, New Jersey, training school for the mentally retarded to devise tests for the U.S. Army. The United States had entered World War I, and Robert M. Yerkes, the president of the American Psychological Association, organized the psychologists' contribution to the war effort. The test committee, chaired by Yerkes, was composed of the leading psychologists in the mental testing field. Terman brought with him a new group-administered version of the Stanford–Binet that had been constructed by his doctoral student, Arthur S. Otis. This test served as the basis for the development of the army group tests (the Alpha and Beta examinations). Although serious questions have been raised about the significance of the psychologists' contributions to the war, there is no doubt that the war provided an enormous boost for the mental testing movement. Approximately 1.75 million men were tested, and on this basis recommendations were advanced with respect to job placements or immediate discharge from the army. The major weakness of the army testing program was the psychologists' failure to consider the impact of cultural differences on tested intelligence. Thus, the lower IQ scores found for foreign-born and poor native-born soldiers were attributed to low levels of native ability rather than such alternatives as limited acculturation and schooling. Terman, like the other members of the army testing committee, subscribed to the Galtonian theory that mental abilities were primarily a product of heredity.

Applying Psychological Testing to Education

After the war, Terman advanced the use of the army group testing methods for education. To this end, he and the other psychologists who constructed the army tests adapted them for school-age children. The resulting National Intelligence Tests for grades 3–8 were published in 1920. Terman promoted the use of intelligence tests as a means of reorganizing schools so that pupils could be categorized into homogeneous ability groups. During the 1920s, intelligence testing and the tracking system of ability grouping became popular practices in schools and Terman played a central role in fostering these policies. He was also a leader in the development of standardized achievement tests, which measured school learning. With a team of Stanford colleagues, he constructed the first achievement test battery—the Stanford Achievement Test. Terman believed that educational testing would be of great value to U.S. society. It would serve as the major means of achieving his vision of a meritocracy within the U.S. democratic ideal—a social order based on ranked levels of native ability. As a measure of native ability, intelligence tests could identify children who were cognitively gifted and therefore had the potential to become the leaders of society. Once these children were identified, it was the responsibility of the schools to devote the necessary time and effort to cultivate their intellectual potential.

Identifying and Enhancing Intellectual Giftedness

To accomplish his meritocratic objectives and with financial support from the Commonwealth Fund of New York,

Terman launched a longitudinal study of gifted children in 1921. This was the first follow-up study to use a large sample. Children with an IQ of at least 135 were categorized as gifted. Terman and his research team generated a sample of approximately 1500 gifted children, based on canvassing elementary and secondary schools in urban areas of California. In an effort to dispel the popular notion that gifted children were underdeveloped in nonintellectual areas, medical and physical assessments were included as well as measures of personality, character, and interests. The gifted sample was compared with a control group of California schoolchildren of comparable age.

In the first of a series of monographs on the gifted study, the major finding was that gifted children excelled in measures of academic achievement when matched for age with control children. The composite profiles of the gifted children also revealed that they were emotionally as well as intellectually mature. Based on these initial results, Terman strongly promoted a differentiated school curriculum that would place gifted children in special classrooms in which they could progress educationally according to their ability rather than their age. With additional research funding, Terman was able to follow up his sample for a period of 35 years. At midlife, the intellectual level of the gifted group continued to be within the upper 1% of the general population, and their vocational achievement was well above the average of college graduates. Moreover, as earlier reports had demonstrated, they showed few signs of such serious problems as insanity, delinquency, or alcoholism. The midlife report also included some marked gender differences. Whereas the men as a group had attained a high level of career success, few women had comparable levels of career achievement. As Terman observed in the 1959 monograph on the gifted sample at midlife, career opportunities for women were restricted by gender role conformity and job discrimination.

Terman's involvement with the gifted study entailed more than data collection and research reports. Especially after he retired in 1942, he devoted himself to the interests of gifted children by promoting gifted education and, through contacts with journalists, disseminated the results of the gifted study in newspapers and magazines. He also popularized his work by making a guest appearance on the radio show "The Quiz Kids." His appearance in 1947 coincided with the publication of the 25-year follow-up. These forays into the popular media also served as a vehicle for Terman to change the public's negative stereotypes of gifted children as maladjusted. In his work with the gifted, Terman experienced particular satisfaction in his personal contact with the participants under study. He maintained correspondence with many of them over the years and in some instances received them as guests in his home. For a number of the gifted who "grew up" and came to be identified as "Termites," he was a benevolent father figure and psychological counselor. By the early 1950s, with plans developing for the continuation of the gifted follow-up, Terman appointed Stanford colleague Robert Sears (who coincidentally was a member of the gifted sample) to succeed him as research director. The gifted sample was thus followed up through late adulthood.

Debating the Testing Critics

As one of the leading advocates of intelligence testing, critics of the testing movement often challenged Terman. These challenges began in the early 1920s when the results of the army testing became widely disseminated. The influential journalist Walter Lippmann wrote a series of highly critical articles about the army tests in the *New Republic*. Lippmann singled out Terman because of his development of the Stanford–Binet and asserted that there was no scientific basis for the claim made by Terman and the other army psychologists that the tests measured native ability. Terman responded in the *New Republic* by dismissing Lippmann as a nonexpert in testing who should thus stay out of issues that he was uninformed about. Lippmann, in fact, was quite technically sophisticated in many of his criticisms, but Terman chose to be evasive in his response to the points that Lippmann raised, such as an environmental interpretation of the correlation between tested intelligence and social class.

During the 1920s, Terman also engaged in a series of published debates about testing with psychologist William C. Bagley, another critic of the hereditarian view of intelligence. In an attempt to settle issues, Terman took on the task of chairing a committee that organized an edited book on the nature–nurture debate. In this monograph, published in 1928, leading advocates of each position marshaled evidence and arguments, but as in previous exchanges, nothing was resolved. In 1940, Terman was once again drawn into the nature–nurture debate, this time challenged by a team of environmentalist advocates at the University of Iowa led by George D. Stoddard. Stoddard campaigned for the limited use of intelligence tests because they were subject to environmental influences that compromised their usefulness in making long-term predictions. Terman was concerned that Stoddard's position against mass testing would threaten his career objective of establishing a meritocracy based on IQ differences. As in previous instances, the 1940 debate led to an impasse. No changes took place in the widespread use of intelligence tests in the schools. It would not be until the 1960s, as a consequence of the civil rights movement, that mass testing was seriously challenged. Terman did modify his position to some extent. In the 1930s, mindful of the racial propaganda of Nazi Germany, he resigned his long-standing membership in

the American Eugenics Society. After World War II, although he still held to his democratic ideal of a meritocracy, he no longer endorsed a hereditarian explanation of race differences, and he acknowledged that among the gifted, home environment was associated with degree of success.

Measuring Gender Identity and Marital Adjustment

Terman's interest in the measurement of individual and group differences extended beyond mental abilities and achievement. Deriving from his study of the gifted, he became interested in assessing nonintellectual traits. By measuring emotional and motivational characteristics, he hoped to demonstrate that the gifted had well-adjusted and well-rounded personalities. To tap this facet of human differences, he set out to measure gender identity, which was viewed as a composite of motivational and emotional traits that differentiated the sexes. He identified masculine and feminine interests from questionnaire preferences given by gifted boys and girls about their play activities, games, and amusements. The initial survey conducted in 1922 revealed that the gifted children were similar in gender orientation to the control children. In 1925, Terman received a National Research Council grant to investigate sex differences and, with his former student Catharine Cox Miles, constructed a masculinity–femininity (M–F) test, the first measure of its kind. The final version published in 1936, called the Attitude–Interest Analysis Test to disguise its purpose, was based on normative samples of male and female groups ranging in age from early adolescence to late adulthood, although the core of the sample was high school juniors and college sophomores. The test comprised approximately 450 multiple-choice items that assessed preferences for a variety of activities and interests, as well as responses to situations that might arouse feelings of anger or fear.

In an attempt to validate the M–F test, Terman was able to collect test protocols from a group of male homosexuals in San Francisco. As he predicted, the results showed that male homosexuals had high feminine scores. He therefore concluded that marked deviations from gender-appropriate behaviors and norms were psychologically unhealthy because such deviations would very likely lead to homosexuality. Even if this "maladjustment" did not develop, other problems could arise. Referring to those with cross-gender identities, Terman and Miles in their 1936 monograph, "Sex and Personality: Studies in Masculinity and Femininity," commented, "One would like to know whether fewer of them marry, and whether a larger proportion of these marriages are unhappy" (p. 468). Underscoring this point, they observed that "aggressive and independent females" could very well be at a disadvantage in the "marriage market" (p. 452). They also expressed the fear that too much competition between the sexes would not be socially desirable. In essence, the authors supported the conventional patriarchal relationship between the sexes. (The extent to which Catharine Cox Miles concurred with this position is not clear since Terman acknowledged prime responsibility for the conclusions in their book.) Terman's conclusions were based on the standardized norms he generated with his M–F test. What the test reflected were the gender norms of the 1930s, but Terman was insensitive to the cultural and historical limits of his measure. He chose to emphasize the need to raise and educate girls and boys so that they would conform to the existing gender norms that fostered a clear distinction between the sexes. As in the case of his vision of a social order ranked by native ability, Terman believed that sex differences also had to follow a prescribed ranking. Paralleling the need to cultivate ability differences to meet the needs of a changing society, in his view it was also important to ensure compatible sex roles in the face of potential conflict between the sexes. Many social scientists during the interwar era, mindful of the feminist challenge, preached the need for compatibility rather than conflict between the sexes.

Terman's interest in gender identity and sex differences expanded to research on marital adjustment. He conducted a large-scale survey study of several hundred married and divorced couples in the San Francisco area. The major finding, according to Terman, was that contrary to previous research results, sexual compatibility was less influential than personality and background factors in predicting marital happiness. He therefore stressed that the key to marital adjustment was the extent to which each spouse accepted the other's needs and feelings and did not fight to get his or her own way. To emphasize this point, he observed that happily married women could be characterized as being cooperative and accepting of their subordinate roles. Terman's conventional views on gender carried over from his masculinity–femininity study to his marital research.

Evaluating Terman's Contribution to Social Measurement

Terman's seminal contributions to the development of psychological testing and the study of the intellectually gifted ensure his position as one of the pioneers in devising social measurement. Perhaps more than any of the other advocates of the testing movement, he was successful in creating a wide variety of methods assessing individual and group differences. His interest in the gifted led

him far beyond the measurement of ability. As a consequence, he was in the vanguard of constructing indices of school achievement, gender identity, marital adjustment, and sexual behavior. Aside from these personal achievements, Terman has left us with an unfulfilled legacy. What he wanted to accomplish with his psychological tests and identification of the intellectually gifted was a more socially just and democratic society. A considerable part of Terman's project, however, has had an unintended dehumanizing effect. For racial and ethnic minorities and lower class individuals, his differentiated educational system based on IQ scores served as an obstacle for personal development and equal opportunity. His views on gender and homosexuality worked against the creation of a more pluralist society. What Terman failed to understand was the intricate way in which scientific knowledge reflects social power. By uncritically accepting the given power inequities of American society, he produced scientific knowledge and technology that functioned to perpetuate the status quo.

Test Equating

Michael J. Kolen
University of Iowa, Iowa City, Iowa, USA

Glossary

alternate forms Versions of a test, each of which contains different items; constructed to be similar to one another in content and statistical properties.
equating design Process used to collect data for conducting equating.
equating method Statistical method used to define and estimate the equating relationship between alternate forms.
raw scores Scores on a test prior to transformation; often, the number of test questions correctly answered by an examinee.
scale scores Scores transformed to a common scale that allows for direct comparison of scores earned on different alternate forms.
test content specifications Detailed description of the numbers of test questions from each of a number of content areas; enables development of alternate forms having similar content.
test statistical specifications Detailed description of the statistical properties of test questions; enables development of alternate forms having similar statistical properties.

Test equating methods are statistical methods used to adjust test scores for differences in test difficulty among alternate forms of educational and psychological tests, with the goal being to use scores on the alternate test forms interchangeably.

Introduction

Alternate forms of educational and psychological tests are often developed that contain different sets of test questions. The alternate forms are administered on different occasions, which enhances the security of the tests and allows examinees to be tested more than once. Test content specifications detail the numbers of questions on a test from each of a number of content areas. Test statistical specifications detail the statistical properties (e.g., difficulty) of the test questions. Alternate forms of tests are built to the same content and statistical specifications, which is intended to lead to alternate forms that are very similar in content and statistical properties.

Although alternate forms are built to be similar, they typically differ somewhat in difficulty. Test equating methods are statistical methods used to adjust test scores for the differences in test difficulty among the forms. A requisite condition for applying test equating methodology is that the alternate forms be built to the same content and statistical specifications. Equating methods adjust for small differences in test difficulty among the forms. As emphasized by Kolen and Brennan (1995, p. 3), "equating adjusts for differences in difficulty, not for differences in content." The goal of equating is to enable scores on the alternate test forms to be used interchangeably.

Test equating is used when alternate forms of a test exist and examinees who are administered the different test forms are considered for the same decision. For example, the ACT Assessment (http://www.act.org) is a college entrance examination used in the United States. The ACT Assessment contains four tests in the areas of English usage, mathematics, reading, and science reasoning. All test questions are multiple choice. The test is administered annually in September, October, December, February, April, and June each year, with different test forms administered on each test date. Examinees who are applying for admission to a particular university might have taken the ACT Assessment on any of the test dates during the past year or even 2 years. Examinees who were administered the test on different test dates might be considered together for admission to a university for

the fall semester. In this situation, it is important that the scores on the test forms be interchangeable.

The implementation of test equating requires a process for collecting data, referred to as an equating design. Statistical equating methods are also a component of the equating process. A variety of equating designs and equating methods exists. Some of the more popular ones are considered here.

Test equating has been conducted since the early 20th century. The first comprehensive treatment of equating was presented by Flanagan in 1951. Subsequent treatments by Angoff in 1971, Holland and Rubin in 1982, Petersen *et al*. in 1989, and Kolen and Brennan in 1995 trace many of the developments in the field. In a 1999 publication, the American Educational Research Association, American Psychological Association, National Council on Measurement in Education, and Joint Committee on Standards for Educational and Psychological Testing provide standards that are to be met when equating tests in practice.

The Scaling and Equating Process

Raw scores on tests are often computed as the number of test questions that a person answers correctly. Typically raw scores are transformed to scale scores. The use of scale scores facilitates score interpretation. Often, properties of score scales are set with reference to a particular population. For example, the ACT Assessment score scale was set to have a mean of 18 for a nationally representative group of examinees who indicated that they were planning to attend college. Often, the score scale is established using an initial alternate form of a test. Raw scores on a subsequent alternate form are equated to raw scores on the initial form. The raw-to-scale score transformation for the new form is then applied to the equated scores on the subsequent form. Later, raw scores on new forms are equated to previously equated forms and then transformed to scale scores. The scaling and equating process results in scores from all forms being reported on a common scale. The intent of this process is to be able to state, for example, that "a scale score of 26 indicates the same level of proficiency whether it is earned on Form X, Form Y, or Form Z."

Equating Designs

Equating requires that data be collected and analyzed. Various data collection designs are used to conduct equating. Some of the most common designs are discussed here.

Random Groups

In the random groups design, alternate test forms are randomly assigned to examinees within a test center. One way to implement the random groups design is to package the test booklets so that the forms alternate. For example, if two test forms, form X and form Y, are to be included in an equating study, the form X and form Y test booklets would be alternated in the packages. When the forms are distributed to examinees, the first examinee would receive a form X test booklet, the second examinee a form Y booklet, and so on. This assignment process leads to comparable, randomly equivalent groups being administered form X and form Y.

Assuming that the random groups are fairly large, differences between mean scores on form X and form Y can be attributed to differences in difficulty of the two forms. Suppose, for example, following a random groups data collection the mean raw score for form X is 80 and the mean raw score for form Y is 85. These results suggest that form X is 5 raw score points more difficult than form Y. Such a conclusion is justified because the group of examinees taking form X is randomly equivalent to the group of examinees taking form Y.

For example, the ACT Assessment is equated using the random groups design. The score scale was initially constructed in 1988 using an initial form. Subsequently, the initial form and a set of new forms were administered using the random groups design in specially selected test centers on a single test date using the random groups design. The new forms were equated to the initial form and then to the score scale using this design. The new forms were then used in later test dates during the first year. In the following years, a previously equated form and a set of new forms have been administered using the random groups design. In all cases, scores on new forms have been expressed on the common score scale.

Single Group Design

In the single group design, the same examinees are administered two alternate forms. The forms are separately timed. Typically, one of the forms has been equated in the past and one of the forms is to be equated. The order of the test forms is usually counterbalanced. One random half of the examinees are administered form X followed by form Y. The other random half are administered form Y followed by form X. Counterbalancing is used to control for context effects. For example, due to the effects of fatigue, examinees who take a form second might not do as well because they may be tired when taking the second form. Also, due to practice, examinees who take a form second might do better because they have had a chance to practice on the form taken first. Counterbalancing requires the assumption that taking form X

prior to form Y has the same effect as taking form Y prior to form X. If this assumption does not hold, then differential order effects are said to be present, and the data on the form taken second are discarded, resulting in a considerable loss of data.

Common-Item Nonequivalent Groups

In the common-item nonequivalent groups design, form X and form Y are administered to different (nonequivalent) groups of examinees. The two forms have items in common. There are two variants of this design. When using an internal set of common items, the common items contribute to the examinee's score on the form. With an internal set, typically the common items are interspersed with the other items on the test. When using an external set of common items, the common items do not contribute to the examinee's score on the form taken. With an external set, the common items typically appear in a separately timed section that is administered during the administration of the form taken.

When using the common-item nonequivalent groups design, the common items are used to indicate how different the group of examinees administered form X is from the group of examinees administered form Y. Strong statistical assumptions are used to translate the differences between the two groups of examinees on the common items to differences between the two groups on the complete forms.

Because scores on the common items are used to indicate differences between the examinee groups, it is important that the common items fully represent the content of the test forms. Otherwise, a misleading picture of group differences is provided. In addition, it is important that the common items behave in the same manner when they are administered with form X as with form Y. Therefore, the common items should be administered in similar positions in the test booklets in the two forms, and the text of the common items should be identical.

For an example of a common-item nonequivalent groups equating design, consider the SAT I (http://www.collegeboard.com). Like the ACT Assessment, the SAT I is used for college admissions in the United States. The SAT I tests are administered seven times per year. The SAT I tests are equated using the common-item nonequivalent groups design with an external set of common items. The SAT I tests contain objectively scored verbal and mathematics tests. Examinees are administered three mathematics sections, three verbal sections, and one "equating section." All examinees are administered the same operational (not including the equating section) form. The equating section contains an external set of common items, so scores on the common items do not contribute to examinees' scores. Examinees are randomly assigned to receive either a verbal common item section or a mathematics common item section. The examinees have no way of knowing which sections are operational sections and which sections are equating sections, so they are equally motivated on all sections of the test. Some of the common item sections were also administered during previous administration and are used to equate the new form to a form that was previously administered.

Comparison of Equating Designs

The benefits and limitations of the three designs can be compared on five dimensions: ease of test development, ease of administration, security of test administration, strength of statistical assumptions, and sample size requirements. Of the designs considered, the common-item nonequivalent groups design requires the most complex test development process. Common item sections must be developed that mirror the content of the total test so that the score on the common item sections can be used to give an accurate reflection of the difference between the group of examinees administered the old form and the group of examinees administered the new form. Test development is less complex for the random groups and single group designs because there is no need to construct common item sections.

However, the common-item nonequivalent groups design is the easiest of the three designs to administer. Only one test form needs to be administered on each test date. For the random groups design, multiple forms must be administered on a test date. For the single group design, each examinee must take two forms, which cannot be done in a regular test administration.

The common-item nonequivalent design tends to lead to greater test security than the other designs because only one form needs to be administered at a given test date. With the random groups and single group designs, multiple forms are administered at a particular test date to conduct equating. However, security issues can be of concern with the common-item nonequivalent groups design because the common items must be repeatedly administered.

The common-item nonequivalent groups design requires the strongest statistical assumptions. The random groups design requires only weak assumptions, mainly that the random assignment process was successful. The single group design requires stronger assumptions than the random groups design in that it assumes no differential order effects.

The random groups design requires the largest sample sizes of the three designs. Assuming no differential order effects, the single group design has the smallest sample size requirements of the three designs because, effectively, each examinee serves as his or her own control.

As is evident from the preceding discussion, each of the designs has strengths and weaknesses. Choice of design

depends on weighing the strengths and weaknesses with regard to the testing program under consideration. Each of these designs has been used to conduct equating in a variety of testing programs.

Statistical Methods

Equating requires that a relationship between alternate forms be estimated. Equating methods result in a transformation of scores on the alternate forms so that the scores possess specified properties. For traditional equating methods, transformations of scores are found such that for the alternate forms, after equating, the distributions, or central moments of the distributions, are the same in a population of examinees for the forms to be equated. Traditional equating methods focus on observed scores. Item response theory (IRT) methods make heavy use of test theory models.

Traditional Methods

Traditional observed score equating methods define score correspondence on alternate forms by setting certain characteristics of score distributions equal for a specified population of examinees. For example, in traditional equipercentile equating, a transformation is found such that, after equating, scores on alternate forms have the same distribution in a specified population of examinees. Assume that scores on form X are to be equated to the raw score scale of form Y. Define X as the random variable score on form X, Y as the random variable score on form Y, F as the cumulative distribution function of X in the population, and G as the cumulative distribution function of Y in the population. Let e_Y be a function that is used to transform scores on form X to the form Y raw score scale, and let G^* be the cumulative distribution function of e_Y in the same population. The function e_Y is defined to be the equipercentile equating function in the population if

$$G^* = G. \tag{1}$$

Scores on form X can be transformed to the form Y scale using equipercentile equating by taking

$$E_Y(x) = G^{-1}[F(x)], \tag{2}$$

where x is a particular value of X, and G^{-1} is the inverse of the cumulative distribution function G.

Finding equipercentile equivalents would be straightforward if the distributions of scores were continuous. However, test scores typically are discrete (e.g., the number of items correctly answered). To conduct equipercentile equating with discrete scores, the percentile rank of a score on form X is found for a population of examinees. The equipercentile equivalent of this score is defined as the score on form Y that has the same percentile rank in the population. Due to the discreteness of scores, the resulting equated score distributions are only approximately equal.

Because many parameters need to be estimated in equipercentile equating (percentile ranks at each form X and form Y score), equipercentile equating is subject to much sampling error. For this reason, smoothing methods are often used to reduce sampling error. In presmoothing methods, the score distributions are smoothed. In postsmoothing methods, the equipercentile function is smoothed. Kolen and Brennan discuss a variety of smoothing methods.

After raw scores on form X are equated to the form Y scale, typically the scores are transformed to scale scores using the raw to scale score transformation for form Y.

Other traditional methods are sometimes used that can be viewed as special cases of the equipercentile method. In linear equating, a transformation is found that results in scores on form X having the same mean and standard deviation as scores on form Y. Defining $\mu(x)$ as the mean score on form X, $\sigma(x)$ as the standard deviation of form X scores, $\mu(Y)$ as the mean score on form Y, $\sigma(Y)$ as the standard deviation of form Y scores, and l_Y as the linear equating function,

$$l_Y(x) = \sigma(Y)\left[\frac{x - \mu(X)}{\sigma(X)}\right] + \mu(Y). \tag{3}$$

Unless the shapes of the score distributions for form X and form Y are identical, linear and equipercentile methods produce different results. However, even when the shapes of the distributions differ, equipercentile and linear methods produce similar results near the mean. When interest is in scores near the mean, linear equating is often sufficient. However, when interest is in scores all along the score scale and sample size is large, then equipercentile equating is often preferable to linear equating. A common rule of thumb is that a minimum of 1000 examinees per form are needed for equipercentile equating, whereas fewer examinees are needed for linear equating.

For the random groups and single group designs, the sample data typically are viewed as representative of the population of interest, and the estimation of the traditional equating functions proceeds without the need to make strong statistical assumptions. However, estimation in the common-item nonequivalent groups design requires strong statistical assumptions. First, a population must be specified in order to define the equipercentile or linear equating relationship. Since form X is administered to examinees from a different population than is form Y, the population used to define the equating relationship is typically viewed as a combination of these two populations. The combined population is referred to as the synthetic population.

Three common ways to define the synthetic population are to equally weight the population from which examinees are sampled to take form X and form Y, weight the two populations by their respective sample sizes, or define the synthetic population as the population from which examinees are sampled to take form X. The definition of the synthetic population typically has little effect on the final equating results. Still, it is necessary to define a synthetic population in order to proceed with traditional equating using this design.

Kolen and Brennan describe a few different equating methods for the common-item nonequivalent groups design. The methods differ in terms of their statistical assumptions. Define V as score on the common items. In the Tucker linear method, the linear regression of X on V is assumed to be the same for examinees taking form X and examinees taking form Y. A similar assumption is made about the linear regression of Y on V. In the Levine linear observed score method, similar assumptions are made about true scores rather than observed scores. No method exists to directly test these assumptions using data that are collected for equating. Methods do exist for equipercentile equating under this design that make somewhat different regression assumptions.

IRT Methods

Unidimensional IRT models assume that examinee proficiency can be described by a single latent variable, θ, and that items can be described by a set of parameters or curves that relate proficiency to probability of correctly answering the item. For multiple-choice tests, the probability that examinees of proficiency θ correctly answer item g is symbolized $p_g(\theta)$. IRT models are based on strong statistical assumptions. The θ scale has an indeterminate location and spread. For this reason, one θ scale sometimes needs to be converted to another linearly related θ scale. If number-correct scores are to be used, then there are two steps in IRT equating. First, the θ scales for the two forms are considered to be equal or are set equal. Then, number-correct score equivalents on the two forms are found.

In many situations, the parameter estimates for the two forms are on the same θ scale without further transformation. In general, no transformation is needed in the following situations: (i) in the random groups design, (ii) in the single group design, and (iii) in the common-item nonequivalent groups design when form X and form Y parameters are estimated simultaneously. The typical situation in which a transformation of the θ scale is required is in the common-item nonequivalent groups design when the form X and form Y parameters are estimated separately.

After the parameter estimates are on the same scale, IRT true and IRT observed score methods can be used to relate number-correct scores on form X to number-correct scores on form Y. In IRT true score equating, the true score on one form associated with a given θ is considered to be equivalent to the true score on another form associated with that same θ. In IRT the true score on form X for an examinee of ability θ is defined as

$$\tau_X(\theta) = \sum_{g:X} p_g(\theta), \tag{4}$$

where the summation g: X is over items on form X. True score on form Y for an examinee of ability θ is defined as

$$\tau_Y(\theta) = \sum_{g:Y} p_g(\theta), \tag{5}$$

where the summation g: Y is over items on form Y. Typically, an integer score on form X is specified. The θ that leads to an equality in Eq. (4) is found by iterative means. This θ is then substituted into Eq. (5) to find the IRT true score equivalent of the integer score on form X. In practice, estimates of parameters are substituted for the parameters in Eqs. (4) and (5).

IRT observed score equating uses the item parameters estimated for each form along with the estimated distribution of ability for the population of examinees to estimate the number-correct score distribution for form X and form Y. Given the item parameters on a test form, Lord and Wingersky provided a recursive equation that can be used to find the distribution of number-correct scores, conditional on θ, which is symbolized as $f(x \mid \theta)$. Many IRT computer programs output an estimate of the distribution of θ, symbolized as $g(\theta)$. The distribution of number-correct scores on form X, $f(x)$, can be related to these two quantities by the following equation:

$$f(x) = \int_\theta f(x \mid \theta) g(\theta) d\theta. \tag{6}$$

Given the item parameters and distribution of θ, Eq. (6) can be used to estimate a smoothed distribution of number-correct scores in the population for form X. A similar process can be used to obtain a smoothed distribution for form Y. Standard equipercentile equating procedures are then used to equate these two smoothed distributions.

Any application of unidimensional IRT models requires that the test forms be unidimensional and that the relationship between ability and probability of correct response follows the model. In these applications, the fit of the models needs to be carefully analyzed.

Equating Error

Minimizing equating error is a major goal when developing tests that are to be equated, designing equating studies, and conducting equating. Random equating error is

present whenever samples from populations of examinees are used to estimate equating relationships. Random error depends on the design used for data collection, the score point of interest, the method used to estimate equivalents, and sample size. Standard errors of equating are used to index random error. Standard error equations have been developed to estimate standard errors for most common designs and methods, and resampling methods such as the bootstrap can also be used. In general, standard errors diminish as sample size increases. Standard errors of equating can be used to estimate required sample sizes for equating, for comparing the precision of various designs and methods, and for documenting the amount of random error in equating.

Systematic equating error results from violations of assumptions of the particular equating method used. For example, in the common-item nonequivalent groups design, systematic error will result if the Tucker method is applied and the regression-based assumptions that are made are not satisfied. Systematic error typically cannot be quantified in operational equating situations.

Equating error of both types needs to be controlled because it can propagate over equatings and result in scores on later test forms not being comparable to scores on earlier forms. Choosing a large enough sample size given the design is the best way to control random error. To control systematic error, the test must be constructed and the equating implemented so as to minimize systematic error. For example, the assumptions for any of the methods for the common-item nonequivalent groups designs tend to hold better when the groups being administered the old and the new forms do not differ too much from each other. The assumptions also tend to hold better when the forms to be equated are very similar and when the content and statistical characteristics of the common items closely represent the content and statistical characteristics of the total test forms. Another way to help control error is to use what is often referred to as double-linking. In double-linking, a new form is equated to two previously equated forms. The results for the two equatings are often averaged to produce a more stable equating than if only one previously equated form had been used. Double-linking also provides for a built-in check on the adequacy of the equating.

Selected Practical Issues

Due to practical constraints, equating cannot be used in some situations in which its use may be desirable. Use of any of the equating methods requires test security. In the single group and random groups designs, two or more test forms must be administered in a single test administration. If these forms become known to future examinees, then the equating and the entire testing program could be jeopardized. With the common-item nonequivalent groups design, the common items are administered on multiple test dates. If the common items become known to examinees, the equating is also jeopardized. In addition, equating requires that detailed content and statistical test specifications be used to develop the alternate forms. Such specifications are a prerequisite to conducting adequate equating.

Although the focus of this article has been on equating multiple-choice tests that are scored number-correct, equating can often be used with tests that are scored in other ways, such as essay tests scored by human raters. The major problem with equating such tests is that frequently very few essay questions can be administered in a reasonable time frame, which can lead to concerns about the comparability of the content from one test form to another. It also may be difficult, or impossible, when the common-item nonequivalent groups design is used to construct common item sections that represent the content of the complete tests.

Recently, computers have been used to administer tests. Often, adaptive tests are used in which questions are selected based on examinees' responses to previous questions. For example, when an examinee incorrectly answers a question, the subsequent question will tend to be an easier item. When an examinee correctly answers a question, the subsequent question will tend to be a more difficult question. In adaptive testing, items are typically selected from an item bank that has been scaled using IRT methods. Periodically, the item banks are updated or replaced. Wang and Kolen demonstrated that when the item banks are modified, it is important to ensure that the scores from the updated bank are comparable to those from the earlier item bank.

Processes Related to Equating

There are processes related to equating properly considered under the general category of "linking" in the terminology of both Linn and Mislevy. One of these processes is vertical scaling, which is often used with elementary school achievement test batteries. In these batteries, students are administered test questions that match their grade level. Scores from the tests administered at different grade levels are placed on the same score scale, enabling school personnel to chart an individual student's growth. Because the tests given at the different grade levels differ in difficulty and content, the process of placing the test levels on the same score scale is not equating. Other examples of linking include relating scores on one test to another (e.g., ACT scores and SAT I scores) and scaling tests within a battery so that they have the same score distribution. Although similar

statistical procedures are used in linking and equating, their purposes are different.

Conclusion

The goal of test form equating is to use scores from alternate test forms interchangeably. Test development procedures that have detailed content and statistical specifications allow for the development of alternate test forms that are similar to one another. These test specifications are a necessary prerequisite to the application of equating methods.

Test–Retest Reliability

Chong Ho Yu
Cisco Systems/Aries Technology, Tempe, Arizona, USA

Glossary

carry over effect A type of data contamination caused by carrying over some influence to the item response from one condition to another, such as recalling answers from the first test administration.
coefficient of stability and equivalence The correlation coefficient yielded from a combination of test–retest and alternate form methods, in which different forms are given to the same subjects on different occasions.
Cohen's Kappa A measure of the degree of agreement between two sets of the frequency counts given that the data are categorical.
deliberative effect A non-spontaneous source of data contamination that could be caused by different motivations, such as deliberately taking the first test less seriously for practice or giving up on the test due to frustration.
intraclass correlation (ICC) A reliability estimate oriented toward the computation of inter-rater reliability, but which also can be employed to estimate the reliability of subjective scoring (same raters on different occasions) in the context of test–retest reliability.
Kendall's tau A nonparametric measure of the agreement between two rankings.
learning effect A type of carry over effect caused by the opportunity of practice in the first testing which results in gaining improvement in the second testing.
maturation effect The real changes in the traits, such as improvement in performance, which will likely occur when the time gap between two tests is very long.
testlet A cluster of items based upon the same scenario, such as items referring to a passage in a comprehension test.
Yule's Q A measurement of association based upon the odds ratio, which measures the ratio between the probability that an outcome would occur and the probability that the same outcome would not occur.

The "test–retest reliability estimate" measures the degree of stability of a test taken by the same subjects on different occasions. In contrast to internal consistency, test–retest reliability estimation compares a set of data with another set external to the first set, and thus test–retest reliability is also known as external reliability. Since data are collected at different times, it is also called temporal reliability. The attribute "stability" could be viewed as the means and "reproducibility" as the end. In other words, a stable test is considered a good test because using the same test would yield reproducible results. Thus, test–retest reliability is also conceived as test–retest reproducibility.

Meanings of Test–Retest Reliability

It is not uncommon that many students identify reliability as a mathematical formula or a computational procedure. For example, Cronbach Alpha is usually equated with internal consistency, whereas Pearson correlation coefficient is strongly associated with test–retest reliability. It is important to point out that reliability should be construed conceptually rather than computationally. For example, besides Cronbach Alpha, Kuder-Richardson 20 (KR-20) and split-half methods can also be employed for estimating internal consistency. By the same token, a test–retest reliability estimate could be computed in more than one way. To be specific, Pearson correlation coefficient is an appropriate indicator of the relationship between two sets of interval-scaled data, while Cohen's Kappa, Kendall's Tau, and Yule's Q are suitable to correlate the frequency of categorical data. But data that involves subjective scoring (same raters on different occasions) necessitate the use of intraclass correlation (ICC). In some other cases, researchers have gone even further to suggest that ICC is a better indicator of test–retest reliability than Pearson's, because Pearson's correlation does not imply stability, but ICC can in principle be interpreted

as a measure of stability. Further, some researchers have employed paired *t* tests, also known as correlated *t* tests, to detect subtle changes between two measures as a supplement to reporting correlation coefficients. When more than two measures are administered, researchers have expanded the *t* test approach to Analysis of Variance (ANOVA) repeated measures. Indeed, ICC can be derived from ANOVA models. Other innovative uses of psychometric procedures can be found in complicated research design. In short, the magnitude of stability could be estimated by more than one procedure. Interestingly enough, kappa, tau, Q, and ICC could also be used for estimating interrater reliability. Thus, these statistical procedures are not exclusively tied to a particular type of reliability. Their proper applications depend on the conceptual understanding of the data. Hence, it is recommended that researchers approach the issue of test–retest in a conceptual fashion rather than confining test–retest to particular computations.

Sample Issues

It is highly recommended that for estimating test–retest reliability, researchers should recruit more subjects than they need because when multiple tests are given to the same group of subjects, it is likely that in a later session some subjects may drop out from the study. Besides sample size, the quality of the sample is also important to test–retest reliability studies. No doubt the quality of the sample is tied to the sample representativeness. If a researcher designs a test for clinical groups, it is essential that the test–retest reliability information is obtained from those particular groups. For example, schizophrenics are said to be difficult to test. It is expected that the mental state of patients who suffer from schizophrenics is unstable, and thus sometimes the use of normal subjects is necessary. However, in a clinical setting a reliability estimate obtained from a normal sample for a test designed for use with abnormal samples may be problematic. Take the Drug Use History Form (DUHF) as another example. DUHF is designed to track usage of drugs among drug users, and its test–retest reliability information is crucial for clinicians to carry out treatment-effectiveness studies. However, due to the physical and emotional weaknesses of drug users, availability of self-report data from drug users may be scarce, and hence sometimes nondrug users participate in test–retest reliability studies of DUHF. As a result, contamination by nondrug users artificially inflates test–retest reliability coefficients of DUHF. The problem of sample representativeness could also be found in widely used diagnosis tests in education. Reports of test–retest reliability of Reading Disabilities (RD) tests have been questioned by certain researchers, because individuals who experience difficulty with reading may exhibit a limited range of reading performance; multiple measures of people who could not read at all would not yield a meaningful test–retest study result. To counteract this shortcoming, it is suggested that measures of RD should be based upon samples who have acquired basic reading skills by receiving interventions.

Another controversial aspect of sample representativeness is the use of convenience sampling rather than true random sampling. Traub criticized that the "canon" of sample representativeness has been overlooked by many social scientists because very often reliability studies are conducted on convenience samples, consisting of subjects who are readily accessible by the experimenter. Traub was doubtful of whether reliability estimates based upon "grab-bag" samples could be generalized beyond the sample itself. While Traub's criticism is true to some certain extent, other researchers have argued that "true random sampling" is an idealization. It is extremely difficult, if not impossible, to randomly draw samples from the target population to which the inference is made. For example, if the target population is drug users in the United States, ideally speaking subjects should be randomly selected from drug users in all 50 states, but in practice this goal may be very difficult to accomplish. Some have suggested that broader generalizations with convenience samples is still possible when different reliability studies using the same instrument are carried out in different places, and then meta-analytical techniques are employed to synthesize these results.

Sources of Errors

Uncontrollable measurement errors are inherent in every test and the test administrators can do virtually nothing to avoid this kind of error. For instance, a subject may quarrel with a spouse before taking the test, and thus this emotional state deeply affects the test performance. Other uncontrollable sources of measurement errors may be physical illness, fatigue, bad weather, or malfunctioning air-conditioning in the test centers. Some uncontrollable errors are specific to a test–retest design. For example, regardless of how much careful control is exercised, the conditions of the second testing would never be exactly the same as that of the first testing. This phenomenon is called person-by-occasion interaction. The estimates of the standard error of measurement would no doubt be inflated by this interaction. However, it is impossible to produce an estimate of test–retest reliability that is totally free of this interaction. In the following, focus is directed to certain controllable errors. These errors either could be avoided at the stage of experimental design or could be taken into account at the stage of computation.

Errors from the Subjects

Carry Over Effect

A carry over effect, as its name implies, is an effect on the item response that "carries over" from one condition to another. In other words, events in the first testing may influence performance in the second testing. This contamination could happen in several ways. In most cases, the test–retest reliability is inflated because the subjects still remember what they answered the first time and thus tend to give the same answer in the second test. In some situations, the carry over effect is the learning effect, also known as the practice effect. In this case, the skill level of the subjects improves because the first test provides them an opportunity to practice.

There is a subtle difference between the carry over effect and the learning effect. The learning effect is a subset of the carry over effect, but the carry over effect may not necessarily be the learning effect. To be specific, on the second occasion of a survey the subject may recall what they have answered on the first occasion. Some influence is definitely carried over from one situation to another, but in this case no learning or skill improvement is involved at all. In an ability test the subjects could put down the same wrong answers in the second test as what they did in the first testing. It could happen when the time interval between the two tests is very close and thus the subjects does not have a chance to look up the right answers. Again, there is no learning effect in this type of carry over.

Some researchers argued that the effect of the regression to the mean may balance out the learning effect. Regression to the mean is a statistical concept invented by Francis Galton in the 19th century. At that time, this notion was used as an argument against the natural selection theory proposed by Charles Darwin. In Darwinism, certain traits of species would get better and better in terms of survival fitness. But Galton argued that very tall parents do not necessarily give birth to very tall children. Instead, it is likely that the height of their offspring would approach the mean height of the population. This phenomenon is called regression to the mean. Galton believed that in the long run the regression effect will cancel out the short-term improvement. In social measurement regression to the mean is regarded by some researchers as a counter-balance against the learning effect. However, it is important to note that the alleged counter-balance effect due to the regression to the mean is most likely to occur in the long run. Due to the fact that in most studies of test–retest reliability subjects are tested two or three times within a short period of time, some researchers have argued that it is difficult to imagine how the regression effect could counteract the learning effect in such a short term. In brief, the threat of the learning effect should still be taken seriously.

Randomization of items is a common technique as a countermeasure against the carry over effect. When the order of items and order of options within an item are shuffled, it reduces the probability that the test takers can recall the answers in the first testing. Another technique is to introduce alternate forms into a test–retest study. In this case, virtually nothing could be recalled from the first test. This will be discussed below in the section Coefficient of Stability and Equivalence.

Deliberative Effect

In the previous discussion, the learning effect is spontaneous. But on some occasions, the learning effect is a result of deliberation. For example, in a certification examination administered in the information technology industry, such as the Microsoft Certified System Engineer Exam, examinees are allowed to retake the exam over and over. In the first testing, some examinees just take it as a learning experience by getting a preview of the test content and format. This preview serves as a guideline for them to study and to take the next exam seriously. Needless to say, the test–retest reliability is affected by this intention.

Other kinds of intentions and deliberate acts that deviate from normal test-taking behaviors could also seriously affect test–retest reliability. For instance, uncooperative test takers may object to the second testing and deliberately mismark the second test. In an ability test, some examinees who performed poorly in the first testing may hope to improve their performance in the second one. But when they find that the second test is equally as challenging as the first one and they are unlikely to get a higher score, they just deliberatively give up the test by skipping questions or answering them arbitrarily. In both cases, the test–retest reliability is deflated. In some situations, some subjects may seek advice from other test takers about how to improve their scores. This behavior leads to a violation of the independence of test scores, in which the measurement for one examinee must not be influenced by or have influenced on the measurement for any other examinee.

Taking all the preceding effects into consideration, it is advised that data patterns should be carefully examined by exploratory data analysis in order to spot observations that display strange patterns. For example, when a test taker is discouraged by the difficulty of the second test and stops devoting effort to answering questions, the scores of the items near the end would be much poorer. These observations in question could be put aside to avoid contamination of the reliability estimates. By the same token, when a test taker did not take the first test seriously but used it for practice only, the gap between his/her two test scores would be substantively large.

Errors from the Administration

Nonidentical Administrative Procedures

The circumstances during the test administration of the first testing should be identical to the circumstances of the second testing. Although it sounds common sense, nonidentical administrative procedures do happen from time to time when different administrators preside on different occasions. For example, in the first testing if a subject leaves the test center to go to the restroom and returns 10 minutes later, the test administrator may give him/her an extra 10 minutes as compensation. But in the second testing another administrator might count the time for the restroom as a part of the testing time, and thus inconsistency arises. In order to achieve identical test administrations, it is strongly recommended that the same people should administrate the tests on all occasions or/and a clear protocol is given to the test administrators.

Poor Test Instruction

The instruction of the test is a commonly overlooked source of error. When the instruction is poor, the subjects may not know what they are supposed to do immediately. This problem is often found in computer-based testing. For example, if a subject is asked to perform simulation-based tasks in a computer test while the instructions are unclear, subjects may do better on one occasion than the other.

Subjective Scoring

If the test format is subjective, such as consisting of essay-type questions, subjective scoring could be a source of measurement error. To be specific, errors from subjective scoring can come from two different sources. One type of error results from different raters (interrater) and the other is caused by the same rater conducting grading on different occasions (intrarater). This issue could be very complicated since it involves multiple sources of errors, or an interaction effect between the time factor (test–retest) and the rater factor. The generalizability theory, which will be discussed later, is proposed as an effective strategy to address the problem of multiple sources of errors. In addition, the intraclass correlation (ICC) coefficient can be computed to estimate the intrarater and interrater reliability. This estimate is based on mean squares obtained by applying ANOVA models. To be specific, in an ANOVA model the rater effect is indicated by the mean square (MS) of the between-subject factor while the multiple measures on different occasions are shown in the mean square of the between-measure factor. The reliability estimate is calculated by

$$r = \mathrm{MS}_{\text{between-measure}} - \mathrm{MS}_{\text{residual}} / \mathrm{MS}_{\text{between-measure}} + \left(\mathrm{df}_{\text{between-subject}} \times \mathrm{MS}_{\text{residual}}\right)$$

In the context of ANOVA, there are separate coefficients for three models:

1. One-way random effects model: Raters are perceived as a random selection from possible raters, who grade all subjects, which are a random sample.
2. Two-way random effects model: Raters, also conceived as random, rate a subset of subjects chosen at random from a sample pool.
3. Two-way mixed model: All raters rate all subjects, which are a random sample. This is a mixed model because the raters are a fixed effect and the subjects are a random effect.

Too Wide or Too Narrow Time Gap

As expected, time gap is a major factor that influences test–retest reliability. If the interval between the two test administrations is short, say three minutes, the correlation between the two test scores, needless to say, is boosted because of the carry over effect. In contrast, if the interval is very long, say three years, the correlation is expected to be low. In the latter case, the ability can substantively change due to the maturation effect, which is a real change in the trait under study. In this case, a low test–retest correlation may indicate low reliability, real changes in the individuals measured, or a combination of both.

Pedhazur and Schmelkin argued that because of these serious deficiencies of the test–retest approach, this should not be used or should be used with caution. Nevertheless, some researchers counterargued that these deficiencies are not insurmountable. Experienced researchers who are familiar with the subject matter usually know how to choose a proper time gap to minimize both the carry over effect and the maturation effect. Further, these so-called deficiencies are not inherent in every test–retest. Crocker and Algina argued that in a test designed for assessing the level of an infant's psychomotor development, it is unlikely that the baby can remember the previous responses. Last but not least, researchers could design test–retest studies with different temporal gaps to provide users with both short-term and long-term reliability estimates.

Errors from the Test

Nature of the Subject Matter

If the researcher attempts to measure personality, interest, attitude, or a transient state or mood, such as anger, fear, and anxiety, test–retest reliability would be bound to be low. On the other hand, test–retest reliability estimates tend to be higher when stable traits are measured. According to Crocker and Algina, among the highest test-test coefficients reported for commercially published tests are aptitude tests, such as the Wechsler Adult Intelligence Scale (WAIS). Thus, researchers are encouraged to carefully examine the appropriateness of

the subject matter before adopting test–retest reliability estimation.

Difficulty Levels of Items

In an ability test, the test–retest reliability tends to be high if the questions are too easy, simply because the subjects will get them right on both occasions. In contrast, if the items are extremely difficult, it will lead to the same effect since the subjects will miss most items both times. Nevertheless, neither case is a good sign because when a test is too easy or too difficult, it cannot discriminate people of high proficiency from those of low proficiency.

Test Length and Item Randomization

Very few people see test length as a source of error for test–retest reliability, but low test–retest reliability could occur when the test is long and the item/option sequence is randomized. As mentioned before, item/option randomization is a way to counteract the carry over effect. However, when an ability test is composed of too many items, test takers may be too fatigued to answer items near the end, and thus performance toward the end of the test may be relatively poor. If the test is an aptitude test, the subject may be too bored to answer questions near the end seriously. As a result, the quality of the answers is affected. In both cases, since the items near the end at the second administration are not the same as those at the first, it is expected that test–retest reliability is affected. As a remedy, it is recommended that the test length be kept short so the quality of answers to randomized items would not be affected by fatigue or boredom.

Test–Retest Reliability in a Wider Perspective

It is a widespread impression that test–retest, internal consistency, and alternate forms are separate methods in both computational and conceptual senses. Actually, test–retest and alternate forms could be blended together for estimating the coefficient of stability and equivalence. In addition, some researchers have proposed that the generalizability theory could be employed to take different sources of error into account, and also stability as a unified theme for all three types of reliability estimates.

Coefficient of Stability and Equivalence

Reliability coefficients can be estimated by combining the test–retest and the alternate form approaches. Instead of giving the same test to the same subjects on two different occasions, in this approach the test administrator gives two different forms to the same subjects in two different situations. The advantage of this method is that the carry over effect is avoided because items in the two tests are not the same, although the contents are equivalent. The tradeoff is that another potential source of error is introduced—the content effect. As a result, there will be two sources of measurement errors in this mixed method. One source is content sampling in the form construction, and the other is change in subject performance over time. The correlation coefficient between the two sets of scores is termed the coefficient of stability and equivalence.

Generalizability Theory for Addressing Multiple Sources of Error

Addressing multiple sources of error is an interesting idea, but classical test theory directs researchers to focus on one source of error with different computing methods. For example, if one computes a test–retest reliability coefficient, the variation over time in the observed score is counted as error, but the variation due to item sampling is not. If one computes Cronbach coefficient Alpha, the variation due to the sampling of different items is counted as error, but the time-based variation is not. This creates a problem if the reliability estimates yielded from different methods are substantively different. To counteract this problem, Marcoulides suggested reconceptualizing classical reliability in a broader notion of generalizability. Instead of asking how stable, how equivalent, or how consistent the test is, and to what degree the observed scores reflect the true scores, the generalizability theory asks how the observed scores enable the researcher to generalize about the examinees' behaviors given that multiple sources of errors are taken into account.

Stability/Reproducibility as a Unified Theme of all Reliability Estimates

Although the meanings of stability, consistency, and equivalency are different from each other, they all share a common theme: All of them address the extent to which scores obtained by a test taker will be the similar if the same person is retested by the same test on different occasions. At first glance, this common thread describes stability or reproducibility rather than consistency and equivalency. Nevertheless, when a researcher computes Cronbach Alpha to obtain an estimate of internal consistency, he/she is not satisfied with the following inference: "The response pattern of this test is internally consistent. Externally speaking, it does not give me any information about what the response patterns would look like when the same set of items are used for another sample on another occasion. Hence, this test can be applied to this local sample only." Actually, this is not the goal of the researcher. He/she would certainly collect more data from other sources and to verify whether the Cronbach

coefficient Alpha is stable across various samples. It is hoped that the same instrument would yield reproducible results elsewhere. The same goal can be found in the use of alternate forms. Thus, while test–retest is a direct way of measuring test–retest reliability, other forms of reliability estimation are also regarded as an indirect means of seeking stability and reproducibility information.

Special Applications

Although the "generalizability theory" and "stability" are proposed as two unified themes of internal consistency, test–retest, and alternate forms, test–retest reliability estimate nevertheless has certain specific applications. To be explicit, in some situations only test–retest could be used for reliability estimation. In the following, three examples will be discussed.

Frequency of Categorical Data

In some tests stability is the only psychometric attribute that can be estimated and thus only test–retest can be applied. The Rorschach test, also known as the Rorschach inkblot test, is a good example. The test is a psychological projective test of personality in which a subject's interpretations of abstract designs are analyzed as a measure of emotional and intellectual functioning and integration. Cronbach pointed out that many Rorschach scores do not have psychometric characteristics that are commonly found in most psychological tests. Nonetheless, researchers who employ the Rorschach test can encode the qualitative-type responses into different categories and frequency counts of the responses can be tracked. Hence, the stability of these tests can be addressed through studies of test–retest reliability. The following three approaches are widely adopted.

Cohen's Kappa

Cohen's Kappa coefficient, which is commonly used to estimate interrater reliability, can be employed in the context of test–retest. In test–retest, the Kappa coefficient indicates the extent of agreement between frequencies of two sets of data collected on two different occasions.

Kendall's Tau

However, Kappa coefficients cannot be estimated when the subject responses are not distributed among all valid response categories. For instance, if subject responses are distributed between "yes" and "no" in the first testing but among "yes," "no," and "don't know" in the second testing, then Kappa is considered invalid. In this case, Kendall's Tau, which is a nonparametric measure of association based on the number of concordances and discordances in paired observations, should be used instead. Concordance could be found when paired observations co-vary, but discordance occurs when paired observations do not co-vary.

Yule's Q

Even if the subject responses distribute among all valid categories, researchers are encouraged to go beyond Kappa by computing other categorical-based correlation coefficients for verification or "triangulation." Yule's Q is a good candidate for its conceptual and computational simplicity. It is not surprising that in some studies Cohen's Kappa and Yule's Q yield substantively different values and the discrepancy drives the researcher to conduct further investigation.

Yule's Q is a measurement of correlation based upon the odds ratio. In Table I, a, b, c, and d represent the frequency counts of two categorical responses, "yes" and "no" recorded on two occasions, "Time 1" and "Time 2." The odd ratio, by definition, is $OR = ad/bc$. Yule's Q is defined as $Q = (OR - 1)/(OR + 1)$.

Testlet

The test–retest approach is recommended when testlets are included in a test. A testlet is a cluster of items based upon the same scenario. A typical example is a comprehension test using the same passage on which a group of items is based. The absence of local independence is a serious problem in assessing internal consistency. But in estimating test–retest reliability, the issue of violation of local independence is less serious, because test–retest reliability is not locally assessed; rather, the response pattern of each item on one occasion is paired with that of another occasion. Even if response patterns of testlet items are internally correlated, this does not increase the measurement error of external correlation.

Single-Item Measures

It is a common practice that psychologists and sociologists use a group of items to measure a single construct. However, certain clinical tests make a direct measurement of a narrowly defined variable. Those tests might contain just a single item. Expanded Disability Status Scale (EDDS) and Functional Systems (FS) are two good examples. Using Cronbach Alpha, which relies on interitem association, to measure reliability of such tests is out of question. Obviously, the most appropriate method

Table I 2 × 2 Table of Two Measures

Time 1 \ *Time 2*	*Yes*	*No*
Yes	a	b
No	c	d

of estimating reliability of single-item measures such as EDSS and FS is the test–retest approach.

Controversies

Cutoff of Test–Retest Reliability

There is no universal agreement about how a test–retest reliability estimate is considered adequate. It is not surprising that different textbooks give different recommendations. A popular suggestion is that a high correlation should be 0.80 or above. However, quite a few researchers warn that this suggestion is too arbitrary to be taken seriously. Critics draw an example in internal consistency as a counterexample: In 1978 Nunnally suggested that a reliability of 0.7 is acceptable, but about a decade later he changed the cutoff from 0.7 to 0.8. Actually, the variable being measured will change the expected strength of the correlation. Rust and Golombok suggested that for IQ tests a reliability of 0.9 is acceptable, but for personality tests, which measures less stable traits, a reliability of 0.7 is good enough. Some have argued that clinicians should hope for a correlation of 0.9 or above in tests that will be used to make decisions about individuals. Other high-stakes examinations should also follow this strict principle.

Moreover, since there is more than one procedure to measure test–retest reliability estimates, the acceptability of a reliability level should also depend on the procedure the researcher adopted. For example, in Kappa coefficient, even if 70% of two datasets concur with each other, it does not mean that the measurements are reliable enough. Since the outcome is dichotomous, there is a 50% chance that the two measurements will agree. Thus, Kappa coefficient demands a higher degree of matching to reach reliability. Fleiss suggested that a Kappa coefficient of 0.75 or above is considered excellent, coefficients between 0.4 and 0.75 represent fair agreement, and a reliability of 0.4 or less is unacceptable. For ICC, Strout and Fleiss regarded 0.7 as the cutoff between acceptable and unacceptable reliability values. Landis and Koch provided a detailed classification of the quality of ICC, as shown in Table II.

As mentioned before, uncontrollable errors always sneak into the measurement process no matter how carefully we plan and implement a study. Thus, rather than reporting a fixed reliability coefficient only, it is a good practice to report also the confidence interval (CI) of the reliability estimation.

Table II Classification of ICC

Slight	$0 < \text{ICC} = 0.2$
Fair	$0.2 < \text{ICC} = 0.4$
Moderate	$0.4 < \text{ICC} = 0.6$
Substantial	$0.6 < \text{ICC} = 0.8$
Almost perfect	$0.8 < \text{ICC} = 1$

Stability as a Psychometric or Datametric Attribute

Although stability is considered a vital property in test–retest and other forms of reliability estimate, in recent years, stability as an indispensable property of test reliability has been challenged by Thompson and Vacha-Haase. They suggested that "psychometrics is datametrics." To be specific, in their view reliability, especially in the form of stability, is not a psychometric attribute of a test; the phrase "the reliability estimate of the test" is misleading. Rather, reliability is associated with the data and thus it inherently fluctuates from sample to sample. Thompson and Vacha-Haase introduced a research methodology called meta-analyses of reliability across studies, also known as reliability generalization studies. Based on their massive empirical studies employing meta-analysis, they found that reliability information fluctuates from sample to sample and thus the so-called stability of a test is a myth. No doubt this notion poses a serious challenge to the concept of test–retest reliability estimation, which is expressed in terms of stability, and to a lesser degree, to other forms of reliability estimate.

Nevertheless, most researchers still accept that stability is a psychometric, not datametric, property for a number of reasons. With the threats of many sources of measurement errors and "noise," it is not surprising to see fluctuations of reliability estimates across data sets. Many researchers realize that testing methods in the social sciences are inevitably imprecise. Within the fields of physical and engineering sciences, direct measurements are possible, such as the strength of electrical-magnetic interference and the throughput of a fiber optics cable. In contrast, in the social sciences, measurements are often indirect; researchers need to relate observables to the latent construct. Therefore, instead of denying reliability as a psychometric attribute, the goal of a test constructor should be to reduce as many measurement errors as possible, and also to identify the relationship between the observable and the hidden construct. On one hand, it may not be appropriate for a test developer to apply a "universal" test to all populations. On the other hand, he/she should retain the goal of constructing a fairly "stable" test, in which the psychometric properties are invariant within a broad range of occasions.

Glossary

classification The process both of constructing a set of categories into which cases may be assigned and the actual assignation of cases to those categories.
complexity theory An interdisciplinary understanding of reality as composed of complex open systems with emergent properties and transformational potential. A crucial corollary of complexity theory is that knowledge is inherently local rather than universal.
constructionism An ontological position which asserts that the social world is the product of human action and is socially constructed.
conventionalism An epistemological position which asserts that the objects of knowledge are specified by agreement among those who work with terms describing them and do not necessarily have any "real" counterparts separate from intellectual use.
methodology The application of ontological and epistemological understanding to the actual practice of research and critique of the methods employed in research.
realism A meta-theory that accepts the existence of a world separate from and preexisting our knowledge of it, understands processes of causation as inherently complex and contingent, and recognizes that the production of knowledge is an inherently social process.

Theory, the role in social measurement: consideration is given to the implications of both ontological and epistemological positions for the understanding of the objects of social measurement and the nature of measurement as a process.

The Necessity for Theory in Social Measurement

There is a general agreement that theoretical understanding is necessary for the proper conduct of social measurement. Blalock emphasized the relationship between conceptual formation and underlying theoretical assumptions in any social research arguing that these must always be associated in the actual practice of research. By theoretical concerns Blalock means substantive social theory which must always be linked to our methodological considerations. Blalock's position typifies that of mainstream quantitative sociology in principle, although the practice has seldom if ever succeeded in establishing the necessary linkages.

Another approach, which has been particularly influential in psychology, emphasizes general theories of measurement applicable in all contexts. Here the theory of measurement—often highly formalized in axiomatic terms—drives the whole measurement process. Kyburg identifies two strands—a mathematical focus on mapping empirical structures onto the structure of real numbers and an experimental focus concerned with the establishment of valid scales that measure real variate aspects. Cicourel in the enormously influential *Method and Measurement in Sociology* drew on both strands in constructing a theoretical justification for the rejection of a programme of quantification in sociology since sociological measurement was incapable of meeting the necessary criteria of either abstract measurement theory or scaling.

Pre-1990 discussions of social measurement often debated the ontological validity of positivism's assertion that the social and physical worlds could be understood as essentially similar, but generally accepted an understanding of the nature of measurement as essentially concerned with quantifying social variables. More recently, developments in the philosophy of science, the innovation in methods, and the history of social quantification have moved the argument in a radically different direction. Although these labels are seldom employed by the protagonists, we can identify a realist tendency and a constructionist tendency. Realists accept the existence

of a social reality external to and separate from observers but recognize that causal processes are complex and contingent, and that any account of reality is socially constructed, albeit that it usually has some relationship to the reality it is seeking to describe. Social constructionists, typified by Desrosières, do not deny the reality of measurements but consider that this is a product of the general social use of them—a conventionalist approach. Social measurements are real because people act on them as if they were.

New Metatheories and Social Measurement

Realism offers a social ontology that can combine social constructionism and an acceptance of the existence of the objects of measurement. The essential relevant realist proposition is that social outcomes are complex, which means that they are generated by a multiplicity of processes and their interaction effects. In consequence, we cannot understand them through analytical processes nor access them through controlled experimentation.

This is compatible with the social constructionist account of social structure, but it does not correspond to Desrosières' extreme formalism in which the reality lies in the conventionally established social measurement that cannot be established as corresponding to anything existing prior to its construction. The realist position regards the objects that we measure as real, although recognizing that the social process of measurement shapes the form in which we know them in quantitative terms.

Realist approaches must be contrasted with the traditional understanding of measurement as constructed around real variables. Abbott has characterized 20th century social science as obsessed with causal analysis purporting to describe the relationships among variables that have a real existence separate from the social entities, macro, meso, or micro, from which analysis has abstracted them. Traditional measurement theory seems doubly Platonist in its assertion first of the necessary isomorphism of mathematical structures with social reality and second in its insistence on the reality of the things—abstracted variables—which vary separate from the cases for which that variation is measured.

The insistence of traditional discussions of measurement on the significance of validity is revealing. Measurement processes are considered to be of value to the extent to which they achieve a valid measurement, i.e., to the extent to which the measurement generated corresponds to the true value of the real variable across the range of cases for which measurements are made—construct validity. Yet, in general, validity can only be established not in content terms, which would necessarily involve an ability to specify the character of the domain of interest prior to and beyond the measurement process, but through predictive validity where it is the performance of the measure which signifies. The influence of factor analytical techniques on such theorization of measurement is considerable since these techniques seem to provide a mathematical solution to the problem of accessing the real—the factors—through indirect measurement of attributes of cases. However, factor analysis cannot establish the reality of the factors. Moreover, factors are intrinsically abstracted from data about cases; they exist separate from any real case.

The Classical Approach—Measuring Variables

Operationalization

All actual measurements of variables are achieved by a process of operationalization in which some rules for the measurement process are specified and these, when enacted, generate the measurement. These rules of process constitute the operational definition of the variable measured. Carley points out in a discussion of the special case of social indicators something which has general force in describing the relationship between a set of measurements based on an operational definition and the underlying concept to which the measurement set is supposed to correspond. We must accept, and properly should specify, the nature of the causal linkage between the observable phenomena which give rise to the measurement and the unobservable underlying reality. For Carley, this requires the specification of a theory of relation between empirical observations and the underlying system that gives rise to them.

Auxiliary Theories

Blalock reiterated his longstanding argument that we cannot rely on a single theory of measurement to sustain the relationship between the enactment of operational definitions and our conceptual formations. Rather, we are forced to bring into play a whole set of auxiliary theories, many of which cannot not be tested. In contrast with approaches in psychology which distinguish between direct and indirect measurement, Blalock suggests that we can never achieve direct measurement but that all social measurement is necessarily indirect and dependent on a causal model that incorporates to the best of its abilities the auxiliary measurement theories that inform the construction of that model.

Measurement by Fiat

Cicourel asserted, correctly, that generally the approach adopted by researchers in order to resolve these problems

was simply to measure by fiat. In effect, whatever indicator is conveniently available is declared to be an indicator of an underlying theoretical construct. There is an interesting literature on definitions of social class which illustrate this issue exactly. We can say with some confidence that whenever things are measured without a specific justification of correspondence between underlying concept and operational definition then the measurement is by fiat alone.

Classification—Problem or Solution?

The Problem of Multidimensionality

The apparently most elementary form of measurement is classification: the assignation of a value on a nominal variable to a case in order to indicate membership of a particular set—for example, to use the number one to indicate membership of the set of males and the number two to indicate membership of the set of females. Traditional variable centered analysis has tended to be scornful of mere categorization. This is in part because until the development of logistic regression and related techniques, it was difficult to employ categorical variables in causal modeling. However, Blalock made a more subtle point when he noted the tendency of social scientists to rely upon classification as a way of handling multidimensional variation. In general, social scientists did not properly engage with issues of multidimensionality in their data. Blalock's specification of the issue again involved intrinsic reification of variables, although the variables were now understood in a more complex way as ordered along multiple rather than single dimensions. Here, classifications can be understood as devices for taking note of multidimensionality which did not handle the real nature of such multidimensional real variables.

Theories of Classification

In general, the theorization of classification has been quite distinctive from the theorization of measurement. Essentially, the establishment of categories has been regarded as the major problem in taxonomy with the assignation of cases to membership of those categories—the actual process of nominal measurement—being secondary. Recently, the actual processes of typing have been subject to theoretical consideration. Bowker and Star, drawing in part on the conventionalist tradition that informs Desrosières' work, have returned to the distinction between Aristotelian and prototypical approaches to classification. In the Aristotelian scheme class membership depends on the possession of a given set of one or more distinctive attributes—nominal variable values in conventional measurement terms. The prototypical approach assigns cases to categories through comparison with a framed "ideal" of the category in a rather holistic sense. This basic distinction has considerable implications for our understanding of measurement because the Aristotelian approach is essentially analytical and compatible with a belief in the reality of variables, while prototypical categorization does not depend on analysis and hence does not require the measurement of variables as such. Of course, real classifications as social practice do, as Bowker and Star point out, usually involve some mixture of the two approaches but the distinction has considerable significance for our understanding of what measurement is actually dealing with.

Generating Typologies through Numerical Taxonomy

In measurement, the development of technology can have a profound influence on the actual processes by which things are measured, and one of the crucial tasks of theory in relation to measurement is to examine this relationship and its outcomes. Any theory of instrumentation must recognize that instruments are part of the process through which measurements are constructed and that developments in them have profound implications for what we are actually doing. Of particular significance in relation to classification has been the development of a set of techniques in which measures of variation across a large number of attributes for a large number of cases can be used not only to assign those cases to a preexisting set of categories but to actually generate categorical schemes ab initio. The original techniques for doing this were based on clustering algorithms using matrix algebra approaches. More recently, neural nets have been used for the same purpose. Although the underlying programming basis of the two approaches is very different, output is much the same and that is what matters here.

In numerical taxonomy, information about a large set of variate attributes of the members of a large set of cases is employed to make comparisons among those cases and to assign the cases to sets which are based on the principle of maximizing within set similarity and minimizing similarities among sets themselves. It is important to realize that this is not a simple Aristotelian polythetic scheme. In such a scheme, which corresponds exactly to locating a case within a cell in a multidimensional contingency table, cases must share all the attributes to be assigned to the set. Numerical taxonomies, which originally required that the attributes used to classify be measured as continuous data, do not impose this stipulation. This applies even when categorical variable attributes are used as the classifying principle. This, intuitively, has much in common with Ragin's understanding of fuzzy sets. The actual process of a hierarchical cluster analysis would

seem to have a considerable prototypical component in that clusters are established on the basis of most similar (in practice least dissimilar) cases and then other cases are progressively assigned to clusters in a process of fusion with the most similar being joined together to form a new cluster. Iterative relocation is possible at any given stage. The mathematically complicated process generates results with considerable intuitive appeal—an outcome which can readily be understood in the light of recent developments in cognitive theory.

Taking Cases as the Focus

Establishing Causality from Case-Based Data

Traditional causal analysis has employed regression-derived techniques that rely on an underpinning general linear model in order to specify causal relationships among variables. In sociology, a radically different approach has been available since Znaniencki's formulation of the approach of analytic induction, which was derived from a contrast between the population based approaches underpinning probabilistic statistical causal reasoning and the focus on single cases of bench scientists. In a series of works culminating in his discussion of fuzzy set approaches, Ragin has developed a method of establishing causal configurations which in contrast with statistical reasoning's emphasis on the (single) causal model, recognizes that particular outcomes may be produced by different combinations (configurations) of causes. The fuzziness indicates that set membership is not an absolute but may be a matter of degree. Although Ragin does not discuss realist metatheory, his approach has much in common with realism's understanding of the nature of causation. Coming from a different direction, Karl Popper's attention in his later work to "single case probabilities" has similar implications for our understanding of measurement.

The issue is that case-based approaches regard the case as the center of attention, not some reified variable that is abstracted out with the case. The contributors to Ragin and Becker review the implications of this important distinction. Traditional measurement theory was concerned with validation of variables. Case-based approaches are concerned more with answering in the particular, the general question posed by Ragin and Becker: What is a case? In quantitative social science the case is typically an entity—a country, a city region, a household, a firm. It might seem that the cases of this kind have a clear and coherent identity, but consideration of the example of city–region shows that this is not necessarily so. Therefore, the establishment of boundary conditions—delimiting cases from other cases—becomes a crucial task of measurement.

Handling Large Numbers of Cases in Causal Inference

Ragin's work was developed for macrosocial comparisons in relation to radical social changes. However, the same case-based logic of measurement can be applied to the elucidation of complex and multiple causal processes when dealing with large numbers of cases at the micro- or mesosocial levels. This requires us to think dynamically, to think about processes of change through time as crucial for social understanding and to recognize that a primary purpose of measurement is documenting the character of such changes through time. Here, a commonplace of general social theory becomes crucial to our understanding of what measurement is for. "Scientific measurement" as part of the Newtonian programme of science has been concerned with documenting changes of degree, hence the status accorded to continuous scale measurement. Social theory is much more concerned with changes of kind, with quality as type rather than quantity as number.

There is a variety of time-ordered approaches in quantitative methodology but they are typically variable centered. Time-ordered numerical taxonomies offer interesting possibilities for measurement in the sense of specifying trajectories of cases through time understood in a socially appropriate fashion. The time dimension for an ensemble of cases need not be calendar time, although that should always be recorded, but rather time of process, for example, stages in the treatment regimes (the plural is necessary) for patients going through a career as a person with a mental illness. We have no difficulty in demarcating the boundaries of the case understood as individual patient, but a crucial task of measurement is the specification of the boundaries of specific stages of process. Such approaches are in the early days of development, but they do seem to have considerable potential for elucidation of complex causation.

The Implications of Complexity Theory

Recent developments in complexity theory have profound implications for our general approach to measurement. Once our interest is focused on complex systems in which the interaction of parts of the system with each other, with the system as a whole, and with other systems becomes central to our process of understanding, then the purpose of measurement can no longer be understood in terms of a variable centered approach to the understanding of causality. Complex systems are characterized by emergence and the character of their trajectories, and in particular, changes of kind (phase shifts) cannot be understood by a programme of analysis. Byrne has proposed that our measurements must now be understood

not as measurements of real variables, except in the special circumstances where some external variation is imposed on the system, but rather as descriptions of variate traces of the system. This usage has two potential advantages. It reminds us that what matters is the system and that the measurement is a temporary, albeit useful, description of a characteristic of the system. It also emphasizes the significance of dynamism in measurement. Measurements are most useful when they enable us to record processes of change. Necessarily measurement of variate traces of complex systems must be multidimensional although there are interesting questions as to direct and indirect measurement to be considered here.

Measurements are external to the system and the variate traces measured do not necessarily correspond to any component of the system. They can be used to type the system. Examination of interaction among variate traces can also offer some clues as to the nature of complex processes driving emergence within the system and in engagement with other systems.

Complexity theory reinforces the significance of categorization as fundamental to social measurement. Complex systems are characteristically robust. Most of the time they remain much the same in character although by no means static. However, they can and do undergo phase shifts—transformations of kind—which we might consider metaphorically as metamorphoses. They become something very different without ceasing to exist. Most social sciences are profoundly engaged with such transformations and we can only identify them if we can specify kinds and measure change of kind, including the possibility that change of kind might involve not just the relocation of a complex system in an existing taxonomy but the creation of a whole new set of available categories of kind. Theorization of both the processes of taxonomy and the nature of transformation is essential to the measurement of complex change.

Cognition and Measurement—A Radical Departure

Lakoff, together with a range of coauthors, has argued for a radical recasting of our understanding of the relationship among human cognition and perception, language, and knowledge. The key phrase in this argument is embodied mind and the proposition is that knowledge as a product of human action derives from the relationship between human cognition and language and the world itself. Our systems of ideas are grounded in bodily experience—a wholly rational and modern version of Heidegger's antirational and antimodern assertion of dasein. Lakoff and Johnson subtitled the first chapter of their book "How cognitive science reopens central philosophical questions." This is a bold claim but they make a very convincing argument. Here, we can simply say that the notion of embodied mind is as fundamental for our theorizing of measurement as it is for everything else in the episteme. It is worth noting that these approaches seem wholly compatible with an emergent realist understanding of measurement. We come equipped—have been rendered equipped through evolutionary process—to understand and to know in a way that reflects and is shaped by our embodied selves' relationship with a real external world. Our inherent classificatory abilities are just one instance, albeit a very important one, of this capacity.

Conclusion—Theory and Measurement at the Beginning of the 21st Century

Twentieth century theorization of measurement was profoundly influenced by the idea of the variable as real. There have always been countervailing currents, particularly from that part of empirical sociology that was explicitly informed by social theory, but the notion of the variable and the problem of validating measurement of it dominated discussion and debate. In the last quarter of the 20th century, a range of new ideas has emerged—from empirical research in terms of the development of case-based methods, from philosophy of social science as critical realism, from systems theory with the development of understanding of complex systems, and from cognitive science with the proposition of the embodied mind. These have the most profound implications for the way we think about what it is we are measuring, what our measurements are, and what our measurements are for. The elements identified above come together as realist in their understanding of the answers to all these questions.

In contrast, the conventionalist approach, which in a somewhat different guise informed the more sophisticated versions of 20th century positivism, has been reinvigorated by arguments grounded in the sociological and historical examination of data construction. We must note however that in the hands of the one of the most sophisticated proponents of this position, Desrosières, even the conventions become real as we act in accordance with the implications of our social measurements. It seems likely that the debate between the conventionalist and realist understandings of measurement will be key to our understandings in the first part of this new century.

Theta Reliability

Mike W. L. Cheung
The University of Hong Kong, Hong Kong

Paul S. F. Yip
The University of Hong Kong, Hong Kong

Glossary

alpha coefficient A measure of internal consistency of a composite score.
composite score A score created by summing over several weighted or unweighted scores.
essentially tau-equivalent tests Measurements of the same construct (true score) with the same units of measurement, with differences by a constant, and possibly with different precision (error variance).
internal consistency The degree of interrelatedness among items.
parallel tests Measurements of the same construct (true score) in identical units and with the same precision (error variance).
principal component analysis A multivariate technique to reduce a large number of items to a smaller number of independent composite scores.
reliability coefficient An estimate of reliability; can be interpreted as the ratio of true score variance to observed score variance.
theta coefficient An alpha coefficient that is maximized by using optimal weights in creating the composite score.

The theta (θ) coefficient is an index of internal consistency for a composite score. It was proposed in the 1970s by David J. Armor as an alternative measure of internal consistency in tackling several problems encountered by the alpha (α) coefficient, which had been introduced in the 1950s by Lee J. Cronbach. Theta reliability can be interpreted as an alpha coefficient maximized by using optimal weights in creating a composite score. It is directly related to principal component analysis. In this article, a real example is offered to demonstrate the procedures for estimating the theta coefficient, and how these procedures contrast against those used for estimating the alpha coefficient is discussed.

Introduction

Reliability is a general term that is used frequently in daily life. For instance, a train schedule may be said to be very reliable, meaning that trains arrive and depart according to the times indicated in the schedule. However, real-world interpretations of reliability are quite different from scientific usages of the reliability concept in social measurement. In social sciences, reliability refers to the dependability, consistency, or repeatability of test scores for a particular population; validity refers to what the tests are supposed to measure. Using the scientific definition of reliability, for example, trains are reliable if they arrive and depart at nearly the same time, regardless of the times indicated on the schedule. If the trains consistently arrive and depart at the same time, as well as match the times indicated in the schedule, then the train schedule can be considered valid. Returning to the definition of reliability, then, there are two types of reliability: (1) consistency of items in a scale and (2) stability (test–retest) of the scores across time. For the purpose of this discussion, the term "reliability" will refer to internal consistency, as opposed to stability.

Reliability

Two concepts of the reliability coefficient merit discussion: the reliability coefficient for a single score and the reliability coefficient for a composite score; the alpha coefficient is an estimate of the latter.

Reliability of Single Scores

The most frequently used model to define reliability is the classical test, or true score, theory. In the classical test

theory, the observed score x is assumed to be an additive combination of the true score t and the measurement error e. The basic equation of the classical test theory is

$$x = t + e. \tag{1}$$

Two reasonable assumptions are generally made. The measurement error, in the long term, is zero and the measurement error and the true score are not correlated. That is,

$$E(e) = 0 \tag{2}$$

and

$$\mathrm{cov}(t, e) = 0, \tag{3}$$

where $E(\cdot)$ is the expected value operator. It can be shown that the variance of the observed score σ_x^2 can be decomposed into the variance of the true score σ_t^2 and the variance of the measurement error σ_e^2,

$$\sigma_x^2 = \sigma_t^2 + \sigma_e^2. \tag{4}$$

The reliability coefficient of the measurement x, $\rho_{xx'}$, where x and x' are two parallel tests, is defined as the ratio of true score variance to the observed score variance. That is,

$$\rho_{xx'} = \frac{\sigma_t^2}{\sigma_x^2}. \tag{5}$$

There are several interpretations of the reliability coefficient. One direct interpretation, as indicated in Eq. (5), is the ratio of the true score variance to the observed score variance. When the reliability coefficient of a test score is high in a particular sample, the suggestion is that a large portion of the variation of observed scores is due to the true score rather than to the measurement error. A second interpretation of the reliability coefficient is the correlation between two parallel tests or items. Thus, the higher the reliability coefficient, the higher the correlation between two parallel tests.

Reliability of Composite Scores

The single-score reliability model is based on a single item x. It is generally accepted that a single item alone is not sufficient to measure constructs in social sciences. Constructs in social sciences are complicated by nature. To measure or define a construct properly, several items are usually required. In addition, the reliability of a single item measurement is usually too low for applied research; a high degree of reliability is a necessary (though not singularly sufficient) condition for a high degree of validity for a measurement. Therefore, social science researchers prefer measurements that include multiple items that can capture constructs comprehensively and reliably.

Suppose that there are several (say p) items $\mathbf{x} = (x_1, x_2, \ldots, x_p)$, where $\mathbf{x}$ is a $p \times 1$ observed vector taken to be distinct indicators of a theoretical variable of interest; the classical test theory for the multivariate case is

$$\mathbf{x} = \mathbf{t} + \mathbf{e}, \tag{6}$$

where $\mathbf{t}$ and $\mathbf{e}$ are the $p \times 1$ true scores and the $p \times 1$ measurement errors. Following Eqs. (2) and (3), it is also assumed that the expected value of the measurement error $\mathbf{e}$ is a $p \times 1$ null vector $\mathbf{0}$ and the variance–covariance matrix between $\mathbf{t}$ and $\mathbf{e}$ is a null matrix $\mathbf{0}$,

$$E(\mathbf{e}) = \mathbf{0}, \tag{7}$$

and

$$\mathrm{cov}(\mathbf{t}, \mathbf{e}') = \mathbf{0}. \tag{8}$$

Then the variance–covariance matrix of $\mathbf{x}$ can be decomposed into two parts,

$$\Sigma_x = \Sigma_t + \Sigma_e, \tag{9}$$

where Σ denotes the $p \times p$ variance–covariance matrix. Two important things are worth mentioning here. First, measurement errors are usually and reasonably assumed to be uncorrelated with each other. Thus, Σ_e is a diagonal matrix in which the diagonals represent the variances of the measurement error for $\mathbf{x}$, whereas the off-diagonals (covariances of the measurement errors) are all zeros. Second, the off-diagonals of Σ_x and Σ_t are exactly the same, because Σ_e is a diagonal matrix. This means that only the observed variances in Σ_x are inflated by the measurement error, whereas the covariances in Σ_x are not inflated by measurement error.

Now consider the composite score y as a linear combination of $\mathbf{x}$ with any nonnull $p \times 1$ vector of weights $\mathbf{w}$,

$$y = \mathbf{w}'\mathbf{x}. \tag{10}$$

Then the variance of the composite y can be expressed as a sum of true score variance and measurement error variance by

$$\begin{aligned} \mathrm{var}(y) &= \mathbf{w}'\Sigma_x\mathbf{w} \\ &= \mathbf{w}'\Sigma_t\mathbf{w} + \mathbf{w}'\Sigma_e\mathbf{w}. \end{aligned} \tag{11}$$

Similar to the definition of the reliability for a single score, the reliability coefficient $\rho_{yy'}$ for the composite score y can be defined as

$$\begin{aligned} \rho_{yy'} &= \frac{\sigma_t^2}{\sigma_y^2} \\ &= \frac{\mathbf{w}'\Sigma_t\mathbf{w}}{\mathbf{w}'\Sigma_y\mathbf{w}} \\ &= \frac{\mathbf{w}'\left(\Sigma_y - \Sigma_e\right)\mathbf{w}}{\mathbf{w}'\Sigma_y\mathbf{w}} \\ &= 1 - \frac{\mathbf{w}'\Sigma_e\mathbf{w}}{\mathbf{w}'\Sigma_y\mathbf{w}}. \end{aligned} \tag{12}$$

Because Σ_t and Σ_e are both latent (unobserved) scores, different estimates may have different reliability coefficients.

Alpha Coefficient

One of the most popular estimates of the reliability coefficient is Cronbach's alpha coefficient proposed. The alpha coefficient is used to estimate the internal consistency of a composite score. Estimating the reliability requires estimating a diagonal matrix represents the variances of measurement error. Assuming the items are essentially tau-equivalent (i.e., the difference between any two true scores is a constant only), internal-consistency approaches operationalize Σ_e as

$$\Sigma_e = \mathbf{D} - \bar{c}\mathbf{I}, \tag{13}$$

where $\mathbf{D}$ is the $p \times p$ diagonal matrix taken the diagonal elements of Σ_y, $\bar{c}$ is the average item covariance of the off-diagonal elements of Σ_y, and $\mathbf{I}$ is the $p \times p$ identity matrix.

The general idea is that the matrix $\bar{c}\mathbf{I}$ will be close to the expected variances of $\mathbf{x}$ when there is no measurement error. Thus, the differences between the observed variances $\mathbf{D}$ and the expected variances without measurement error $\bar{c}\mathbf{I}$ are used as the estimates for the elements in Σ_e. Following this rationale, Eq. (12) can be operationalized as follows (which is also equivalent to the general form of the alpha coefficient):

$$\alpha = \frac{\mathbf{w}'[\Sigma_y - (\mathbf{D} - \bar{c}\mathbf{I})]\mathbf{w}}{\mathbf{w}'\Sigma_y\mathbf{w}}. \tag{14}$$

It can be shown, with some calculations, that the alpha coefficient can be simplified to

$$\alpha = \frac{p}{p-1}\left(1 - \frac{\mathbf{w}'\mathbf{D}\mathbf{w}}{\mathbf{w}'\Sigma_y\mathbf{w}}\right). \tag{15}$$

If a composite score is formed by an unweighted method, that is, $\mathbf{w}$ is taken to be a $p \times 1$ unit vector of 1s, the alpha coefficient can be reduced to the familiar form,

$$\alpha = \frac{p}{p-1}\left\{1 - \sum_{i=1}^{p}\frac{[\mathrm{var}(x_i)]}{\mathrm{var}(y)}\right\}. \tag{16}$$

It is well known that the alpha coefficient equals the reliability coefficient only when all the items are essentially tau-equivalent. In instances when essentially tau-equivalence is not established, the alpha coefficient sets a lower bound for the reliability coefficient.

Theta Reliability

The alpha coefficient has several unrealistic assumptions imposed on the items. Several researchers have tried to release some assumptions required by the alpha coefficient (for instance, the maximum alpha proposed by Peter M. Bentler and the theta coefficient proposed by Armor). Armor proposed the theta coefficient as an alternative index for the internal consistency of a composite score, whereas the alpha coefficient assumes items are essentially tau-equivalent, meaning that true scores of all items are different only by a constant. Therefore, equal weightings are used to calculate the composite score and to estimate the internal consistency.

Practically speaking, the assumption of essentially tau-equivalence is difficult to satisfy. First, items may measure more than one single construct. Second, they may measure one single construct differently by a different proportion of true score variances, even if they are measuring only one single construct. In other words, items contribute different proportions of true score variances to the composite score when items are not essentially tau-equivalent. Thus, using unit weights for the alpha coefficient is not the optimal choice in this situation.

Formula

As indicated in Eq. (15), the estimated internal consistency depends on the chosen weighting vector $\mathbf{w}$, given the same set of data. A unit vector of 1s is chosen as the weighting vector in the alpha coefficient, whereas Armor proposed to estimate the theta coefficient by finding an optimal weighting vector $\mathbf{w}$ where the alpha coefficient is the maximum. From Eq. (15), the alpha coefficient will be at a maximum when $\mathbf{w}'\mathbf{D}\mathbf{w}/\mathbf{w}'\Sigma_y\mathbf{w}$ is at a minimum, or $\lambda = \mathbf{w}'\Sigma_y\mathbf{w}/\mathbf{w}'\mathbf{D}\mathbf{w}$ is a maximum. Thus, if the maximum of λ is found, a maximized alpha coefficient can also be obtained directly. It is usually more convenient to define a $p \times 1$ vector $\mathbf{u} = \mathbf{D}^{1/2}\mathbf{w}$, or equivalently, $\mathbf{w} = \mathbf{D}^{-1/2}\mathbf{u}$, such that λ can be rewritten as

$$\hat{\lambda} = \frac{\mathbf{u}'\mathbf{D}^{-1/2}\Sigma_y\mathbf{D}^{-1/2}\mathbf{u}}{\mathbf{u}'\mathbf{u}}. \tag{17}$$

It is then recognized that $\mathbf{D}^{-1/2}\Sigma_y\mathbf{D}^{-1/2}$ is the correlation matrix (say $\mathbf{R}$) of $\mathbf{x}$. Thus, λ can be simplified as

$$\lambda = \frac{\mathbf{u}'\mathbf{R}\mathbf{u}}{\mathbf{u}'\mathbf{u}}. \tag{18}$$

To maximize λ, it can be differentiated with respect to $\mathbf{u}$ to give

$$\frac{\partial\lambda}{2\,\partial\mathbf{u}} = \frac{\mathbf{R}\mathbf{u} - \lambda\mathbf{u}}{\mathbf{u}'\mathbf{u}}. \tag{19}$$

Setting the derivative to zero yields

$$(\mathbf{R} - \lambda\mathbf{I})\mathbf{u} = \mathbf{0}. \tag{20}$$

Then maximizing λ is equivalent to finding the eigenvalues of the correlation matrix $\mathbf{R}$. Because $\mathbf{u}$ is a nonnull vector, this suggests that

$$|\mathbf{R} - \lambda\mathbf{I}| = 0, \tag{21}$$

where $|\cdot|$ denotes the determinant of a matrix. There is a well-known solution for this problem in the context of principal component analysis. The solution for λ in Eq. (21) equals the largest root (say λ_1) in the principal component analysis. The theta coefficient can then be expressed as

$$\theta = \frac{p}{p-1}\left(1 - \frac{1}{\lambda_1}\right), \tag{22}$$

with

$$\mathbf{w} = \mathbf{D}^{-1/2}\mathbf{u}, \tag{23}$$

where $\mathbf{u}$ is the eigenvector of $\mathbf{R}$ corresponding to λ_1.

Relationship to Principal Component Analysis

From the preceding formulas of the eigenvalue equation, the theta coefficient is directly related to principal component analysis. Indeed, it can be shown that the proportion of variance explained by the first principal component equals $1/[p - \theta(p-1)]$. Thus, the results of the principal component analysis are generally used to estimate λ_1 and its corresponding eigenvector $\mathbf{u}$ to calculate the theta coefficient and its corresponding $\mathbf{w}$ for creating the composite score. It is important to note that although principal component analysis and theta reliability are closely related, they serve different purposes and interpretations. Theta reliability measures the internal consistency (interrelatedness) for a set of items whereas principal component analysis measures the dimensionality of a set of items. Items with high internal consistency do not necessarily imply that they are unidimensional.

Advantages

Armor suggested two conditions in which the theta coefficient is more useful than the alpha coefficient in estimating internal consistency. The first condition is when items measure two or more independent constructs either equally or unequally. The second condition is when the items measure a single construct, but do so unequally. For the first condition, the theta coefficient does not require all items to be unidimensional. Because theta reliability is related to the largest eigenvalue and its corresponding eigenvector, items not related to the primary dimension (the one with the largest eigenvalue) are downweighted with a smaller eigenvector. Thus, the effects of items not related to the first dimension will be minimized in the composite score by using smaller weightings. Second, when items are not loaded equally on the true scores, theta reliability uses optimal weights to create the composite score and to estimate its reliability. Therefore, the theta coefficient is always larger than (or at least equal to) the alpha coefficient. Because the estimate of the theta coefficient is based on the correlation matrix of these items, it is also invariant to the scales of the items. In other words, changing the scales of the items has no effect on the theta coefficient.

Procedures and Illustrations

To illustrate the procedures for calculating theta reliability and contrasting it with the alpha coefficient, a real data set on the Center for Epidemiologic Studies Depression Scale (CES-D) conducted in 2001 by the Family Planning Association of Hong Kong was used. The data were collected from 2864 Secondary 3 (Grade 10) to Secondary 7 Hong Kong Chinese students. The scale consisted of 20 5-point Likert scale items measuring a unidimensional factor. The descriptive statistics are shown in Table I. The alpha coefficient is 0.90, which suggests that the items, on average, are reasonably interrelated. As suggested by many researchers, the values of the alpha coefficient are affected by two factors: (1) the average interitem correlation and (2) the number of items. Consider, for example, the alpha coefficient for a set of weakly interrelated items can still be very high when there are numerous items in the scale. Moreover, the alpha coefficient may not be good enough to indicate which items are problematic (not related to other items).

By conducting a principal component analysis, the largest eigenvalue λ_1 is 8.22. Substituting λ_1 into Eq. (22), the estimated theta coefficient is 0.92. The principal component loadings, also known as factor loadings, and the weightings for creating the composite score with the theta coefficient are shown in Table II. The optimal weights for the theta reliability are created by the principal component loadings divided by their corresponding standard deviations. All of the principal component loadings are reasonably high except for the recoded items. As shown in Table II, the recoded items (x_4, x_8, x_{12}, and x_{16}) appear to be problematic. To adjust for this, these items were downweighted in the composite score.

Apart from using the theta coefficient, an attempt can be made to delete the problematic items and recalculate the alpha coefficient. After deleting the four problematic items, the alpha coefficient is 0.93. The largest root, λ_1, after deleting the problematic items is 8.12 and the theta coefficient is 0.94. In this case, the alpha coefficient and the theta coefficient are quite similar.

Conclusions

Theta reliability provides an alternative measure of internal consistency for a set of items and has been shown to be a good index for measuring internal consistency. For instance, it is less influenced by the violation

of unidimensionality and unequal loadings of the true scores on the items. It is also scale invariant, meaning that it is not affected by scale changes. It is not difficult for applied researchers to estimate theta reliability and to calculate the optimal weights by using results from principal component analysis. Practically speaking, the alpha coefficient is generally close to the theta coefficient if the items are reasonably good. The discrepancy between them is large only when there is more than one independent dimension and/or when the items are loaded differently on the true scores.

Glossary

achievement test An instrument intended to measure what has been learned, such as arithmetic computation skills.
aptitude test An instrument intended to measure learning potential or capability to learn; college entrance examinations, for example, measure aptitudes.
Army Alpha A standardized job placement test used by the U.S. Army in World War I; was the largest mass testing effort in human history up to that time.
law of effect A principle of learning proposed by E. L. Thorndike stating that responses that are followed by satisfaction become more strongly associated with the situation and responses that are followed by dissatisfaction become less strongly associated with the situation.
learning curve The quantitative functional relationship between a measure of experience (such as number of practice sessions) and a measure of amount learned (such as time to perform a task).

Edward Lee Thorndike (1874–1949), the world's first educational psychologist, was influential in shaping the field to include educational measurement. Thorndike viewed rigorous quantitative measurement as the key to turning educational psychology (and other social sciences) into scientific enterprises. "Whatever exists at all exists in some amount." This quote from E. L. Thorndike in 1918 epitomizes his unwavering faith in quantitative measurement, and is the premise underlying many of his contributions to educational and social measurement. Thorndike contributed to improving educational methods by measuring learning outcomes, improving college admissions and personnel selection by measuring human characteristics, improving school dictionaries by measuring word frequencies, and improving communities by measuring quality of life.

The Life of E. L. Thorndike

Edward Lee Thorndike was born on August 31, 1874 in Williamsburg, Massachusetts, and remained in New England until his final year of graduate study in 1897. His childhood was shaped by time (i.e., growing up in the late 1800s), place (i.e., living in the uncomplicated and self-sufficient communities of New England), and family (i.e., being the son of a Methodist minister who moved from congregation to congregation). Thorndike's most prolific biographer, Geraldine Joncich, notes that growing up in a "clergyman's household, combined with a New England setting, was the best predictor of a future career in science" for those of Thorndike's generation.

Thorndike's education did not at first concentrate on psychology. He received a B.A. degree from Wesleyan University in 1895, where he took some psychology courses but, according to Joncich, "never publicly committed himself to psychology." Late in his undergraduate career, Thorndike read William James' *Principles of Psychology*, which Thorndike said had been more stimulating than any book he had previously read. Thorndike moved to Harvard for graduate study, where he hoped to take a course from James, but he still listed English and French as his course of study. Within his first year, he dropped English and French in favor of psychology, and became William James' doctoral student. After the Harvard administration refused to allow him to study children, Thorndike selected chickens—and eventually cats and dogs—as the focus of his soon-to-be-classic research on learning. When William James was unable to secure lab space on campus for Thorndike's research, the project was moved to the attic of the James family house. Thorndike has written that the "nuisance" (to Mrs. James) of his presence was "somewhat mitigated by the entertainment to the two youngest children." A final challenge to Thorndike's work was that his advisor, William James,

had given up on conducting experimental research in psychology and was moving back to philosophy.

After receiving a Master's degree from Harvard in 1897, Thorndike moved to Columbia University; continuing the research he began at Harvard, he received a Ph.D. from Columbia in 1898 under the sponsorship of James McKeen Cattell. His thesis, later published as *Animal Intelligence*, revolutionized the field of learning but did not interest his teachers. In the thesis, he articulated the law of effect, which was to become one of psychology's most important principles. Following a year of teaching education students at the College for Women of Western Reserve University in Cleveland, Thorndike accepted a faculty position at Teachers College, Columbia University in 1899. Thorndike remained at Teachers College for the next 50 years. Although he retired in 1940, he remained active in emeritus status until his death in 1949. During his career, Thorndike produced more than 250,000 pages of original writing in more than 500 publications. He served as President of the American Psychological Association in 1912 and as President of the American Association for the Advancement of Science in 1934. His incessant research studies revolutionized the fields of learning, transfer, and individual differences. Most importantly, he established the field of educational psychology as a science, promoting the scientific method for educational research and demonstrating its application in educational practices.

Measurement to Improve Behavioral Research: The Learning Curve

"Thorndike's lifelong preoccupation with measurement was first expressed," wrote Joncich, by the learning curves of his chickens, cats, and dogs reported in his landmark book, *Animal Intelligence*. In a typical study, a hungry cat (e.g., a 4- to 6-month old called "No. 12") was placed in a puzzle box and could escape to food outside by clawing at a loop of string that would open a small door. Over the course of many sessions, Thorndike placed the cat in the puzzle box and measured the time needed to get out. During the first session, the cat required 160 seconds; the cat took 30 and 90 seconds during the second and third sessions, respectively, and was down to 7 seconds by the 24th (and final) session. Figure 1 shows a learning curve for cat number 12; the curve represents the quantitative relationship between a measure of learning on the *y* axis (i.e., time needed to escape) and a measure of training on the *x* axis (i.e., the number of sessions). Thorndike summarized his time curves as curves for which the "lengths of one millimeter along the abscissa represent successive experiences in the box, and heights of one millimeter above it each represent ten seconds of time." Thus, Thorndike joined Hermann Ebbinghaus (who wrote *Memory* in 1885), being among the first to demonstrate a quantitative relation between amount of training and amount of learning. It is interesting to note that early training had a much stronger effect than did later training—that is, the learning curve is steep at first and then flattens out. Thorndike's meticulous measurements resulted in this characteristic shape of the learning curve that was to be replicated countless times over the ensuing century.

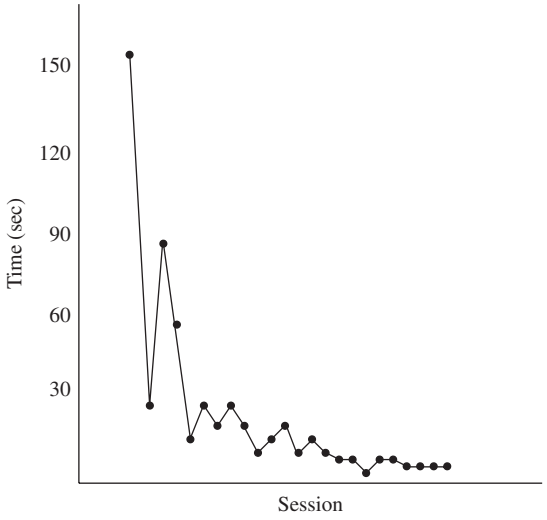

Figure 1 Thorndike's learning curve, showing the quantitative relationship between amount of experience (i.e., quantified as session number) and learning (i.e., quantified as time needed to escape from the puzzle box).

The precision of Thorndike's measurements helped reorient the field of animal learning from the realm of pseudoscientific speculations based on vague qualitative observations to an experimental science based on quantitative measurement. The precision of Thorndike's learning curves allowed him to propose the law of effect, which for more than a century has been a central pillar in psychology:

> *Of several responses made to the same situation, those which are accompanied or closely followed by satisfaction to the animal will, other things being equal, be more firmly connected with the situation so that when it recurs, they will be more likely to recur; those which are accompanied or followed by discomfort to the animal will, other things being equal, have their connections with that situation weakened, so that when it recurs, they will be less likely to occur. The greater the satisfaction or discomfort, the greater the strengthening or weakening of the bond.*
>
> [Thorndike, *Animal Intelligence*, 1911]

Most importantly, Thorndike's learning curves helped establish the fact that it was possible to quantify learning.

By measuring changes in learners due to their experience, Thorndike contributed to a breakthrough that had tremendous implications for education.

Measurement to Improve Educational Methods: Achievement Tests of Learning Outcomes

The most fundamental challenge facing Thorndike in his efforts to shape the new science of educational psychology was how to promote learning in students. He quickly realized that the improvement of education depended on appropriate quantitative measures of learning outcomes. In short, in order to determine whether a particular instructional method worked better than another did, it would be necessary to measure what was learned. Thus, educational measurement was at the center of Thorndike's vision of educational science.

In his first educational psychology textbook, *Educational Psychology*, published in 1903, Thorndike laid out the role of quantitative measurement as a vehicle for improving education: "The work of education is to make changes in human minds and bodies. To control these changes we need knowledge of the causes which bring them to pass. Such knowledge necessitates some means of measuring mental and bodily conditions; adequate knowledge necessitates accurate and complete measurements. . . . " Further, he recognized that the improvement of education depended on the use of high-quality measurements, writing in the textbook that "Commonly our measurements of mental conditions and so of the changes due to any educational endeavor are crude, individual, and incomplete . . . An adequate measurement of mental traits will be one that is precise enough for us to draw the conclusions we desire; objective or subject to individual repetition by another observer, and complete enough to take in all the features of the condition that are important for our purpose." Thorndike thus called for the creation of tests for every school subject, measuring arithmetic skills, music appreciation, English language writing abilities, and even skills of dexterity, such as the ability to use woodworking tools. To accomplish this goal, Thorndike often had to adapt new forms of measurement to academic tasks. For example, how might the handwriting of elementary school students be measured? Thorndike's solution was to have several trained raters judge the quality of handwriting using a 20-point rubric consisting of examples of each level. In creating such scales, Thorndike recommended providing "specimens at each level of goodness," ensuring that "differences between each level and the next are known with some exactitude," and making sure that "the scale extends down to a true zero." Foreshadowing more recent developments in the measurement of reliability, Thorndike also called for "measurement by a consensus of judges" in which "it is sound practice to correlate the rating by half of the judges with the rating by the other half and to increase the number of judges, if necessary, to obtain a half-with-half correlation of at least 0.90." Overall, Thorndike's advice on how to measure learning outcomes still makes sense more than a century later.

Thorndike's prescription for educational improvement was to conduct what today might be called clinical trials. In Thorndike's 1903 textbook, he wrote that "We should be able to state exactly the difference between any two human beings, between the condition of any one before and after any course of study or other educational influence; we could compare the results of different systems of education, describe the changes. . . . In the instance just quoted, A could say: 'The 600 children in my school under the old method made an average gain of 4 per cent in a year in arithmetic knowledge. . . . Under the new method the [gain is] 6 percent.'" For Thorndike, improving the effectiveness of educational methods was intimately linked to the creation of useful measures of learning outcomes.

Throughout his career, Thorndike was concerned with precise mental measurement in schools; this was exemplified in 1904 by his now classic book, *An Introduction to the Theory of Mental and Social Measurement*. One important result of Thorndike's call for quantified measures of student learning outcomes was a series of standardized tests and scales for school-related performance. These tests and scales included quantitative measures of English, composition, drawing, handwriting, reading ability, and arithmetic ability. Although the specific tests are no longer in wide use, measuring student learning has become a standard practice in education and training. Overall, Thorndike's relentless efforts to measure the learning outcomes of students resonates well with current calls for accountability based on educational standards.

Measurement to Improve Academic Admissions and Personal Selection: Aptitude Tests of Human Characteristics

Although Thorndike created or instigated many achievement tests (i.e., tests intended to measure what has been learned), he also was involved in the creation of many aptitude tests (i.e., tests intended to measure potential to learn or to perform some task). For example, suppose it is necessary to determine which college applicants should be admitted to Columbia University or which Army recruits were best suited for which jobs in the Army.

During his career, Thorndike was called on repeatedly to devise tests for college admissions and job placement.

In 1925, Thorndike devised an examination to be used for college entrance screening. To ensure proper sampling of relevant cognitive skills, he included four different types of cognitive tasks most likely to measure academic intelligence: sentence completion, arithmetic, vocabulary, and directions (the exam was thus named the CAVD exam). To ensure reliability, he devised many statistically parallel forms for each of the subtests. To insure validity, he coupled intelligence items and school content to prevent high scores by bright but poorly prepared students. The CAVD exam was not used as extensively as Thorndike had expected, partly because of the 3 hours required to take it and partly because Thorndike chose not to call it a test of general intelligence. Yet, the CAVD exam is an excellent example of Thorndike's inventory approach to mental testing—the test focused on four well-defined cognitive skills and contained a representative inventory of items measuring each of them. In addition to his contributions to general college admissions, Thorndike developed entrance tests for professional schools for engineering students and law students. He considered standardized tests, as opposed to a variety of entrance examinations, to be prognostic of future success, rather than being measures of previous educational opportunities.

In 1917, Thorndike was recruited into the Committee on Classification of Personnel for the U.S. Army in World War I; the committee was charged with the task of determining appropriate job classifications for the overwhelming number of soldiers called into action. The result was the creation and implementation of the Army Alpha, which, at the time, was the largest mass testing effort in human history. Thorndike was also instrumental in creating the Army Beta for people not literate in English. The Thorndike biographer G. J. Clifford, in the 1984 book *Edward L. Thorndike: The Sane Positivist*, noted that "by the spring of 1917 a small but active testing movement is evident with Thorndike near its center." Thorndike had already devised personnel selection tests for industry leaders, including businessmen for the American Tobacco Company. Joncich noted in his 1968 piece in the *American Psychologist* that "modern personnel divisions in industry may be dated from the time that Metropolitan vice-president Dr. Lee K. Frankel approached Thorndike to request a new kind of examination." In 1921, Thorndike and two of his colleagues, Cattell and Woodworth, established the Psychological Corporation to foster the development of tests and other kinds of measurements useful to business and industry. The goal was to apply the methods and principles of psychological science.

Are there any basic principles for designing aptitude tests? In one of his last books, *Human Nature and the Social Order*, published in 1940, Thorndike summarized his approach to the measurement of mental abilities: "There are two simple golden rules: Measure all of the ability. Measure nothing but it." Concerning the first rule, Thorndike explained that mental measurement involves taking a representative sample of the target skills: "To measure all of it does not, however, require measuring every item of it, but only that the sample be large enough and well-proportioned enough to give the same result that would be had if every item had been measured. For example, if the ability is knowledge of the meanings of English words (excluding proper names) . . . a test with even only a thousand will measure accurately enough for most purposes." Concerning the second rule, Thorndike recognized that, even though it was desirable, "to measure nothing but it" did not require obtaining a perfectly pure sample, free from all contamination by other abilities. If pure samples are unobtainable or obtainable only at enormous cost of time and effort, it is possible to manage the situation by determining the amount of contamination and allowing for it. In summary, Thorndike wrote that "measuring a human ability is usually more like taking an inventory than using a tape, or balance, or thermometer."

Is it possible to describe the character of person using numbers? For Thorndike, the answer was a resounding "yes." In his 1911 book *Individuality*, Thorndike argued that "All intelligible differences are ultimately quantitative. The difference between any two individuals, if describable at all, is described by comparing the amounts which A possesses of various traits with the amounts which B possesses of the same traits. . . . If we could list all the traits, each representing some one characteristic of human nature, and measure the amount of each of them possessed by a man, we could represent his nature—read his character—in a great equation." Thus, Thorndike was a strong proponent of the factor theory of human ability, namely, the idea that people differ along a number of dimensions. He rejected the idea that people should be classified into types: "The customary view has been that types, or particular combinations of amounts of human traits, could be found so that any individual would be much like some type and much less like any of the others. But no one has succeeded in finding such types." Thus, "there is much reason to believe that human individualities do not represent ten or a hundred or a thousand types, but either one single type or as many types as there are individuals". Overall, Thorndike's view of ability as a collection of small skills is consistent with modern views.

Measurement to Improve Educational Materials: Dictionaries for Each Age Level

How can quantitative measurement be used to improve school materials? Consider the case of school dictionaries.

Thorndike was the first to design school dictionaries based on empirical quantitative measurement. Because dictionaries at each age level could contain only a limited number of words, those words should be words that are most commonly found in normal usage. To determine the most commonly used words, Thorndike collected a corpus of 10 million running words sampled from 279 common publications such as newspapers, school books, adult literature, and even the Bible. He counted how many times each word occurred in these publications, and for each of the 20,000 most common words he determined the average number of occurrences per million words of printed text. On the basis of his word frequency counts, he was able to exclude words and technical terms not used by school children.

Thorndike then determined the specificity of his definitions based on the frequency count of the to-be-defined word. Simple words with high frequencies, such as "spoon" or "little," should be defined as simply as possible, because young readers would be most likely to look up the simple words. Difficult words with low frequencies, such as "factitious" or "feminine," could be defined more formally, because older readers would be more likely to look these up. Thus, Thorndike constructed his definitions so that the words used in definitions were as common as or more common (i.e., had the same or higher word frequency counts) than the word being defined. The following definition of "cow" violates Thorndike's principle: "The mature female or any bovine animal, or any other animal the male of which is called bull." Thorndike would replace that definition with one using terms at least as common as "cow," i.e., "(1) The large animal that furnishes us with milk, butter, and cheese. (2) The female of various animals, such as a buffalo cow, an elephant cow, and a whale cow." To make definitions clear, Thorndike included an illustrative sentence. For example, the definition of "facilitate" was "make easy; lessen the labor of; forward; assist. A vacuum cleaner facilitates housework." When a word had multiple definitions, Thorndike's dictionaries grouped similar meanings together and ordered them based on frequency of usage. For example, the most common usage of "club" is as "a stick," so this definition would be first; a less common usage of is as "a group of members," so this definition would come later. For example, the definition of "club" would be "(1) A heavy stick of wood, thicker at one end, used as a weapon. (2) Beat with a club or something similar. (3) A stick or bat for some games played with a ball, such as golf clubs. (4) A group of people joined for some special purpose, such as a social club, tennis club, yacht club, and nature-study club. (5) The building or rooms used by a club. (6) Join together for some purpose. The children clubbed together to buy their mother a plant for her birthday."

Thorndike's data-based strategy helped prune and organize definitions. For example, the *Oxford English Dictionary* available to Thorndike listed five definitions of "amenable." Thorndike would cut this list to the two definitions that actually had occurred in his frequency counts—"open to advice" (which was most common) and "accountable" (which was less common). Thorndike's dictionaries began with the *Junior* version in 1935, followed by *Senior* in 1941, *Revised Junior* in 1942, and *Beginning* in 1945. These volumes instantly became the most widely used student dictionaries in the United States, setting the standard for all subsequent student dictionaries. By applying his skills in quantitative measurement, Thorndike became one of the most important lexicographers of the era. In addition to his creation of curricular materials in language arts, he created arithmetic books (nicknamed *Thorndike Arithmetics*) that become so successful that they provided more income than his salary from Columbia.

Measurement to Improve Society: Ranking the Quality of Life of U.S. Cities

In his later years, E. L. Thorndike turned his attention to social issues such as the question of how to improve communities. This issue led Thorndike to the measurement challenge of determining what makes a good community. Consistent with his lifelong record of inventive applications of quantitative measurement, Thorndike sought ways to quantify what he called the "goodness" of all U.S. cities with populations above 30,000 in 1930. In 1939, he published *Your City*, in which he measured 310 U.S. cities on 297 quantitative dimensions, ranging from the infant death rate, to the per capita expenditures for schools, to the per capita number of telephones. Later, he published a follow-up study that examined the goodness of smaller cities. Foreshadowing similar rankings that are commonplace today, ranging from retirement communities to graduate schools, Thorndike demonstrated how it is possible to use a single number to express the quality of life of each city.

In order to create an index of the "General Goodness of Life" (which he labeled the "G score"), Thorndike selected a weighted collection of 37 measures. The measures focused on health (e.g., the infant death rate and the general death rate), education (e.g., per capita public expenditures for schools, percentage of persons 16 to 17 attending schools, and average salary of a high school teacher), recreation (e.g., per capita public expenditures for recreation), economic and social items (e.g., percentage of extreme poverty and percentage of working boys or girls ages 10 to 14), creature comforts (e.g., per capita domestic installations of telephones and per capita domestic installations of electricity), and other items (e.g., ratio of value of schools to value of jails and per capita

circulation of *Better Homes and Gardens*, *Good Housekeeping*, and the *National Geographic Magazine*). Based on this goodness index, each U.S. city with a population above 30,000 could be assigned a goodness score (or G score) ranging from 0 to above 1000. In 1930, Pasadena came in first, followed by Montclair, Cleveland Heights, Berkeley, Brookline, Evanston, Oak Park, Glendale, Santa Barbara, and White Plains.

Thorndike's task was to determine what makes a city good, and his solution was to use quantitative data and lots of it. In addition to four versions of his 37-item goodness scale, he created an 11-item P-scale of "certain desirable personal qualities" (including measures such as per capita number of high school graduates), a 9-item I-scale of "per capita private income" (including measures such as per capita number of income tax returns of $2500 or more), and a 10-item "City Yardstick" that simulated the G-score but contained items that "anyone can obtain for almost any city in a few hours." Overall, he collected more than a million facts and he seemed to revel in exploring them. For example, he noted that "per capita membership of the Boy Scouts correlates 0.56 with G" whereas "church membership correlates negatively with G." Thorndike's study of the "what makes a city good" reflects his faith in the value of measurement as a tool for improving society. He tells the reader that "Industry and business have found it profitable to use measurement as a major factor in control and improvement . . . Citizens may well do the same." Thorndike recognizes that not everyone shares his faith in numbers: "Certain humanists who abominate all efforts to measure human values, will object to the list of items and to the scores computed from them." For example, critics could argue that the G-score does not include the important things: "Radio sets, free schools, swimming pools and baby clinics cannot atone for bigotry and bad taste. What use are free libraries when people read trash?"

Thorndike's response to such criticism of his attempts to measure goodness of life were twofold: that the G-index is imperfect but "is good as far as it goes," and that "if those personal qualities which the humanist rightly admires and finds neglected by our list could be measured, and the three hundred cities were rated according to them the results would correlate with [the G-score] positively."

Thorndike's quantitative measurement of the quality of life in American cities led to some controversial observations. Commentary ran from "it is good for a city to have few very poor families," to "too much unskilled labor is bad for a city," to "disparity in income does no harm whatsoever." For Thorndike, these were factual statements based on his measurements and statistical analyses. In perhaps his most controversial analysis, he noted a strong negative correlation (−0.60) for the "percentage of Negro families with G," leading him to observe that "the fewer the Negro families, the better the score of the city on G." Yet, Thorndike saw his role as an honest presenter of facts. He stated that "The recital of these facts is in no sense an attack upon the Negro race. It would be no kindness to hide the truth." In interpreting the implications of his data, Thorndike calls for providing better treatment of minorities and full opportunities "to all human beings" as a way of eliminating this correlation, but insists that "the truth about . . . one's group is far better than misleading silence or flattery." Further, he condemned racially segregated ghettos as "wasteful and dangerous, as well as cruel" and stated that "a city should try to improve the personal qualities of all its residents."

Thorndike offers an optimistic vision of how society can use social measurement, such as his G-index, to improve life for everyone. "Any city can improve itself. Not by trying to be bigger . . . Not by building factories, shops, or offices . . . except where they are needed." In reviewing his measurements, Thorndike concluded that a city's quality of life is highly dependent on the education level and personal wealth of its inhabitants: "At least four-fifths of the differences of cities in goodness is caused by the personal qualities of the citizens and the amount of their incomes. These then are the main things to improve . . . attracting good people to their city and earning more money." Thus, improving a city requires improving the educational and economic status of the human beings who reside in it: "A community becomes great and good by giving opportunities to those who crave and deserve them." Except for his peculiar advocacy of eugenics (the "science and art" of breeding humans), much of Thorndike's evidence-based advice for improving cities still seems highly relevant today.

Conclusion

Thorndike was a quantifier. Who but Thorndike would have counted the number of times each word appeared in a large corpus of common printed materials, ranging from newspapers to school books to the Bible, resulting in a list of 10,000 or 20,000 or 30,000 common words and their rates of occurrence per million words? Each time he was confronted with a fundamental educational or social problem, his first step was to count something. He demonstrated that it was possible to assign a number to an amazing array of human activities, including the quality of a student's handwriting, the level of a college applicant's academic skill, the frequency of use of words in common publications, and the goodness of life in American cities. Thorndike's career is replete with many other examples of his quantification of social measures.

Thorndike was a pioneer who shaped the field of educational measurement. In 1901, he established in the United States the first true course in educational measurement. In 1904, he wrote *An Introduction to the Theory of Mental and Social Measurements*, which

G. J. Clifford called "the first complete theoretical exposition and statistical handbook in the new area of social-science measurement." Also, from the start, Thorndike provided a guiding vision for the field that the task of education to alter the human experience cannot be evaluated without means of measurement.

More than a century ago, Thorndike foresaw his legacy as a quantifier. In *Educational Psychology*, he wrote that "In education everything is said but nothing is proved. There is a plentiful lack of knowledge while opinions more and more abound. . . . The science of education when it develops will like other sciences rest upon direct observations of and experiments on the influence of educational institutions and methods made and reported with quantitative precision . . . Long after every statement about mental growth made in this book has been superseded by a truer one . . . the ideals of accuracy and honesty in statistical procedure by which I hope it has been guided will still be honored." Clearly, Thorndike's use of educational and social measurement created a formidable collection of products, including achievement tests, placement tests, dictionaries, and city rankings. Yet his most important contribution rests in demonstrating the inseparable relation between measurement, science, and the solution of social problems. To solve social problems (such as how to teach language arts or how to place job candidates or how to improve cities), Thorndike turned to science, and in applying science to human life, the first step involved measurement. Thus, Thorndike's most important legacy, demonstrated through his daunting list of accomplishments, is the value he placed on quantitative measurement as an indispensable feature of educational and social research. Indeed, his articulation of the role of measurement has an unmistakably contemporary ring. In an article in *Teachers College Record* in 1921, he wrote that "In proportion as it becomes definite and exact, this knowledge of educational products and educational purposes must become quantitative, taking the form of measurements."

Glossary

Alcibiades Athenian general initially chosen to lead the Sicilian expedition. He was recalled from the expedition and condemned to death by Athens, but he escaped to Sparta and helped them strategize against Athens toward the end of the war.
Athens The leading democratic city–state in Ancient Greece, of which Thucydides was a citizen.
Cleon Vengeful Athenian general and rival of Thucydides whom Thucydides consistently portrays in a negative light.
Melian dialogue Diplomatic exchange presented by Thucydides in which Athenian ambassadors justify their subsequent slaughter of the male population of the island of Melos.
Pericles Creator of the Athenian empire and the leader of democratic Athens at the beginning of the Peloponnesian War.
Sparta (Lacadæmon) The leading aristocratic city–state in Ancient Greece; the eventual victor in the Peloponnesian War.
The Peloponnesian War A 27 year military conflict between Athens and Sparta that took place between 431 and 404 B.C.E.

Thucydides (5th Century B.C.E.) is arguably the first person to engage in systematic social measurement. His lone surviving masterwork, *The Peloponnesian War*, stands as a founding text for the disciplines of history and political science. On its surface, *The Peloponnesian War* comprehensively and objectively chronicles the 27 year military struggle between Athens and Sparta from which the latter emerged victorious in 404 B.C.E. Yet Thucydides' aim and approach in recounting the Peloponnesian War is extensively debated, often reflecting enduring disagreements about the philosophy and methodology of social science.

Thucydides the Person

We know little about Thucydides' life beyond the few things he tells us in *The Peloponnesian War* itself. An Athenian citizen, Thucydides was probably born a few years prior to 460 B.C.E., likely dying shortly after the end of the Peloponnesian War. Perhaps significantly, we do know that he was elected to the office of general (*strategos*) in the eighth year of the war (424 B.C.E.) but then exiled from Athens shortly thereafter (for failing to prevent Sparta's capture of the strategically important city of Amphipolis). Thucydides also tells us that he began work on his history at the war's outset (I 1) and lived through its entire 27 years (II 65, V 26). He did not, however, live to complete the narrative, which breaks off abruptly in the autumn of 411, the 21st year of the conflict.

Overview of the Work

Far from a single cohesive nation, Ancient Greece in the 5th century B.C.E. was composed of dozens of independent city–states (*poleis*). Most of these states were, however, militarily subject to either Athens or Sparta, the two great powers in Greece at the time. At its most basic, therefore, the Peloponnesian War was a struggle for regional hegemony between these two powers: Although democratic Athens has exerted a greater influence on

the thinking of Thucydides' contemporary interpreters than has aristocratic Sparta, the latter of these two powers was clearly the stronger at the war's beginning. Indeed, as Thucydides tells us, most Greeks initially believed that the Spartans and their allies would emerge victorious from the conflict within three years (VII 28). Sparta's obvious military superiority on land, however, was offset by the supremacy of Athenian sea power, which prolonged the war and left its outcome uncertain until the fall of Athens and its empire.

Book I of Thucydides' chronicle features a wide-ranging "Archaeology" of Greek society and politics prior to the Peloponnesian War. As Thucydides recounts, the Athenians and Spartans had once been allies, forming the Hellenic League in 481 B.C.E. in order to help all of Hellas rebuff a Persian invasion. Despite major victories against their common enemy, relations between the two powers were strained, eventually resulting in the withdrawal of Sparta to lead its prewar alliance, the Peloponnesian League. The Athenians in turn created an alternative alliance, the Delian Confederacy, which accepted Megara, a defecting member of the Peloponnesian League. War broke out between the two alliances in 460 and continued until 446, when both sides accepted a peace treaty. The remainder of the narrative commences with the broken peace of 431.

From the beginning of Book II through the beginning of Book V, Thucydides recounts the first, indecisive phase of the conflict often called the Archidamian war. While the Spartans regularly attacked the Attic countryside, the Athenians responded by ravaging the Peloponnesian coastline. In this 10-year period, the Athenians also suffered a plague, intervened in Sicily, and routed the Spartans at Pylos-Sphacteria; they subsequently lost important holdings in battles near Thrace. This phase of the war culminated with what was to be a 50-year peace treaty, the Peace of Nicias, in 421.

The treaty, however, collapsed after only eight years (many of which were actually spent in open dispute). In 415, the Athenians intervened a second time in Sicily, assisting their allies, the Egestæans, and attempting to expand their empire through the conquest of Syracuse, the preeminent Spartan ally in Sicily. The subject of Books VI–VII, the so-called Sicilian war, ended with a crushing defeat for the Athenians. The effect of this defeat on Athens was all the more pronounced because it coincided with the resumption of hostilities by the Spartans and their allies closer to home. Facing Spartan troops permanently based in the Attic countryside, an increasing number of subjects in revolt, and hostile naval forces subsidized by their old enemy, Persia, the Athenians were overmatched. Despite these unfavorable circumstances, this final phase of the conflict, the Ionian or Declean war, lasted another 10 years. It ended, however, with the destruction of the Athenian navy in 405 and (after being starved into submission) the surrender of Athens in 404.

Thucydidean Method

What exactly Thucydides hoped to achieve via his history of the Peloponnesian War has been endlessly debated. Though some might make a claim for Herodotus, the more rigorous Thucydides is generally considered the inventor of descriptive history as such. Noting the absence of "romance" in his narrative, Thucydides avers that it might nonetheless "be judged useful by those inquirers who desire an exact knowledge of the past (I 22)." In turn, many have suggested that Thucydides' aim is no more and no less than to provide an accurate empirical description of the events that he recounts. Indeed, historians often remind us that Thucydides' narrative contains an astounding volume of painstaking detail, detail that Thucydides' more social-scientifically inclined readers may ignore at their peril. Yet while we cannot underestimate the importance of Thucydides' invention of comprehensive historical description, social scientists are understandably drawn to the few "causal" or "explanatory" claims that he appears to be making throughout the work.

Perhaps the most significant of these claims is Thucydides' famous comment about why the Peloponnesian War began: "The growth of the power of Athens, and the alarm which this inspired in Lacedæmon, made war inevitable" (I 23). At first blush, this passage seems to imply that Thucydides possesses a broadly "materialist" view of empirical causation. Specifically, he seems to suggest that the onset of the Peloponnesian War is fully explained by the existence of a single, concrete and observable variable: namely, *increasing Athenian power*. To be sure, many have noted that an accurate measurement of Athenian power proves elusive. In discussing the Peloponnesian War, as in other cases, debate among international relations scholars and military strategists abounds with disagreements over the degrees to which, e.g., population, wealth, geography, and munitions determine a state's "military capabilities," and, in turn, over whether it is "absolute" or "relative" military capabilities that are most significant.

More important, however, this single sentence of *The Peloponnesian War* is characteristic of Thucydides' occasional "editorial" statements in that it has likewise spawned more radical disagreement among his interpreters. Specifically, numerous scholars have noted that the most proximate cause of the war mentioned by Thucydides is not the material change in Athenian power, but rather, the more "ideational" variable of fear or "alarm" that this change inspired in Sparta. In

other words, debate over this passage closely reflects debate between idealist and materialist approaches to social science in general (as evidenced most famously via Marx's methodological critique of Hegel). Indeed, generation after generation of philosophers of social science have claimed a methodological pedigree from Thucydides. Contemporary constructivist and postmodernist scholars, for example, argue that the onset of the Peloponnesian War is explained by the breakdown of social and diplomatic discourses in 5th Century Hellas. In point of fact, however, debate over Thucydides' account of the onset of the Peloponnesian War provides only one example of how arguments about Thucydides reflect broader debates about social measurement. If anything, Thucydides' incomplete account of the outcome of the Peloponnesian war—that is, his account of why Athens loses—has proven still more suggestive to those interested in social-scientific theory and method.

As noted, a purely materialist account of Athens' defeat in the war is by no means difficult to construct. If we attend simply to the balance of power between the Spartan and Athenian sides, the fact that Athens avoided defeat as long as it did is arguably the greater mystery. Understandably, however, the balance of military power between the two sides is by no means the only variable that scholars have noted as contributing to the war's eventual outcome.

Many of Thucydides' interpreters, for example, stress the critical role in the conflict played by individual Athenian leaders. The charismatic Pericles is seen as crucial to Athens' initial pursuit of empire, the vengeful Cleon blamed for the subsequent alienation of her subject states, the perplexing Alcibiades alternately celebrated and condemned for his role in the initiation and execution of the Sicilian expedition. Despite the no doubt significant role played by these individual citizens, however, a still more common mode of explaining Athens' defeat centers on the political context in which they came to power: namely, as leaders of the Athenian democracy. Even the most prominent defenders of the benefits of democracy in the conduct of foreign policy, including Michael Doyle, note that the experience of Athens during the war casts the *demos* in a not entirely favorable light: "It is here, in Thucydides' *History*, that democracy first acquired its reputation for such disastrous factionalism" (79). In Athens, of course, the *demos* exercised much more direct control over foreign policy than it does in representative democracies today. Moreover, even insofar as it delegated some of this authority to the elected *strategoi*, Thucydides notes that the most jingoistic of these Athenian generals, such as Cleon, were often successful in appealing to what he seems to have regarded as the lowest common denominator of popular support.

We return to the question of Thucydides' moral stance in regard to the Athenian polity and its foreign policy in a moment. At present, it is enough to note that *The Peloponnesian War* raises many of the classic causal questions about whether a state's system of government influences its foreign policy: Advocates of the "democratic peace" proposition, for example (sometimes called the one "iron law" of contemporary international relations scholarship) argue that even if Athens was bellicose in its relations with Sparta and other autocracies, it avoided conflict with democratic states. In contrast, those who see democracies as possessing a particularly pronounced tendency for the foolish overextension of empire have likewise found an early cautionary tale in Athens. Last but not least, scholars intrigued by the fact that modern democracies rarely lose the wars they enter—the so-called "powerful pacifists" hypothesis—look back to the counterexample of Athens in hopes of determining whether anything inherent in democracy predicts its military success.

Yet is it appropriate for scholars to cavort across the millennia in search of universal social-scientific laws? Is not everything that Thucydides says about democracy and foreign policy so wrapped up in a bygone social context that to try and apply it to today's world constitutes a fateful *hubris*? To argue as much is certainly credible, but, to claim that Thucydides himself would have made this argument strikes us as less so. For just as he can be claimed as the inventor of "ideographic" methods and "thick description," so too can Thucydides be noted as the first researcher to possess a universalizing or "nomothetic" urge. He makes this evident, of course, in telling us that "the future ... in the course of human things must resemble if it does not reflect [the past]," and in turn that, "In fine, I have written my work, not as an essay which is to win the applause of the moment, but as a possession for all time" (I 22). It is this justly famous remark, perhaps, that constitutes Thucydides' most important and controversial contribution to the history of social measurement.

Measurement and Morality

Even if Thucydides is attracted to the project of a nomothetic social science, however, this as yet tells us nothing about how this may or may not comport with his other aims in writing *The Peloponnesian War*. He is, after all, read far less by methodologists than he is by political theorists, and apart from the question of his empirical aims stands the question of what, if any, moral lesson he wishes us to take from the narrative. Asking this question is interesting for various reasons. First, there is the possibility that Thucydides displays normative bias in recounting the events of the war, leading us to think twice about his status as an objective historian and social scientist. Alternatively, it could be that Thucydides felt that even an unbiased presentation of the facts of the war would lead the reader to certain moral or ethical conclusions. But just what are Thucydides' moral and

ethical commitments, if any? Many readers have seen Thucydides as the father of *realpolitik*, that is, of the view that morality and politics are incompatible. Such an ethos was, to be sure, frequently articulated in Ancient Greece, as, for example, by some of Socrates' more famous interlocutors. In Thucydides, *realpolitik* is most clearly defended by the Athenian ambassadors to Melos. For various reasons, however, most scholars now aver that Thucydides is little more sympathetic to these ambassadors than is Plato sympathetic to, e.g., Thrasymachus or Callicles.

While the preceding section discussed the claim that Sparta began the war out of fear, Thucydides also notes that the Spartans were compelled by the Corinthians to oppose Athenian injustices at Potidæa (I 71). The Athenians, for their part, argued that they were obligated to acquire and expand their empire out of fear of external threats, despite the knowledge that to do so would result in widespread opprobrium. In addition to this line of thought, they also suggested that "honour and interest afterwards came in" (I 75). These claims, in addition to the Athenian assertion that they are uniquely entitled to rule others, serve as the ground upon which Thucydides bases his discussion of Athens.

The most famous defense of the ethical underpinnings of Athenian war aims comes from Pericles, in an oration for the war's first fallen soldiers. He encourages the Athenians to love their city as the soldiers have and to be ready to make the same sacrifice should they be called on to do so (II 43). Athens, he says, is so beautiful and noble as to inspire love among its citizens, not merely because it is powerful but also because it acts for reasons beyond self-interest (either individual or collective). Arguably, however, this still falls well short of acting justly. As David Bolotin points out, Pericles "boasts that Athens has everywhere established everlasting memorials of evils as well as goods . . . And when he speaks of everlasting memorials of evils and goods, he has in mind the evils that Athens has suffered as well as the harm it has done to others" (20).

While Pericles may exaggerate the virtues of the Athenian people, Thucydides himself is often critical of the city in the post-Periclean era. At times, to be sure, Thucydides clearly approves of the workings of Athenian democracy. After a lengthy siege succeeded in crushing a rebellion at Mytilene, the Athenians initially determined that all the male citizens should be punished with death, and the women and children sold into slavery (III 36). A day after dispatching a ship to deliver the order, however, they experienced a change of heart and Thucydides gives a lengthy recounting of their second debate, with speeches by his perennial rival Cleon, who favored the original decree, and Diodotus, who opposed it. In the end, the Athenians adopted the position of Diodotus and hastily sent a second ship to prevent the original order from being carried out (III 49). As Michael Walzer observes, "It is the appeal to interest that triumphs—as has often been pointed out—thought it should be remembered that the occasion for the appeal was the repentance of the citizens. Moral anxiety, not political calculation, leads them to worry about the effectiveness of their decree" (9).

In stark contrast, Thucydides provides no account of any democratic process leading to the decision to attack the island of Melos and, ultimately, to kill its male citizens and enslave its women and children. Unlike Mytilene, a former ally of Athens that rebelled and joined the Spartans, Melos had chosen to remain neutral until the Athenians violently encroached on their territory (V 84). All that is recorded, this time, is the exchange between the Athenian generals, Cleomedes and Tisias, and the Melian representatives prior to the official outbreak of hostilities. Here, the Athenians remove the notion of justice from the discussion at the very outset:

> *For ourselves, we shall not trouble you with specious pretences—either of how we have a right to our empire because we overthrew the Mede, or are now attacking you because of wrong that you have done us—and make a long speech which would not be believed; and in return we hope that you, instead of thinking to influence us by saying that you did not join the Lacedæmonians, although their colonists, or that you have done us no wrong, will aim at what is feasible, holding in view the real sentiments of us both; for you know as well as we do that right, as the world goes, is in question only between equals in power, while the strong do what they can and the weak suffer what they must (V 89).*

In the end, the Melians chose not to subject themselves to Athens and were besieged. After months of fighting, Melos was betrayed by a number of its citizens and yielded to the Athenians, who put to death all the men, and sold the women and children into slavery (V 116). According to Walzer, "We are to understand that Athens is no longer itself. Cleomedes and Tisias do not represent that noble people who fought the Persians in the name of freedom . . . They represent instead the imperial decadence of the city state" (7). Whether or not the potential for imperial overreach was always present in Athenian democracy, however, it is eventually this imperial impulse that carries the day, ultimately leading to the ill-fated Sicilian expedition.

What did Thucydides himself think of Athenian imperialism and this final campaign to extend it? Thucydides clearly does not possess the outright aversion to imperialism that Walzer and most of the rest of us do today. He presents Pericles, the father of Athenian empire, in a highly favorable light, and various commentators note grounds on which the Athenian empire would have been viewed as a progressive enterprise at the time. (It is, for example, generally agreed that

the limited democracy brought by Athenian rule was embraced by the lower classes in her subject cities.) Even if this is the case, however, it is unclear that Thucydides himself was sufficiently fond of the political system of post-Periclean Athens to advocate its export to other Greek states.

In any case, a quite different account of Thucydides' stance regarding Athenian imperialism suggests that he actually condemns it for being too hesitant. This reading centers upon the mysterious destruction of the city's statues of Hermae that occurred just prior to the Sicilian expedition. The expedition was decided upon at a time of great factional conflict within Athens, and citizens sympathetic to Alcibiades, the brilliant general chosen to lead the expedition, were widely blamed for the statues' destruction. Eventually, this led to Alcibiades being stripped of his post. Thomas Pangle and Peter Ahrensdorf, among others, argue that the expedition might have succeeded were it not for this strange turn of events: "According to Thucydides, the Athenians could have conquered Sicily, and consequently could have won the war, if only they had retained the services of Alcibiades" (26).

Such a reading returns us to a view of Thucydides as an advocate of *realpolitik*. That is, rather than responding to the mutilation of the Hermae with the cool rationality that Thucydides, it is argued, himself recommends, the Athenians took drastic action in the face of a religious crime that they also interpreted as a sign of divine displeasure with their imperial ambition. "It would seem," Pangle and Ahrensdorf argue, "that the Athenians interpret the mutilation of the Hermae not in the light of their own argument on justice and self-interest but in the light of their suspicion or fear that they are guilty of injustice" (27–28). Like much else in Thucydides, however, the suggestion that he sympathizes with Alcibiades is controversial: Alcibiades is likewise responsible for undoing the Peace of Nicias, and Nicias is perhaps the only figure for whom Thucydides expresses even greater personal fondness. Commenting on his "unwarranted butchering" during the war, Thucydides remarks that "of all the Hellenes in my time, [Nicias] least deserved this fate, seeing that the whole course of his life had been regulated with strict attention to virtue" (VII 86).

Many scholars thus point to Thucydides' remark about Nicias, among other passages, as evidence that he views war as fundamentally tragic. While it would be a stretch to view Thucydides as a thoroughgoing pacifist, a case can certainly be made that he came to see the Peloponnesian War as a mistake—not just for Athens, but for all of Greece. Such a view is perhaps most strongly evidenced in Thucydides' discussion of prewar Hellenic society and politics at the beginning of Book I. For here, Thucydides speaks less of Athens and Sparta than he does of the Pan-Hellenic "country" (I 2) and "race" (I 1). Indeed, on more than one occasion, Thucydides seems to regret the fact that, except for during the war against Persia, the states of Greater Hellas proved "incapable of combination for great and national ends" (I 15), much less of uniting in "a spontaneous combination of equals" (I 16). While hardly a contemporary global citizen, then, it would seem that Thucydides is, like Socrates, drawn to the Pan-Hellenic ideal of cooperation and perhaps even confederation among Greek states (an ideal by no means uncommon in his time). Viewed from this perspective, *The Peloponnesian War* becomes a tragic story indeed, one in which an unwarranted and essentially "civil" conflict slowly engulfs a divided Hellas.

Conclusion

Obviously, we will never know exactly what sort of justice, if any, Thucydides felt that his native Athens owed to the rest of Greece and the world beyond. Nor, for that matter, will we know in what sense, if any, he thought it inevitable that states powerful enough to engage in hegemonic war will do so. We should, perhaps, take seriously the possibility that Thucydides changed his views of these issues while writing a very long narrative about a very long conflict. In any event, not only the diverse ethical thinking that Thucydides has inspired but also the numerous methods that he introduced to social measurement will continue to prove important gifts to posterity.

Glossary

centroid method A stepwise method of factor extraction, with the first factor representing the common variance in all tests, and further extracted factors representing bipolar dimensions with lower factor loadings.
g A general factor underlying scores of tests for mental ability.
oblique rotation The rotation of factorial axes with a departure from a constant angle of 90° between two axes. Rotated factors are correlated to a certain extent.
orthogonal rotation The rotation of factorial axes where the angle between two axes is held constant at 90°.
primary factors Psychologically interpretable, rotated factors derived from factor analysis of the correlations between psychological variables.
secondary factors Factors derived from factor analysis of primary factor scores.
simple structure Rotating factorial axes in order to obtain a limited number of tests loading high on a factor, and maximizing zero loadings of other tests.

One of the recurring issues in research on intelligence concerns the question of whether intelligence is one ability or whether it represents manifold dimensions of mental abilities. During the first decade of the 20th century, C. Spearman's research stressed the importance of a single, general ability underlying the performance on mental tests. L. L. Thurstone, on the other hand, argued that intelligence represented several separated mental faculties. He obtained nine uncorrelated primary factors while using another method of factor analysis (centroid extraction and rotation to simple structure) in his analyses of various test data from 240 college students. Thurstone found no evidence in favor of a common general factor (*g*). Therefore, he argued that an individual's intellectual ability should not be represented as a single IQ index, but rather should be described in terms of a profile of factor scores on the primary mental abilities. Correlations among tests in Thurstone's battery, however, appeared to be substantial. Consequently, Thurstone eventually had to acknowledge that a factor analysis of the primary factor scores revealed a general secondary component, a conclusion that is in line with findings from J. Carroll's extensive survey and reanalysis of factor-analytic studies on the structure of intellectual abilities. It is concluded that Thurstone's bequest may be the best of both worlds: IQ does indeed represent a general intelligence factor, but a more specified profile of primary mental abilities might add to the understanding of an individual's mental capabilities.

Spearman's Early Work

In 1904, Spearman used a basic form of factor analysis in order to substantiate his assumption that only one general factor was underlying the matrix of correlations between all possible pairs of tests. According to his two-factor model of intelligence, each mental test would load on a general factor (which was referred to as *g*), as well as on a factor that was specific to that test (referred to as *s*). Spearman argued that *g* should not be equated with intelligence because he regarded *g* merely as the factor common to all mental tests. At first, he assumed that each test would further load on its own specific *s* factor. Later on, he had to admit that certain groups of mental tests might have factors other than *g* in common. These so-called group factors would reveal loadings of a limited set of tests, but certainly not all tests. For instance, Spearman identified group factors for tests of verbal or spatial ability. Eventually, Spearman's two-factor model consisted of

a general factor common to all mental tests, a limited number of group factors, and residual *s* factors. Spearman, however, still stressed the importance of the general factor *g*.

Thurstone's Theoretical Focus

Thurstone's initial position was antagonistic to Spearman's. Thurstone believed that group factors were far more important than the general factor that was advocated by Spearman. He postulated intelligence to be an assembly of mental faculties, not a generalized mental ability. He argued that the general factor was an artifact of Spearman's method of factor analysis, as Spearman failed to rotate the factorial axes after obtaining an initial solution.

Thurstone's Contribution to Factor Analysis

Thurstone was an ardent advocate of factor analysis. Together with his co-workers, he developed the centroid method of factorizing, defined principles for orthogonal and oblique rotation to simple structure, and was among the first to apply matrix algebra to factor analysis.

The first step in Thurstone's method of factor analysis was to compute correlation coefficients between all mental tests in a given test battery. This matrix of correlations was expected to contain only few negative correlations, low in magnitude, because complex mental tests were assumed to be composed of a variety of common elements or grouping factors.

The second step concerned the factorization of the correlational matrix. According to the parsimony principle, the number of factors extracted was restrained: scores on a test battery were to be accounted for by fewer factors than the number of tests. In line with this principle, the centroid method for transformation of a correlational matrix to an orthogonal factorial matrix was developed. Factors were extracted stepwise, which meant that factors were extracted one at a time, and the procedure was cyclically repeated on correlational matrices with formerly extracted factors partialed out. The first centroid factor that was extracted accounted for the highest variance in common to all tests. Hence, this factor had the highest mean of factor loadings, which were positive as a rule. Next, this first centroid factor was partialed from the correlational matrix of all tests, yielding a new matrix of residuals. Then the extraction procedure was repeated, rendering a second factor with less variance accounted for, lower factor loadings, and possibly bipolar dimensions. This procedure of repeated extraction of factors was terminated whenever the residuals approached chance level. In fact, the centroid method of factor extraction resembled principal components analysis. At the time, however, the centroid method was mathematically less demanding relative to principal components analysis, which became more readily available for the analysis of large matrices after the introduction of computers.

According to Thurstone's view, the extracted centroid factors were merely mathematical constellations without psychological salience. The orientation of centroid factorial axes represented arbitrary dimensions, and the coherence of groups of tests would only reveal itself after rotation of these axes to simple structure. One of the principles underlying simple structure was the positive manifold. Thurstone did not allow tests to load highly negative on an extracted factor, as he regarded it as unlikely that factorized mental abilities would negatively contribute to intellectual performance.

Figure 1 depicts a hypothetical rotation to simple structure. Evidently, the projection of tests (i.e., the circles) on the factorial axes of A and B is not perfect, resulting in relatively low, sometimes even negative, factor loadings. Orthogonally rotating the factorial axes to the left by 20° results in high factor loadings for a number of tests (represented by black circles) on either of the rotated axes A′ or B′, whereas the tests represented by white circles load high on neither A′ nor B′. The latter tests, however, may load substantially on another factor C or its rotated equivalent C′. Rotation to simple structure starts with a first pair of factorial axes and then resumes stepwise with further pairs of factorial axes.

Returning to Thurstone's position, the aim of rotation to simple structure essentially has been to obtain a factor matrix with a limited number of highly positive loadings on each factor, while maximizing the number of zero entries of the remaining factor loadings. If *g* existed, simple structure could not be attained, as one factor would show nonzero loadings for every test. To Thurstone it was

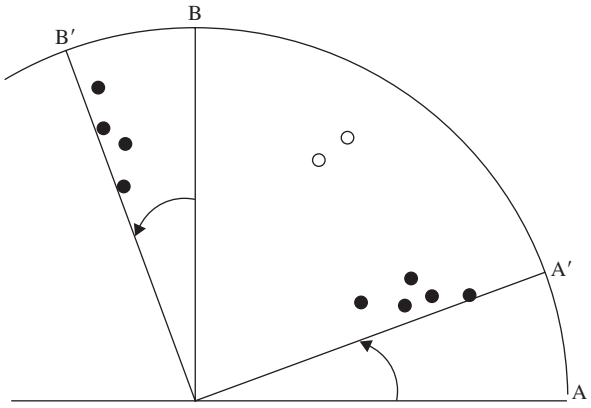

Figure 1 Orthogonal rotation to simple structure.

highly unlikely that, for instance, numerical tasks would make high demands on verbal or memory primary factors, and vice versa. Rotation to simple structure in fact endeavored to separate the sheep from the goats for each factor extracted.

At first, Thurstone relied on orthogonal rotations, which meant that the angles of all factorial axes were held constant at 90° during rotation (as depicted in Fig. 1). Orthogonally rotated factors were uncorrelated and, therefore, relatively "pure." In the 1940s, Thurstone developed the technique of oblique rotation because the primary factors emerged even more clearly from the data. With oblique rotations, he departed from the independency of factors, as he allowed for the angles between factorial axes to be less than 90°. Now the primary factors, which were intended to be entirely separated group factors, at least had some variance in common.

Primary Factors

In the late 1930s, Thurstone administered 56 mental tests to 200 students from the University of Chicago and 40 YMCA college students, who volunteered to participate in the test sessions. Mean age of participants was 19.7 years. The test battery covered a variety of mental tasks that were verbal, spatial, or numerical by nature. Tests measured fluency of production, abstraction, reasoning, or rote learning of paired associates. Some tests were adapted from existing materials, while others were especially designed and developed by Thurstone and his wife in order to cover a broad range of tasks. Many of these tests or equivalent tests are still being used in contemporary intelligence testing, e.g., figure rotation, surface development, arithmetic speed, number series, verbal analogies, syllogisms, and vocabulary. After collecting the data, a matrix of intercorrelations was first calculated from scores on the 56 tests. Almost all intercorrelations appeared to be positive, and the modal correlation coefficient was about 0.35. Next, 12 centroid factors were extracted. Orthogonal rotation to simple structure rendered nine primary factors with positive and near-zero loadings, but without substantial negative loadings. These nine factors were psychologically interpretable through the identification of common elements in tests that loaded 0.40 or more on the rotated factors. In the following paragraphs, a keyword and content description will be given for each primary factor, along with examples of pure tests that typically loaded on that factor only.

1. Spatial ability (S): The 13 tests that substantially loaded on this factor had a visual or spatial nature in common. This first primary factor should not be confused with the next factor, perceptual ability, as spatial abilities relate to mental imagery, rather than the perception of stimuli. Two representative tests were "flags," which required the rotation of nation flags, and "pursuit," which required participants to follow lines from start to end in a complex line pattern.

2. Perceptual ability (P): The nine tests that loaded on this factor to a large extent represented the facility in finding or recognizing items in a perceptual field. For instance, it involved the perception of an object that was embedded in irrelevant material. Two representative tests were "identical forms," which simply required participants to pick an object identical to the stimulus object out of an array of highly similar objects, and "word grouping," which required the categorization of easy words through the speeded perception of apparent relations among them and the identification of words that did not belong in these categories.

3. Numerical ability (N): The eight tests that highly loaded on this factor had in common a numerical nature. These tasks demanded a considerable proficiency in numerical calculation and reasoning. Pure numerical tests included those of arithmetic speed, such as "addition," "multiplication," and "division." The tests for numerical reasoning, however, also loaded on various other factors.

4. Verbal relations ability (V): The 13 tests that clearly loaded on this factor concerned the logical relations between ideas and the meaning of words. This fourth primary factor should be separated from the next verbal factor, word ability, as verbal relations pertained to the classification and association of ideas and semantics, rather than to the production of isolated words. Two characteristic tests were "inventive opposites," in which participants had to find two words with a meaning opposite to the stimulus word, and "verbal analogies," which required participants to find a relationship between two given words and to choose a target word by applying that relationship to another stimulus word.

5. Word ability (W): The six tests that loaded on this fifth primary factor were characterized by a fluency in dealing with isolated words. Both "disarranged words" and "anagrams" were relatively pure W-tests, which required participants to rearrange a jumbled sequence of characters in order to obtain a meaningful word.

6. Memory ability (M): The five tests that substantially loaded on this sixth factor concerned the recall or recognition of paired associates that had been presented shortly before. The two most unambiguous tests were "word-number," which involved the memorization and recall of paired associates of stimulus words and response numbers, and "initials," which required the memorization and recall of a list of names with initials.

7. Inductive ability (I): The five tests that loaded on this seventh factor asked participants to find a rule or principle underlying a set of stimulus items in a test. Two representative tests were "areas," which required participants to determine the total white surface area

from increasingly complex figures, and "tabular completion," which required participants to fill in missing numerical entries in a table by examining column headings. Even though "number series" loaded highest on induction, apparently this test also loaded on other factors.

8. Restriction in solution ability (R): This far less distinct factor concerned tasks that involved some sort of restriction in obtaining a solution. J. Guilford might have referred to the description of this factor as "convergent production." Seven tests loaded on this factor, but it is not entirely obvious that the two most representative tests, "sentence completion" and "mechanical movements," had task elements in common. Sentence completion required participants to add one appropriate word to an incomplete sentence, whereas mechanical movements asked participants to determine the direction of movements for interacting gear wheels.

9. Deductive ability (D): Finally, the ninth factor also appeared to be less well defined. The four tests that loaded on this last factor required participants to apply a rule to target stimuli. Relatively pure tests for D concerned the verbal syllogisms tasks of "reasoning" and "false premises." Participants had to judge whether an inference (e.g., "Mr. White is wealthy") logically followed from the given premises ("All wealthy men pay taxes. Mr. White pays taxes.").

As Thurstone rejected the existence of *g*, he also strongly opposed the use of a single IQ index as a general indicator of mental ability. He preferred a description of mental abilities in terms of an individual profile of factor scores on the primary abilities. In fact, he even tried to relate such individual mental profiles to the vocational interests of his participants. He selected certain atypical participants with extreme profiles as case studies and argued that their profile of mental abilities matched their vocational preferences. For instance, one student with a profile high on verbal relations V and perception P, but low on the problem-solving factor R, appeared to pursue a career as an actor. These highly selected case studies, however, are not entirely convincing. Indeed, Thurstone acknowledged that more than 90% of his participants were not extremely profiled. Thurstone, however, maintained that more pure, that is, factorially less complex, tests would further substantiate the simple structure of primary abilities.

Critiques on Thurstone's Work

A major critique, which has been put forward in the literature quite often, is that the sample in Thurstone's research was a highly selected group. Indeed, college and university students may be expected to score relatively high on mental tests. This appeared to be even more the case for Thurstone's sample. Thurstone compared the data of the university freshmen from his sample on a psychological examination of the American Council of Education with those of all freshmen from the University of Chicago and with the national norms, in order to prove that the distribution of ability in his sample met with requirements of normality. This comparison, however, also revealed that his freshmen participants performed much better relative to the national norms. Moreover, it showed that they even outperformed University of Chicago freshmen in general. Obtaining test data from such a highly selected group might have reduced the *g* factor due to restriction of range, and, consequently, it might have overstressed factorial loadings on primary factors.

A related issue concerns the conspicuous simplicity of many tests included in Thurstone's test battery. About half of the tests showed a distribution of scores that was skewed to the left, indicating that these tests were far too simple for the highly selected participants. Perhaps ceiling effects occurred; they might have contributed further to an overemphasis of primary factors, relative to *g*.

Another major point of criticism is that the scores on his 56 tests were almost invariably positively and considerably correlated. A modal correlation coefficient of 0.35, uncorrected for attenuation, indicated that the tests at least might have had a general factor in common. Furthermore, out of 48 tests that substantially loaded on any of the nine primary factors, 17 tests substantially loaded on two factors or more. Despite Thurstone's striving for factorially pure tests, multiple-factor loadings continued to exist. His later use of oblique rotation, which allowed for correlated factors, might also be indicative of a more general factor.

Finally, a fundamental dispute arose about whether to rotate or not. Those in favor of *g* would argue that simple structure rotations tended to eliminate or weaken the general factor. By rotation of the factorial axes, the first centroid factor was distorted and *g* was rotated out of existence. Thurstone, on the other hand, claimed that the extracted centroid factors were just mathematical orderings, without psychological relevance. However, both Spearman's and Thurstone's methods of factor analysis were mathematically justifiable.

Reconciliation of Spearman and Thurstone's Positions

Later on in 1945, Thurstone had to admit that second-order factor analysis, that is, factor analysis of the primary factor scores, yielded a general second-order factor that might represent Spearman's *g* factor. This eventually brought the antagonistic positions of Spearman and

Thurstone together. In fact, it turned out to be rather arbitrary whether to extract a general factor without rotation at first and then allow for group factors, or, conversely, to extract primary factors through rotation at first and then obtain a general secondary factor.

This arbitrariness is precisely the reason why some factor analysts have preferred confirmatory factor analysis to exploratory factor analysis. Confirmatory factor analysis requires factors and their parameters to be described beforehand, whereas no such restrictions are imposed on exploratory factor analysis. Despite the exploratory character of Thurstone's factor-analytic work, his contribution to the field has been that he took group factors seriously and that he developed methods for studying them more closely. After reading Thurstone's work, one has to acknowledge that, despite the manifestation of a higher order general component, intelligence also incorporates a number of lower order ability components of a more specific nature. In fact, the reconciliation with Spearman's position in Thurstone's later work was the overture to later hierarchical models of intelligence, such as Carroll's three-stratum structure, in which Spearman's *g* may be found at the top of the pyramidal structure and Thurstone's primary abilities may be found in the lower strata.

Recent Developments

In 1993, Carroll published his state-of-the-art book, in which he reported the results of his reanalysis of virtually all factor-analytic data on the structure of intelligence. This reanalysis covered over 450 data sets and included the data of more than 130,000 participants. Carroll used hierarchical factor analysis in order to extract primary, secondary, and eventually tertiary factors. He obtained about 70 primary factors, far more than Thurstone did. A closer inspection of Carroll's primary factors, however, revealed that Thurstone's primary abilities were distinctly represented by one or more primary factors of Carroll. Thurstone's V factor, for instance, might be equated with Carroll's verbal comprehension factors. Carroll explicitly mentioned Thurstone's inductive and deductive abilities as part of reasoning abilities. Memory is also ubiquitously present in Carroll's categorization of primary abilities. Both Thurstone's spatial and perception factors could be retraced in Carroll's category of visual perception abilities. Numerical facility was classified by Carroll as part of cognitive speed abilities. In fact, only Thurstone's R factor could not unequivocally be retraced from Carroll's categorization of primary abilities. Some of Carroll's primary abilities, on the other hand, were not represented in Thurstone's test battery, such as abilities of auditory perception and abilities of idea production (or divergent production in terms of Guilford). Obviously, the greater diversity of tests in Carroll's extensive data sets was responsible for a more fine-grained extraction of numerous primary abilities relative to Thurstone's work.

Because many of Carroll's primary factors were obtained by oblique rotation, these factors were substantially correlated. Therefore, higher order factor analysis was performed on each separate data set. In many cases, general intelligence (*G*) was extracted as a second-order factor common to all primary factors. Other second-order factors concerned fluid intelligence, crystallized intelligence, visual perception, auditory perception, cognitive speed, retrieval ability, and memory ability. Additional third-order factor analysis only yielded a general intelligence factor. Carroll concluded that his survey produced "abundant evidence" for the existence of a general intelligence factor at the secondary or tertiary order. He further asserted that mental tasks involve a variety of abilities, not only higher order abilities such as general, fluid, or crystallized intelligence, but also a number of primary abilities. This latter statement did not depart far from the conclusions Thurstone arrived at during the last decades of his scientific career.

factor analysis A statistical procedure for data reduction designed to extract a small number of components to account for interrelations among a larger number of variables.
primary mental abilities The basic mental abilities identified by L. L. Thurstone as being the components of human intelligence.
psychometrics The branch of psychology concerned with measurement.
psychophysics An area of psychology concerned with the quantitative relationships between physical stimuli and the psychological experiences of them.
simple structure In factor analysis, the stage at which factor rotation has met a set of criteria that maximize the number of variables with trivially small projections on most factors.

L. L. Thurstone was the pre-eminent 20th century advocate of a mathematical basis for scientific psychology. The influence of his work extends beyond his native United States to Europe, Canada, Central and South America, Australia, and the Far East. Effects of his contributions also transcend the bounds of psychology and remain a basis both of current measurement methods and of the future development of mathematical modeling in the social sciences.

A Peripatetic Childhood

Louis Leon Thunstrőm was born in Chicago, Illinois, on May 29, 1887. Both of his parents had emigrated from Sweden. His father had been an instructor of mathematics in the Swedish army, and later was a Lutheran minister, then a newspaper editor and publisher. His mother, born Sophie Strath, displayed a strong interest in music, and she taught both Louis and his younger sister to play the piano from an early age. Louis became an accomplished pianist, and his piano playing remained important to him throughout his life.

Louis entered elementary school in Berwyn, Illinois, transferred to a school in Centerville, Mississippi, and then between the ages of 8 and 14 attended both a public school and a private boys' school in Stockholm, Sweden, where he had moved with his family. He studied diligently to master the Swedish language so as to feel more comfortable in the company of his fellow students.

In 1901, the family returned by ship to the United States. To minimize travel costs, they brought with them only essential personal belongings. Louis announced that he would not leave Sweden without his three favorite books, a world atlas, Euclid's *Geometry*, and an encyclopedia of philosophic essays. With some reluctance, his parents acquiesced, but only if he would carry those weighty tomes in his arms, which he did.

The Thunstrőms settled in Jamestown, New York, where Louis entered high school. As a high school sophomore he sent a letter to *The Scientific American*, proposing a time-sharing arrangement for the Niagara River whereby it could be diverted to produce power for the region without serious harm to the tourist attraction at Niagara Falls. The letter became his first publication, in 1905.

When Louis became self-conscious about his imperfect mastery of the English language, his high school principal volunteered to serve as a tutor, and Louis would repeat words and sentences over and over, trying to speak English without a Swedish accent. Later he discovered that, in order to graduate from Jamestown High School, every senior had to present a five-minute talk to an assembly of several hundred students. He told the principal that he could not possibly do that, and he was excused from the requirement. At about this time,

the family officially changed the surname Thunstrőm to Thurstone, hoping that the change would promote greater acceptance of family members in their new surroundings.

A First Career in Engineering

Thurstone enrolled at Cornell University and earned a Master of Engineering degree in 1912. Prophetically, at Cornell he had attended lectures of psychologists Edward Titchener and Madison Bentley. He believed that an essential ingredient of good engineering was an understanding of how people would learn to use an engineering innovation, and he hoped that psychology could provide that understanding.

As a student at Cornell, Thurstone patented his own invention, a motion picture camera and projector that avoided flicker, a major problem with movies at that time. He actually succeeded in demonstrating a working model before Thomas A. Edison and his staff. They showed keen interest but did not adopt Thurstone's invention, citing the prohibitive cost of changing production in their plant from the Edison movie machine to Thurstone's. However, Edison invited Thurstone to become his laboratory assistant, and Thurstone accepted. Following his graduation from Cornell in 1912, he worked daily with Edison, an experience that had a lasting influence, shown later in several ways. When Edison was dissatisfied with a manuscript or a work in progress, he would discard that product and begin again, rather than edit or amend the product. Thurstone assumed that same habit: whenever not satisfied with a draft manuscript, he would abandon it and start over, rather than modify it. Thurstone was impressed by the fluency of ideas displayed by Edison; later, as Thurstone attempted to characterize human abilities, he sought to include several kinds of fluency as important components of creativity.

Thurstone left Edison's laboratory to become an instructor of engineering at the University of Minnesota, where he remained from 1912 to 1914. At Minnesota, he taught engineering courses and also enrolled in psychology classes taught by Herbert Woodrow and by J. B. Miner, continuing to follow his earlier interest at Cornell, the possibility of studying the learning function as a scientific problem.

Becoming a Psychologist

In 1914, Thurstone began graduate study in psychology at the University of Chicago. His sponsor was James Rowland Angell; he also was strongly influenced by the lectures in social psychology of sociologist George Herbert Mead. His term of residence as a student, however, was short-lived. In 1915, Walter Bingham visited the Psychology Department at Chicago to recruit assistants for the newly established Division of Applied Psychology at the Carnegie Institute of Technology in Pittsburgh, and Thurstone accepted Bingham's offer to become Bingham's assistant. While at Carnegie Tech, he completed his Ph.D. dissertation on the learning curve equation and was awarded the Ph.D. degree from the University of Chicago in 1917.

Carnegie Tech and Washington, D.C., 1915–1924

After two years as an assistant to Bingham, Thurstone became an instructor at Carnegie Tech in 1917. He then was promoted to assistant professor in 1918, to associate professor in 1919, and to professor and department head in 1920. (Thurstone had been rejected for the draft of World War I because he was underweight.) Much of his work at Carnegie was related to the development of classification tests for the U.S. Department of the Army. Among a number of publications that he completed at Carnegie was a substantial monograph on the nature of intelligence.

Thelma Gwinn had begun graduate study in Thurstone's Department of Applied Psychology in 1920, and she earned a Master of Arts degree in 1923, the year of the discontinuation of that department. Thurstone had arranged for a one-year position at the foundation-supported Institute for Government Research in Washington, D.C., and he brought Thelma Gwinn with him as his research assistant. Their assignment was to prepare materials and manuals based on new objective methods from which civil service commissions throughout the country could improve civil service examinations.

The office of the Institute for Government Research happened to be in a building also occupied by the American Council on Education (ACE), and Thurstone discussed with ACE staff members the creation of examinations that could be useful to colleges and universities for student guidance and placement. Those discussions foreshadowed more than 20 years of development and maintenance of ACE examinations for college freshmen and high school students, undertaken by Thurstone when he became a faculty member at the University of Chicago.

In 1924, L. L. Thurstone and Thelma Gwinn were married in Washington, D.C.

The University of Chicago, 1924–1952

At the University of Chicago, Thurstone was appointed Associate Professor of Psychology in 1924, then was

promoted to professor in 1928 and to Charles F. Grey Distinguished Service Professor in 1938.

First Approaches to Psychometrics

Starting in 1924, Thurstone taught a course in descriptive statistics, but his primary interest was in mental test theory. He initiated a course on test theory for which he developed the content, as there was no precedent for such a course. That led to a plethora of research publications on psychological measurement during the ensuing years. He was especially pleased with his first publication on the topic in 1925 that set forth the principle on which his theory of psychological measurement was to rest, namely, that at a given age group, a construct could be assumed to have a Gaussian distribution over individuals and thus could be described by two parameters, a mean and a measure of dispersion, thereby providing a scaling method for psychological traits. He extended this principle from its application to mental testing to the realm of psychophysics. Fifty years after the appearance of these papers on psychophysics, R. Duncan Luce presented an appraisal of their impact, especially on signal detection theory. In 1977, Luce noted that research results "clearly complicate the Thurstonian model without, however, destroying its basic spirit" (p. 487).

Thurstone went on to apply his basic theory to the assessment of attitudes and values. Prior to Thurstone, attitudes and values had been viewed as resistant to quantification. By developing objective procedures for their measurement, Thurstone placed social psychology on a quantitative scientific conceptual platform.

From 1924 to 1947, Thurstone developed annual editions of the ACE Psychological Examinations for High School Graduates and College Freshmen. He also annually published (usually jointly with Thelma Thurstone) norms for each current year of testing. (After earning the Ph.D. degree in psychology, Thelma continued to assist and then to collaborate and co-publish with her husband.)

Thurstone's office was located in the basement of the social science research building at the University of Chicago, while all other faculty members in the Department of Psychology were in other locations. Near his office, Thurstone maintained a spacious workroom, filled with tables and with books and tools used primarily for test development and related analyses. At dinner at home one evening, probably around 1930, Leon (the first name that he preferred as an adult) confided to Thelma that he thought it appropriate to establish the workroom as a psychometric laboratory, and that he would be the laboratory director. Thelma immediately commented that she thought that neither the Department Chairman nor the Dean of the college was likely to approve that. In reply, Leon agreed that she was quite right, which was why that afternoon he had attached to the door of the workroom a nameplate on which was etched "Psychometric Laboratory." No higher authority ever questioned that action, and the world-renowned Psychometric Laboratory thus was established.

Factor Analysis

The development of new annual forms of the ACE examinations was a labor-intensive undertaking, and the Thurstones were delighted when they were approached by the Community Work Education Service, the higher education branch of the Works Progress Administration (WPA) of Franklin Roosevelt's first term, and asked if they could employ some personnel. The WPA representative suggested 100 people. "No, not 100," said Thurstone, "but as many as 20 would be welcome." (Among those recruited in this way was Ledyard Tucker, who later earned his Ph.D. with L. L. Thurstone.) With an increased staff, the Thurstones developed a battery of 57 tests, which then were administered to about 300 University of Chicago freshmen who had volunteered to spend about 15 hours to take the tests during a week of vacation from classes. Test answers were scored by hand and then were subjected to detailed analyses, guided by the development of mathematical methods to facilitate the interpretation and classification of the aptitude and achievement tests.

In 1904, Spearman had postulated the existence of a common general factor of intelligence, and had shown that correlations between parts of a test could be ascribed to the action of this common factor. Thurstone, who had amassed experience with a great variety of test batteries, soon realized that one would have to consider not just one, but several common factors, and that the "partial correlations" that remained after common factors had been extracted could be attributed to "unique" parts or measurement error. Thus was born multiple factor analysis.

Today there may be insufficient understanding of the enormity of the analysis task undertaken in Thurstone's Psychometric Laboratory. There were no computers. Electrical calculators (frequently only half-automatic), slide rules, and graphical aids were used to perform the tedious item analyses and calculations. The use of tabulating machines for mathematical operations was still in its infancy. Extraction of factors had to be done by approximation (the centroid method). To interpret the nature of these factors, L. L. Thurstone invented the "simple structure" concept. By transforming (rotating) the factor loadings, usually graphically, a display was produced that had only very few of the "loadings" significantly high, while the majority were near zero. Thus, the few high loadings identified the nature of each factor. Thurstone stressed as a major advantage of simple structure the relative invariance of factorial description under alternative samplings

from a universe of tests as well as from a population of test takers. He believed that the formulation of simple structure and of the procedures to achieve it constituted his most important contributions to factor analysis.

Results from the analyses of the battery of 57 tests supported a set of "primary mental abilities" defined by Thurstone. The predominant factors were verbal, numerical, perceptual, spatial, word fluency, memory, and reasoning. The immediate consequence of the gigantic work on primary mental abilities was the development of batteries of tests to be used for the assessment of scholastic aptitude of students in grade school and high school.

In 1938, Thelma Thurstone joined the faculty of Chicago Teachers College, which gave her access to the Chicago public schools. Soon there were batteries of test forms for a broad age range. In 1946, L. L. Thurstone, Robert Burns, and Lyle Spencer formed Science Research Associates (SRA), a Chicago company that published and analyzed many tests and educational materials. At first, these were just those contributed by the Thurstones, but this quickly expanded to include other specialized tests commissioned by schools and private corporations, e.g., tests for U.S. State Department applicants, Sears Roebuck & Co. management applicants, and the National Merit Scholarship Test used nationwide until 1967 for the selection of National Merit Scholars. (Later, SRA was acquired by IBM, in response to an increasing demand for computerized educational materials.)

Psychometrics as a New Branch of Applied Psychology

In 1929, at age 29, Robert Hutchins had been named President of the University of Chicago. Among many innovations, Hutchins in the early 1930s encouraged individuals as young as 15 or 16 to enroll as university students. A related provision provided course credit by examination as an alternative to enrollment in required courses. L. L. Thurstone was appointed chief examiner, responsible for the development, administration, scoring, and reporting of examinations. Over the years, many of the individuals who served under Thurstone as examiners became prominent contributors to quantitative psychology, e.g., Dorothy Adkins, Harold Gulliksen, Paul Horst, Marion Richardson, John Stalnaker, and Dael Wolfle, among others.

In the mid-1930s, prompted by graduate students and the examiners, Thurstone helped to establish the Psychometric Society, dedicated to the support of psychology as "a quantitative rational science." The society founded the journal *Psychometrika*, which has been maintained for all ensuing years as a quarterly international journal. The first President of the Psychometric Society was L. L. Thurstone. Thelma Thurstone said that he really had labored over his 1936 presidential address, an abstract of which, published in *Science*, is still worth reading today.

The presidency of the Psychometric Society was one of a large number of honors bestowed during Thurstone's tenure at the University of Chicago. He was President of the Chicago Psychology Club, 1928–1929, President of the Midwestern Psychology Association, 1930–1931, and President of the American Psychological Association, 1932–1933. In 1938, he was elected a member of the National Academy of Sciences, one of 18 psychologists who were members at that time. Among other honors, he was a Fellow and a member of the Board of Directors of the American Statistical Association, a member of the American Philosophical Association, a Fellow of the American Academy of Arts and Sciences, and an Honorary Fellow of the British Psychological Society. In 1949, he received a career award from the American Psychological Association.

During World War II, Thurstone served on the Committee on Classification of Military Personnel of the U.S. Adjutant General's Office, and also authored psychological tests that were used for the classification of military personnel. Following the war, his research was supported by contracts both from government agencies such as the Army Quartermaster Corps and the Air Force Office of Scientific Research, and from corporate bodies such as Sears Roebuck & Co. Such outside support continued until his retirement from the University of Chicago and even beyond, after he moved to the University of North Carolina (UNC).

By 1950, the Psychometric Laboratory at the University of Chicago had become one of the university's great attractions. Visiting scholars, research fellows, and doctoral and postdoctoral students arrived from all over the United States and Europe to study with L. L. Thurstone. To all those who were at the Psychometric Laboratory at that time, the experience, both personal and professional, was unforgettable. Many of them later became leaders in the fields of psychometrics, sociology, and statistics. In Sweden, France, Germany, Switzerland, and in several universities in the United States, scholars referred to themselves as "Thurstonians" and continued to work in the Thurstone tradition. Today, many Ph.D. students of those scholars think of themselves as Thurstonian grandchildren.

The Thurstones' home in south Chicago was only two blocks from the Social Science Research building on campus, the location of Thurstone's office and laboratory. He spent long hours at the office, and typically joined faculty members from other departments for lunch at the faculty club, located midway between his home and office. At home he had installed a seminar room, fully equipped with blackboard and podium. On many Wednesday evenings, the Thurstones would entertain a guest speaker and invite as many as 30 guests to attend a seminar, to

participate in discussion, and then to enjoy cakes and coffee served by Mrs. T., as Thelma was affectionately known. Invitees typically felt privileged to be included at these events.

In 1952, Thurstone turned 65, the age of mandatory retirement at Chicago. He received offers for continued employment from the University of California, Berkeley, the University of Washington, and the University of North Carolina. All three offers were attractive, but only one included a faculty appointment for Thelma Thurstone, the offer from North Carolina, and that feature was a determining factor when that offer was accepted.

Final Years at the University of North Carolina, 1952–1955

At Chapel Hill, the Psychometric Laboratory occupied all of Nash Hall, a two-story building on the edge of campus, about two blocks from New West building, the location of the Psychology Department. With research funding from outside sources, Thurstone was able to pay salaries for laboratory personnel (including his own) and to provide stipends for graduate students who served as research assistants.

At Chicago, Lyle V. Jones had been supported on a National Research Council Fellowship in 1950–1951; he was one of several postdoctoral fellows from the United States and abroad in the Psychometric Laboratory that year. Jones became an Assistant Professor of Psychology in 1951, and also was Thurstone's successor as Director of the Psychometric Laboratory at Chicago when Thurstone departed in 1952. Some of Thurstone's research contracts were transferred to North Carolina, while others stayed at Chicago as the joint responsibility of Thurstone and Jones, who visited Chapel Hill periodically to review progress on ongoing projects.

In 1953, the Thurstones moved into their newly constructed home a few blocks from the campus in Chapel Hill. This home was built with a special seminar room off the living area, and the practice of inviting speakers and guests for evening seminars, so long maintained at Chicago, now was reinstated in this new location.

After only three years at UNC, L. L. Thurstone died at age 68 in September of 1955. Mrs. Thurstone, Professor of Education, agreed to become Acting Director of the UNC Psychometric Laboratory, but only until work on current research contracts was complete. (She remained a research associate in the laboratory for nearly four decades, and she continued to develop, revise, and publish—through SRA—reading materials for schools until a year or two before her death in 1993.)

The Thurstone legacy at Chapel Hill has continued to flourish. In 1957, Lyle V. Jones moved from Chicago to UNC to direct the Psychometric Laboratory. From that time until the present, the laboratory has maintained active programs of research, has hosted nearly 50 visiting faculty and postdoctoral fellows, and has graduated about 100 Ph.D. recipients, many of whom continue to occupy prominent positions in academia, as well as in corporate and government research agencies.

In 1967, the Psychometric Laboratory relinquished occupancy of Nash Hall to be housed in a wing of newly renovated Davie Hall with the Department of Psychology. In 1977, to celebrate its 25th anniversary and to recognize its founder, it was renamed the L. L. Thurstone Psychometric Laboratory, and it hosted the annual meeting of the Psychometric Society. Jones served as Director from 1957 to 1974 and from 1979 to 1992. John B. Carroll was Director from 1974 to 1979, and David Thissen succeeded Jones in 1992. In 2002, to mark the laboratory's 50th anniversary, the Psychometric Society again held its annual meeting on the Chapel Hill campus. Robert MacCallum became Director of the laboratory in 2003.

Currently, laboratory personnel engage in research on test theory and practice, on other facets of psychological and educational measurement, on mathematical models of human behavior, and on applied statistics. The laboratory provides both graduate and undergraduate courses on these topics, and awards the MA and Ph.D. degrees in psychometrics/quantitative psychology.

Time Sampling

David G. Steel
University of Wollongong, Wollongong, NSW, Australia

Glossary

composite estimation Method of estimation that uses data for the current and previous time periods and gives different weights to matching and non-matching sample units.
longitudinal survey A survey that uses a sample in which the same units are included for several time periods.
panel survey Equivalent to a longitudinal survey.
repeated survey A survey conducted at different times with no attempt to have sample units in common.
rotating panel survey A panel survey in which a proportion of units are removed from the survey at some time periods and replaced by other units.
rotation pattern The pattern of inclusion of sample units over time.

Sampling over time enables researchers, analysts and decision makers to monitor, analyze, and understand social processes through the estimation and analysis of changes in variables of interest. In addition to the usual sample design issues considered for a sample used for one time period, the design of a time sampling scheme needs to consider the frequency of sampling and the spread and pattern of inclusion of selected units over time. A key issue is whether to use overlapping or non-overlapping samples over time. For overlapping samples, the precise pattern of overlap must be designed. Repeated, panel, and longitudinal surveys, rotating panel surveys, split panel surveys, and rolling samples are important examples of the application of time sampling. Factors that affect the design of a sample over time are the key estimates to be produced, the type and level of analyses to be carried out, cost, data quality, and reporting load. The interaction between the design of the sample in time and the other features of the design, such as stratification and cluster sampling, also needs to be decided. Time series may be produced and analyzed, which may involve seasonal adjustment and trend estimation.

Sampling and Surveys

Information obtained from samples selected using probability sampling methods can be used to provide estimates of characteristics of a population of interest and to analyze relationships between variables. Probability sampling involves methods in which members of a population have a known, non-zero probability of selection. Simple random sampling, probability proportional to size sampling, stratification, and cluster and multi-stage sampling are common probability sampling methods. Using these methods, population quantities such as means, totals, proportions, medians, and other quantiles that describe the current population can be estimated. Standard errors can also be estimated and used to make inferences, for example, by constructing confidence intervals. Relationships between variables can be analyzed, for example, by estimating linear or logistic regression coefficients. Samples are also useful because they allow estimates and analyses for subpopulations, provided subsamples of sufficient size have been selected.

Sampling is often used in surveys of human populations, collecting information on social topics such as health, income, expenditure, employment, crime, education, opinions, and attitudes. Samples of people are often obtained by selecting a sample of dwellings and including the households and people in the selected dwellings in the sample. Coverage rules are used to associate people with households and dwellings. Sampling is also used for surveys of other entities such as hospitals, schools, and businesses. Sampling of physical units, such as areas of land, can also be used.

Repeated Surveys

A particular survey may be conducted only once, or it may be repeated on several occasions on an irregular, regular, or periodic basis. Therefore, surveys can be classified as either one-off or repeated surveys. A one-off survey can provide cross-sectional estimates referring to the population at a particular time. A repeated survey also provides these estimates, but also enables estimates of changes to be calculated for the population.

The frequency of sampling depends on the purpose of the survey. Monitoring and detecting important changes will usually be a key reason for sampling in time. Common frequencies for surveys are monthly, quarterly, and annual, although even more frequent sampling may be adopted, for example, in opinion polls leading up to an election or monitoring TV ratings. How quickly changes are likely to occur and how quickly any associated decisions are needed are factors in deciding the frequency of sampling. The budget available is also a consideration. Sampling should not take place so often that the sample is registering unimportant short-term movements of no practical interest.

In any survey, the collection or interview period and reference period have to be considered. The interview period is the time period in which the sample is to be interviewed or data collected, and the reference period is the period used to define the variables about which information is collected. For example, a survey may be conducted over a particular 4-week period, collecting information on visits to the doctor for a reference period of the previous 12 months. The spread of the sample over the interview period should ideally be balanced over the important spatial dimensions used in the sample design. For example, a health survey may be conducted over an entire year to allow for seasonal effects, and the sample in each month should be of the same size and design. The design of the sample should be taken into account when deciding on the sample in each month. Ideally, the monthly sample should replicate the annual sample. In a stratified, multistage design involving the selection of primary sampling units (PSUs), the sample should include each stratum and PSU in each month. However, cost considerations may lead to each PSU being included in only one month or time period. The sample weighting used in estimation may be implemented by month if the population varies across the year or if the sample size or composition varies considerably across the year.

The reference period is a fundamental part of the definition of the variable. Having a long reference period may increase the number of episodes or incidents included in the survey, but the impact of telescoping, when events are incorrectly reported as having occurred in the reference period, and other recall errors must be taken into account. The reference period used will depend on the specific variable. For some variables, a 12-month reference period might be feasible, whereas for other variables a 1-day reference period might be appropriate. Some variables are even defined at the time of interview, for example, an opinion.

In deciding on the time periods for which data are collected a decision is being made about which time periods to sample. A sample or census of time periods may be used. For example, in a monthly survey all weeks may be included, or a single week may be used to represent the month. This aspect of the sampling needs to be considered. The possible impact of variation and cyclic patterns within the month may be relevant.

Time also has to be considered in the definition of the sampling frame from which the sample is selected, and also the definition of sampling units such as a household. Changes in the population can be important contributors to the change in the variables of interest over time. If estimates referring to the population at each time period are required, it is important that the population frame is updated to incorporate changes in the population as quickly as possible. The sample should also be updated to give new units a chance of selection and to remove defunct units whose presence may affect the sampling errors. Systems to update the sampling frame and sample therefore must be developed. In household surveys, this is sometimes done by developing a master sampling frame that is updated regularly to add new housing and to reflect other significant changes to the population. This frame also can be designed to implement a rotation pattern if necessary, by dividing the frame into rotation groups, and controlling overlap between different surveys using the same frame. For surveys of businesses and institutions, the list or register must be maintained and the sample updated. Rotation of the sample for a particular survey and overlap between the samples selected for different surveys can be controlled using permanent random number sampling.

Sampling in time may be used within a particular survey through multiphase or double sampling. An initial relatively large sample is selected, and some basic information that is relatively cheap to obtain is collected. A smaller subsample, in which more detailed information is obtained, is then selected. The initial sample is used to provide information used in stratification of the subsample or as auxiliary information in ratio or regression estimation. A particular case is when the variables in the subsample are conceptually the same as that in the initial sample, but the information is collected using more reliable methods. The subsample then provides information to adjust for the measurement or misclassification errors in the first-phase data. A multiphase design can be used to take a subsample of non-respondents to the first phase,

which is followed intensely. The resulting data can then be combined with the data obtained initially in an attempt to reduce the bias due to non-response.

Panel and Longitudinal Surveys

In a panel survey, an initial sample is selected and information is collected on several occasions. This can be done to provide estimates of change for variables for which information is collected at each occasion. A panel survey can also used to provide estimates for different variables over time. Cost savings often arise because there are higher setting-up costs for the first time a person is included in the survey than on subsequent occasions. Television rating surveys are an example of a panel survey; Internet surveys can also use this approach. Panel surveys allow longitudinal data analysis and so are also called longitudinal surveys.

A distinction can be made between a repeated survey and a longitudinal survey. In a longitudinal survey, an initial sample is selected, and then at each occasion that the survey is conducted, an attempt is made to include the members of the initial sample. The different time periods for which units are included are sometimes called waves. In a repeated survey, there is not necessarily any overlap of the sample for the different occasions. A longitudinal survey permits analysis of changes at a micro level, ultimately at the level of an individual.

Following rules need to be developed for a longitudinal survey and will be influenced by the objectives of the survey. At one extreme, people would not be followed when they leave a selected dwelling, so the panel unit is the dwelling. At the other extreme, people would be followed wherever they go, unless they die or leave the country. For cost reasons, in a cluster sample, people may be followed only if they move within a PSU.

In a household panel survey, households are often retained in the survey when they change dwellings, and individuals are retained in the sample even if they change households. Although the initial sample can provide estimates for the population existing at that time, the sample cannot provide unbiased estimates for the current population, that is, cross-sectional estimates, unless it is updated to include new entrants to the population. A decision has to be made as to whether such estimates are required. If cross-sectional estimates for each period are of interest, strategies must be adopted to keep the sample representative of the population at each time period. This implies adding to the sample so that population changes are reflected in the sample.

Even if cross-sectional estimates are not required, there may be interest in household composition or characteristics and their association with individuals. Information about the households to which sample members move should then be obtained.

Some examples of longitudinal surveys are the British Household Panel Survey (United Kingdom), the Survey of Family, Income and Employment (New Zealand), the National Longitudinal Surveys (United States), the Households, Income and Labour Dynamics in Australia Survey (Australia), and the Survey of Income and Program Participation (United States).

Rotating Panel Surveys

A longitudinal survey is a form of panel survey. Longitudinal surveys are specifically developed to permit analysis of changes at the individual level. A panel survey may use a panel at the dwelling level, so that when people or households move they are not followed, and people moving into a dwelling in the panel may be included in the survey. Rotating panel surveys also use a sample that is followed over time, but in general the main focus is on estimates at aggregate levels.

When the emphasis is on estimates for the population and possibly subpopulations, an independent sample may be used on each occasion, which is often the case when the interval between the surveys is quite large. An alternative is to try to use the same sample at each occasion, with some additions to ensure that the sample estimates refer to the current population. For regular monthly or quarterly surveys, the sample is often designed so that there is considerable overlap in the sample between successive surveys. Overlap in the sample reduces the sampling variance of estimates of change and reduces costs. Sampling variances on estimates of change in the variables of interest are reduced because the variation due to including different people is reduced. The reduction in variances depends on the correlation of the variable at the individual level over time and the degree of sample overlap. If the correlation is low, then the reduction is small and is not a major consideration. The correlation must be positive for this reduction to apply. A negative correlation will increase sampling variances; such cases are not common, but can occur.

These considerations would lead to maximizing the sample overlap at each time period at almost 100%, with the only change in the sample arising from the need to update the sample to represent people moving in and out of the population in the scope of the survey. However, such a design would lead to selected people being included in the survey indefinitely. In practice, a limit must be placed on how many times a person is surveyed to spread the reporting load and maintain response rates and the quality of the reported data. When deciding the degree of sample overlap, these considerations must be balanced.

An overlapping sample design can be implemented using a rotation pattern or design. A rotation pattern can be designed to efficiently manage the sample over time. Rotation patterns can be developed that have the same proportion of the sample in common between any two time periods the same time apart and the same proportion of sample rotated out and into the sample at each period. The rotation sample design should ensure that the cross-sectional estimates are unbiased, while reducing costs and sampling variances on important estimates of change. A rotation pattern would usually ensure that at each time point the sample is balanced according to the number of times a person has been included in the survey. This can be important because of the potential effect that the number of times a person has been included in the survey has on the data reported.

A rotation sampling design can be implemented using rotation groups and panels. The sample will consist of several rotation groups. A panel is the set of selected units that enter and leave the sample at the same time. When a panel leaves the sample it is replaced from the same rotation group. For example, in the Australian Labour Force Survey, the PSUs are allocated to eight rotation groups. In a particular month, the dwellings in one of the rotation groups are rotated out of the survey and replaced by an equivalent sample of dwellings in the same PSU.

A further aspect of the design is the level of information collected, which is the number of time periods for which information is collected on a particular occasion. For example, in a monthly survey, information may be collected from a unit for the current month and for the previous month. This approach is used in the U.S. Retail Trade Survey.

There are many different rotation patterns in use, and many that can be considered. Consider a monthly survey. The simplest rotation pattern is when a unit is included for a months. A more general class of rotation patterns is when a unit is included initially for a months, then leaves the sample for b months, and then returns to the sample for a further a months. This pattern is repeated until the unit is included for a total of c months. This can be denoted as an $a{-}b{-}a(c)$ rotation pattern. For example, the U.S. Current Population Survey uses a $4{-}8{-}4(8)$ rotation pattern, whereas the Australian Labour Force Survey uses an in-for-8 rotation pattern, which can be denoted 8(8). The Canadian Labour Force Survey uses an in-for-6 rotation pattern. These surveys use one level, so that information is collected referring to 1 month. More generally, a pattern of the form $a_1{-}b_1{-}a_2{-}b_2{-}\cdots a_m(c)$ can be considered, in which the number of months included and excluded from the survey varies.

By using sampling in time, an analysis of changes can be carried out. Consider a key variable of interest that is estimated for time period t by y_t. The simplest analysis of change is the estimate of one period change, $y_t - y_{t-1}$. In a monthly survey, this corresponds to a 1-month change. For a survey conducted annually, this corresponds to annual change. In general, the change s time periods apart can be estimated, using $y_t - y_{t-s}$. For a monthly survey, looking at 3-month and 12-month changes can be useful. Because $\mathrm{Var}(y_t - y_{t-s}) = \mathrm{Var}(y_t) + \mathrm{Var}(y_{t-s}) - 2\mathrm{Cov}(y_t, y_{t-s})$, a positive covariance between the estimates will reduce the variance, which can be achieved through sample overlap. If comparisons are made with time periods for which there are no sample units in common, then the variance of the estimate of change will be the sum of the variances, which will often be approximately twice the variance of the estimate of the level for a particular time period. These considerations result in designing the sampling so that there is overlap between the samples for time periods between which the movements are of major interest. So if there is strong interest in monthly movement, there should be high sample overlap between successive months. If there is also interest in changes 12 months apart, then consideration should be given to designs that induce sample overlap at this time-lag. However, for many variables the correlation 12 months apart may not be high enough for there to be appreciable gains.

Overlap in the sample may occur at different stages in a multistage design. In a cluster sample, even if there is no overlap at the individual level, there can be some small gains for estimates of movement by having overlap at the PSU level. Rotation is often carried out within PSUs for cost reasons, and a rotation group consists of a sample of PSUs, so that each PSU is allocated to a particular rotation group.

Averaging of estimates can be used in an attempt to produce more stable estimates when the original estimates have high sampling variances, for example, for small sub-groups or domains in the population. A particular case is estimates for small geographic areas. However, averaging over time changes the length of the time period to which the estimate refers and will hide any variation within the period over which the average is calculated. Time series methods are available to help combine data across time and space to produce small area estimates from rotating panel surveys.

For estimation of averages of estimates, positive correlation between the survey estimates involved will increase the sampling variance. It is better to average uncorrelated estimates, which can be obtained from independent or non-overlapping samples. If both averages and differences of estimates are of interest, the relative importance of each type of estimate must be considered and the impact of different options assessed on both types. To assess the impact of different rotation patterns on various estimates, some information or assumptions about the covariances involved are needed.

A longitudinal survey can be used to provide estimates of changes at aggregate levels, but these estimates refer to the population at the time of the initial sample selection, unless attempts have been made to add to the sample to make it representative of the current population. However, the main purpose of a longitudinal survey is to enable estimates of changes at the person or household level.

In a rotating panel survey, the panel aspect is often implemented at the dwelling level, which implies that people and households are not followed when they leave a selected dwelling. People and households moving into a selected dwelling are included in the survey. This approach is suitable when the main objective is to provide unbiased aggregate estimates.

In a rotating panel survey, the main focus is on aggregate estimates of change. However, any overlapping sample can also be used to analyze change at the micro level. For example, from the matched sample, a table can be produced showing the change of a variable between two time periods. An important example is when a table of change in status is produced, which is referred to as a gross flows table. It is possible to create longitudinal data from rotating panel surveys, but the length of the total time period and the time interval between observations are determined by the rotation pattern used. Also, the resulting sample of individuals for which longitudinal data are available will be biased against people who move permanently or are temporarily absent.

An alternative to a rotating panel survey is a split panel survey, which involves a panel survey supplemented on each occasion by an independent sample. Such a design permits longitudinal analysis from the panel survey for more periods than would usually be possible in a rotating panel design, but cross-sectional estimates can also be obtained from the entire sample.

Rolling Samples

In deciding on the sample design, in general the three dimensions of space, time, and variables need to be considered. A survey may be conducted continuously, but the sample size in any time period may not be sufficient to provide reliable estimates for that period, at least for subnational estimates. However, by cumulating samples over several time periods, reasonably reliable estimates may be produced. In this approach, sample overlap is detrimental. The sample design can be developed so that it is effectively a rolling sample with non-overlapping samples that over time cover many areas and eventually all areas. This approach can be useful in producing sub-national and small area estimates. A major example of this approach is the American Community Survey.

A related approach is rolling estimates. For example, in the UK Labour Force Survey, a non-overlapping sample is interviewed in each week of the quarter. Each month, estimates based on an average of the latest 13 weeks are produced.

Estimation

In a repeated survey, estimates can be calculated independently using standard sample weighting methods. When there is sample overlap implemented through a rotation sample design, it is possible to exploit the correlation structure for different rotation groups to produce estimates of levels and changes with smaller sampling variances. These methods are called composite estimators and effectively weight the common and non-overlapping samples differently.

In composite estimation, the sample for the previous time periods is used along with the sample for the current period. In its simplest form, the estimate for the current period is obtained by updating the estimate of the previous period using an estimate of the change that has occurred in which the matched and non-matched samples are given different weights. More generally, the estimates for each rotation group can be determined and combined in an efficient manner, taking into account the correlation structure of these estimates over time. However, issues of time in survey bias need to be considered.

Composite estimation methods have mostly been applied in monthly labor force surveys. Regression composite estimators have been developed and applied by several national statistics institutes to combine the benefits of composite estimation and regression estimation, which is a technique for exploiting extra information on auxiliary variables.

In assessing the potential gains from using composite estimation, attention is usually focused on the estimate of level for the most recent period and the movement between the two most recent time periods. The gains arising from composite estimation depend on the degree of overlap and the individual level correlation. The gains for estimates of levels are greatest when the degree of overlap is moderate and the correlation is high. For estimates of movement, high sample overlap is still preferred.

Methods of estimation assuming a time series structure for the population mean or total have also been developed. Estimation for panel surveys involve weighting the sample to provide population estimates. For the first wave, this will be relatively straightforward, but for subsequent waves, different weights may be required depending on the population for which estimates are required. Auxiliary information, such as population benchmarks used in estimation, may also need to be

updated if estimates for the current population are required. In developing weights for estimation, the following rules must be considered in determining a person's probability of selection, because after the first wave they can be included in the survey in more than one way.

Analysis

Producing estimates at regular intervals enables trends to be assessed. Various methods of estimating trends are available using model-based or filter-based methods. For surveys producing monthly or quarterly estimates, seasonal adjustment may be used to remove the impact of regular factors operating at different times of the year. Producing seasonally adjusted estimates can also assist in assessing the underlying direction or trends in the series. The rotation pattern chosen affects the correlation structure of the sampling errors over time, which can affect the properties of seasonally adjusted and trend estimates.

Analysis of net change using aggregate estimates may hide important gross changes occurring at the individual level, which may be revealed from longitudinal data. Longitudinal analysis can help determine the relationships between variables and look at causes by examining the temporal sequences of events. Longitudinal survey data can be used to undertake a variety of analyses, including survival analysis, event history analysis, and analysis of transition probabilities. Multilevel models that take account of the repeated nature of the data are being increasingly used. Longitudinal surveys with panels starting in different periods permit the disentangling of cohort/age/period effects.

Data Quality Issues

Including people in a survey for several occasions can affect the quality of the information reported. Non-response is a source of error in any survey, but in a longitudinal survey there is usually an accumulation of non-response over the waves, which can lead to attrition bias. There will also be cases in which a particular sample individual does not respond for one or more of the waves, affecting any analysis based on a set of data for all waves. Panel surveys have the advantages that the interviews at each wave can act as a boundary for the collection of data and reduce the impact of telescoping. However, conditioning and learning effects may occur.

Glossary

ARIMA model Autoregressive, integrated, moving average model of a time series variable.
autoregessive, distributed lag model A time series model with a lagged endogenous variable and one or more independent variables.
cointegrated variables Time series variables that form stationary linear combinations.
error correction model A model that specifies a long-term cointegrating relationship among two or more time series variables.
GARCH model Autoregressive, moving average model of the conditional heteroskedasticity in the stochastic error component of a model of the mean of a time series process.
Granger causality If the history of one time series variable can improve the explanation of a second variable beyond what can be explained by the history of the latter variable, the first variable "Granger causes" the second variable.
nonstationary variable A time series variable with a nonconstant mean, variance, or covariance.
vector autoregression A multiequation reduced-form model with two or more endogenous time series variables.
weak exogeneity An independent variable in a model is weakly exogenous if parameters of interest rest solely in that model and there are no cross-equation restrictions between a model for the independent variable and the model for the dependent variable.

Time series analysis in political science was invigorated in the 1970s by a combination of growing methodological sophistication and growing interest in the dynamic interplay of economic and political processes. Time series analyses in political science employ many of the same tools used by economists in their empirical work. Historically, political scientists have relied heavily on ordinary least squares and generalized least squares regression techniques for the estimation of parameters in single-equation models. However, starting in the late 1970s, Box-Jenkins ARIMA models became increasingly popular, particularly among researchers concerned with the impact of salient events (e.g., energy price shocks, policy interventions, and foreign crises or wars) on variables such as presidential approval and governing party support. Since the early 1990s, an increasing number of studies have marshalled the methodology of cointegration and error correction for investigating the dynamics of nonstationary variables. In a related development, researchers have begun to employ the concepts of fractional integration and, very recently, fractional cointegration. Perhaps reflecting their discipline's widespread lack of interest in forecasting, political scientists have paid little attention to vector autoregression (VAR) or ARCH models. An important current development is the EITM initiative, which attempts to forge strong linkages between the development of formal models and empirical testing with time series statistical methods.

Traditional Time Series Analysis

Research using time series data in political science typically has utilized many of the same regression techniques as are employed to analyze cross-sectional data. The vast majority of these traditional time series analyses

have considered single-equation models such as the following:

$$Y_t = \beta_0 + \sum \beta_{1-k} X_{1-k,t-i} + \varepsilon_t, \quad (1)$$

where Y_t is the dependent variable at time t, X_{t-i} are 1 to k independent variables at time $t-i$, β_0 is constant, β_{1-k} are the parameters associated with variables X_{1-k}, and ϵ_t is the stochastic error term $\sim N(0, \sigma^2)$.

For a model such as Eq. (1), the possible (non)stationarity of the variables is ignored, and ordinary least squares (OLS) is employed to estimate the values of the parameters β_0, β_{1-k}. The effects of the X's may be specified to occur simultaneously (i.e., at time t or with a lag i). Also, as in analyses of cross-sectional data, inferences regarding the statistical significance of the β's are made by calculating t ratios (i.e., β/s.e.). When doing diagnostic tests on such regression models, particular attention is given to the possibility that the stochastic errors (ϵ's) are correlated [i.e., $cov(\epsilon_t, \epsilon_{t-i}) \neq 0$]. Correlated errors do not bias parameter estimates but affect standard errors and, therefore, pose a threat to inference by affecting the size of the t ratios. The standard test for correlated errors has been the Durbin–Watson test, which tests only for first-order autocorrelation in the residuals of the estimated regression Eq. (1). If the null hypothesis that the residuals do not suffer from first-order autocorrelation is rejected by this test, the conventional approach is to conclude that the errors are generated by the following process:

$$\epsilon_t = \rho \epsilon_{t-1} + v_t, \quad (2)$$

where ρ captures the relationship between temporally adjacent errors, and v_t is a "well-behaved" (uncorrelated) error proces $\sim N(0, \sigma^2)$. This (assumed) relationship between the errors is treated as a "nuisance" to be "corrected." The alternative possibility, that the correlation among the residuals represents the result of model misspecification, is not considered.

The correction employed is a form of generalized least squares (GLS) that involves multiplying both sides of the model of interest by the "quasi-differencing" operator $(1-\rho L)$, where L is a backshift operator such that $L^k y_t = y_{t-k}$. This model is then subtracted from the original one. For example, for a model with a single right-hand-side variable, the result is

$$Y_t - \rho Y_{t-1} = \beta_0 - \rho\beta_0 + \beta_1 X_t - \rho\beta_1 X_{t-1} + \epsilon_t - \rho\epsilon_{t-1}. \quad (3)$$

The error process for the transformed model is $\epsilon_t - \rho\epsilon_{t-1} = v_t$, which, by assumption, is uncorrelated. Since ρ is unknown, it must be estimated from the data. Various techniques may be used for this purpose, and the resulting procedures are known as feasible GLS.

Political scientists adopting this approach to addressing the threat to inference have often failed to recognize that they have, in effect, respecified their original model in autoregressive distributed lag form and imposed a common-factor restriction $(1-\rho L)$. This may be seen by rewriting Eq. (3) as

$$(1-\rho L)Y_t = (1-\rho L)\beta_0 + (1-\rho L)X_t + (1-\rho L)\epsilon_t. \quad (4)$$

As Hendry emphasizes, the warrant for this restriction should be determined empirically, rather than simply assumed. The vast majority of time series analyses in political science have not done so. By failing to recognize that autocorrelated residuals do not necessarily imply autocorrelated errors, such analyses risk model misspecification.

Although many political scientists continue to use GLS procedures, it is increasingly common to attempt to capture the dynamics in a time series by specifying an autoregressive, distributed lag model that includes a lagged endogenous variable Y_{t-1}:

$$Y_t = \beta_0 + \gamma Y_{t-1} + \sum \beta_{1-k} X_{1-k,t-i} + \epsilon_t. \quad (5)$$

A model such as Eq. (5) may be specified initially on theoretical grounds, or after the analyst finds evidence of first-order autocorrelation in Eq. (1), a common practice is to use Eq. (5). In any event, the presence of the lagged endogenous variable Y_{t-1} means that the analyst is hypothesizing, either explicitly or implicitly, that the effects of all of the X variables are distributed through time and that all of these effects decline at exactly the same rate. That rate is γ, the coefficient on Y_{t-1}. For example, the impact of $\beta_1 X_{1t}$ in Eq. (5) is β_1 at time t, $\beta_1\gamma$ at time $t+1$, $\beta_1\gamma^2$ at time $t+2$, etc., and the long-term (asymptotic) impact of X_1 is $\beta_1/(1-\gamma)$. Clearly, the assumption that the effects of all X's evolve in exactly the same way is very strong. ARIMA intervention and transfer function models considered later relax this assumption.

ARIMA Models

ARIMA models constitute another major set of tools for analyzing time series data of interest to political scientists. ARIMA models are the product of pioneering work by Box and Jenkins. Reflecting widespread discontent with the forecasting failures of large multiequation models in the "Cowles Commission" tradition, Box and Jenkins proposed the radical alternative of forecasting a variable using only its past values. The ARIMA acronym for the models they developed has three parts: (i) AR for autoregressive, (ii) I for integrated, and (iii) MA for moving average. ARIMA models are specified as a combination of the three parts.

In a sharp departure from what had been prevalent practice in earlier regression-based approaches to time series analysis, Box and Jenkins emphasized part (ii), arguing that it was crucial to determine whether the

time series variable under consideration was stationary. Stationary variables have the following properties:

a. $E[y] = \bar{y}$; constant mean
b. $E(y - E[y]) = \sigma^2$; constant variance
c. $Cov(y_t, y_{t-k}) = \gamma_k$: constant covariance at lag k for all t.

Nonstationary variables may be the result of two different data-generation processes. In one of these processes, the nonstationarity reflects the presence of a deterministic component, e.g.,

$$y_t = \lambda T + \epsilon_t, \tag{6}$$

where λ is a parameter, ϵ_t is a stochastic shock, and T is a time counter. Historically, this type of model had been synonymous with the notion of "trend" as used by political scientists (and economists), and it was assumed that trending variables could be rendered stationary by simply regressing them on "time."

However, Box and Jenkins believed that nonstationarity in social science data was likely the result of another type of data-generating process, one that produced a "nondiscounted" accumulation of stochastic shocks. The simplest such model is the random walk:

$$y_t = 1.0 y_{t-1} + \epsilon_t. \tag{7}$$

In Eq. (7), the coefficient for y_{t-1} is 1.0, thereby ensuring that the effects of successive shocks, ϵ_t, are not discounted over time but rather continue at their full, time t, value. The result is a time series variable with an asymptotically infinite variance. Adding a constant β_0 to Eq. (7) yields a model with a deterministic trend component, $\beta_0 T$. This may be seen by recursive substitution in Eq. (7), which gives

$$y_t = \beta_0 T + y_0 + \sum_{i=1} \epsilon_i \tag{8}$$

In Eq. (8), y_0 is the initial value of y. The implication of assuming that nonstationarity is the result of such a data-generating process is that stationarity may be achieved by differencing a variable one or more times (e.g., for the random walk, $y_t - y_{t-1} = \epsilon_t$), where ϵ_t is a stationary "white nose" (uncorrelated) process. Integration, then, is the number of times a variable must be differenced to achieve stationarity. In the Box-Jenkins methodology, the initial step is to use diagnostic techniques (graphs, autocorrelation functions, and unit-root tests) to determine whether a variable is nonstationary. If the variable is nonstationary, it is differenced, and the diagnostics are repeated. If it is still nonstationary, it is differenced again, and diagnostics are performed again. After the variable is rendered stationary by differencing once or more, additional diagnostic procedures are used to identify the presence of AR and/or MA components in the data-generating process.

A pure autoregressive process is one in which a series is a function of one or more lags of itself, plus a contemporaneous stochastic error. For example, a first-order autoregressive process is

$$y_t = \phi_1 y_{t-1} + \epsilon_t, \tag{9}$$

where ϕ_1 is a parameter that will have an absolute value <1.0 if y_t is stationary. The general pth-order AR [AR(p)] model is a straightforward extension:

$$y_t = \phi_1 y_{t-1} + \phi_2 y_{t-2} + \cdots + \phi_p y_{t-p} + \epsilon_t. \tag{10}$$

Pure moving average processes reflect the operation of short-term shocks. Suppose ϵ_t is a purely random process with mean $\mu = 0$ and variance σ_ϵ^2. A process y_t is said to be a first-order moving average process if

$$y_t = \epsilon_t - \theta_1 \epsilon_{t-1}. \tag{11}$$

By taking a nonzero value, the parameter θ_1 indicates that a portion of a shock at time $t-1$ continues to influence y at time t. The general moving average process of order q [MA(q)] is

$$\begin{aligned} y_t &= \epsilon_t - \theta_1 \epsilon_{t-1} - \theta_2 \epsilon_{t-2} - \cdots - \theta_q \epsilon_{t-q} \\ &= 1 - \theta_1 L - \theta_2 L^2 - \theta_3 L^3 - \cdots - \theta_q L^q \mathbf{XX} \epsilon_t \end{aligned} \tag{12}$$

An MA(∞) $= \theta(L) = 1 + \mathbf{XX}_{j=1}^{\infty} - \theta_j L^j$. The MA process does not depend on time and the ϵ_t's are independent. The mean is constant and the MA process is strictly stationary when $(\epsilon_t \sim N\mathbf{XX}\mu, \sigma^2\mathbf{XX})$.

Some time series exhibit mixed AR/MA behavior. Thus, the general AR(p), MA(q) model is

$$\begin{aligned} y_t = \phi_1 y_{t-1} + \cdots + \phi_p y_{t-p} + \epsilon_t + \theta_1 \epsilon_{t-1} \\ + \cdots + \theta_{t-q} \epsilon_{t-q}. \end{aligned} \tag{13}$$

Using the lag operator (L), the model may be written as $y_t = \theta(L)/\phi(L)\epsilon_t$, where $\phi(L)$, $\theta(L)$ are polynomials of order p and q, respectively. Taking into account the possibility of differencing (one or more times) to eliminate nonstationarity in y_t, this general ARIMA model becomes

$$(1 - L)^d y_t = \theta(L)/\phi(L)\epsilon_t, \tag{14}$$

where d is the number of differences required to achieve stationarity. ARIMA models are often described in terms of (p, d, q), where p is the number of autoregressive parameters, d is the number of differences needed for stationarity, and q is the number of moving average parameters. For example, a first-order MA model for a variable requiring one difference to attain stationarity would be a (0, 1, 1) model. The specification of ARIMA

models thus involves determination of p, d, and q, both generally and, possibly, at seasonal spans. Box and Jenkins discuss how to use autocorrelation and/or partial autocorrelation functions to determine plausible values for p, d, and q. The key point is that analytic results indicate what the nature of the autocorrelation and autocorrelation functions should be. For example, a stationary first-order autoregressive process will have an autocorrelation function that decreases at a geometric rate across successive lags and one significant correlation (a "spike" in Box-Jenkins terminology) at lag 1 in the partial autocorrelation function. Contemporary practice for determining d involves the use of unit-root tests.

After plausible values of p, d, and q are specified, parameters in the ARIMA model are estimated, and then a battery of diagnostic tests are performed. Since forecasting is a principal purpose of the construction of univariate ARIMA models, diagnostics often include out-of-sample forecasting performance. In keeping with the strong empiricist spirit that infuses ARIMA methodology, models deemed inadequate are respecified, reestimated, and rediagnosed. This procedure continues until the analyst is satisfied with the model's performance. Since more than one model may have satisfactory diagnostics, choice among rivals will be made on the basis of model selection criteria (Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC)) and relative forecast accuracy.

Intervention and Transfer Function Models

ARIMA models may be augmented by the inclusion of dummy (0-1) and continuous right-hand-side variables. The former are known as interventions and the latter as transfer functions (a term from chemical engineering). In political science applications, intervention variables are typically used to measure the effects of public policy innovations (e.g., the effect of the introduction of seat belt laws on traffic fatalities); the effects of various unanticipated events such as foreign policy crises or wars on levels of presidential approval and also scandals; or the impact of economic shocks such as the OPEC oil embargo on economic growth. Examples of continuous variables include levels of consumer confidence in models of public support for governing political parties and their leaders and interest rates in models of unemployment rates. These intervention and transfer function components can be hypothesized to exert either abrupt or gradual effects and, in the case of interventions, the effects can be hypothesized to be either permanent or temporary. Moreover, unlike the ADL model Eq. (5) the ARIMA intervention and transfer function models may specify different dynamics of the effects of various right-hand-side variables.

Specification of the effects of continuous variables in transfer function models is often accomplished by "cross-correlating" the dependent and independent variables. Cross-correlations are the correlations between Y_t and X_{t-i}, where $i = 0, 1, \ldots, p$. The aim is to detect at what lag X might affect Y. Typically, the variables are "prewhitened" (i.e., filtered) to purge them of possible spurious correlations before cross-correlations are computed. Although useful when theory is weak or absent, cross-correlations are not required when the analyst has hypotheses about when effects should occur. Since cross-correlations are bivariate measures of strength of relationship, they always should be viewed as heuristic devices in the model specification process.

An example of a (0, 1, 1) ARIMA model with one intervention and one transfer function component is

$$(1-L)Y_t = \frac{\omega_1}{(1-\delta_1 L)}(1-L)I_t + \frac{\omega_2}{(1-\delta_2)}(1-L)X_t + \epsilon_t - \theta\epsilon_{t-1}, \quad (15)$$

where I_t is an intervention (a 0-1 dummy variable) hypothesized to affect Y_t immediately (at time t). By scoring I_t as 0 for each period except t, the effect is temporary, declining at rate δ_1. Thus, the impact of I is ω_1 at time t, $\omega_1\delta_1$ at time $t+1$, $\omega_1\delta_1^2$ at time $t+2$, etc. In contrast, the impact of X_t begins as ω_2 at time t and increases to $\omega_2 + \omega_2\delta_2$ at time $t+1$, to $\omega_2 + \omega_2\delta_2 + \omega_2\delta_2^2$ at time $t+2$, etc. X_t's long-term effect on Y is $\omega_2/(1-\delta_2)$. A key point is that δ_1 and δ_2 may have different values. Note that in this example model, Y_t and X_t are $I(1)$ variables that have been "first differenced" (differenced once) to achieve stationarity. I_t is also differenced—a requirement to maintain the hypothesized nature of the effect of the intervention (temporary or permanent) if the dependent variable is differenced. After a model such as Eq. (15) is estimated, various diagostic procedures are employed to check its adequacy. As is the case for univariate ARIMA models, respecification, reestimation, and rediagnosis may be required.

Political scientists typically have used ARIMA intervention and transfer function models to test hypotheses about the nature and strength of various independent variables on a dependent variable of interest. In particular, there is a large literature in the United States about the impact of economic conditions and political events on the dynamics of presidential approval. Comparable bodies of research in Great Britain and other mature democracies examine the effects of such variables on the evolution of support for governing political parties. Although most of these studies have relied on the traditional time series analysis procedures described in the preceding section, some have used ARIMA modeling techniques. Contrary

to the original intentions of Box and Jenkins, only a few political scientists have used these techniques for forecasting purposes.

Cointegration and Error Correction

During the past two decades, political scientists have become increasingly aware of the threats to inference posed by nonstationary variables. In most cases, the reaction to this "spurious regressions" threat has been to difference variables suspected of nonstationarity and then to use the traditional procedures described previously. However, a growing number of analysts have recognized that such analyses ignore possible long-term relationships among the variables of interest. Following Engle and Granger, they have attempted to study such long-term relationships by using the concepts of cointegration and error correction. Two nonstationary variables are cointegrated when there exists a stationary linear combination of the variables. Cointegration among three or more nonstationary variables is defined the same way, although it is possible that the variables will form multiple cointegrating variables. Note that cointegration cannot be assumed; rather, it is an empirical question. There are two types of tests for cointegration—one proposed by Engle and Granger and the second by Johansen. Most political science applications have used the former and avoided the potential problem of multiple cointegrating vectors by focusing on only two variables. The Engle-Granger approach involves two steps: (i) Test the variables under consideration for nonstationarity, and (ii) if the variables are nonstationary, regress one of the variables on the other(s) and test the residuals for nonstationarity. If the residuals are stationary, the variables are cointegrated. As demonstrated by Engle and Granger's "representation theorem," cointegrating variables can be modeled in error correction form.

Error correction models are theoretically attractive because they enable one to study both the short- and long-term relationships among a set of variables. Error correction models have the following form:

$$(1-L)Y_t = \beta_0 + \beta_1(1-L)X_t + \alpha(Y_{t-1} + \lambda_1 X_{t-1}) + \epsilon_t, \quad (16)$$

where Y_t and X_t are nonstationary variables and have been rendered stationary by first differencing. β_1 captures the short-term effect of a change in X on a change in Y. Y and X are cointegrated, and the expression $(Y_{t-1} - \lambda X_{t-1})$ is the "error correction mechanism" that captures the long-term relationship between these variables. The strength of this cointegrating relationship is indicated by the adjustment parameter α. For a cointegrating system such as that depicted in Eq. (16), it is expected that α will carry a negative sign and be less than 1.0 in absolute value. The magnitude of α is theoretically interesting because it tells the speed with which a shock to the system is reequilibriated by the cointegrating relationship between Y and X. For example, if $\alpha = -0.5$, a shock at time t will be eroded at the rate of 50% in each subsequent period. In the Engle–Granger methodology, the error correction mechanism is measured as the residuals from the cointegrating regression of Y_t on X_t. Thus, there is a two-step estimation process. Step 1 is estimating the cointegrating regression, and step 2 is estimating the error correction model. Both analyses can be performed using OLS procedures. Recently, analysts have recommended that gains in statistical efficiency will be obtained by estimating Eq. (16) in a one-step process. If Y and X do not cointegrate, α will not be significantly different from zero.

Error correction models are attractive because they address the threat of spurious regressions while simultaneously enabling the analyst to study long-term relationships among a set of variables. However, these models are not a panacea. As in traditional time series regression models with lagged endogenous variables, the effects of all of the X variables are specified such that they have a common dynamic captured by the α parameter. As noted previously, this restriction may (often) be theoretically implausible. Also, important questions regarding the exogeneity of the X's need to be addressed to warrant confidence in the parameter estimates. These questions are not particular to error correction models, but they naturally arise in the context of demonstrating cointegrating relationships that ground the development of error correction models.

Exogeneity

With rare exceptions, the time series models estimated by political scientists are single-equation specifications. The concept of exogeneity as it has been developed by econometricians during the past two decades is crucial for evaluating inferences based on these models. The word "inference," in the econometric sense, refers to a single regression coefficient. In the 1940s and 1950s, the Cowles Commission discussed issues of identification and exogeneity by distinguishing between variables that were predetermined and those that were strictly exogenous within the context of a particular structural model or system of simulaneous equations. In subsequent work on the conditions for valid inference, Engle *et al*. developed weak exogeneity requirements that shift the focus to

parameters of interest as opposed to variables. These concepts may be defined as follows:

Predetermined: A variable is independent of the contemporaneous and future disturbances in the equation in which it appears.

Strict exogeneity: A variable is independent of contemporaneous, future, and past disturbances in an equation.

Weak exogeneity: A variable is weakly exogenous if the parameters of interest rest solely in that (conditional) model and the parameters of interest are variation free. There are no cross-equation restrictions between a (marginal) model for the process generating the independent variable and the conditional model for the dependent variable.

If the parameters of interest are variation free, the models are independent, and knowledge of a specific parameter in the marginal model provides no information about the range of values for parameters in the conditional model. Hence, no information is lost if the marginal model is ignored and only the conditional model—a single equation—is estimated. Tests for weak exogeneity are thus crucial for establishing the credibility of single-equation models such as the error correction models considered previously. In the context of an error correction model with one right-hand-side variable, a three-step process may be employed to test for weak exogeneity. First, specify a model for the marginal process (i.e., for the X). Second, add the error correction mechanism to this model. If X is weakly exogeneous to Y, the error correction mechanism should be insignificant in the model for X. Third, the residuals of the model for X (absent the error correction mechanism) should be insignificant when added as a predictor in the error correction model for Y.

Granger Causality

Granger developed a widely used definition of causality that is frequently employed by political scientists interested in the intertemporal flow of effects between two variables X and Y. Y is said to "Granger cause" X if information about the history of Y improves one's ability to predict the behavior of X, above what can be achieved when only information about the history of X is used for this purpose. Thus, if Y does not Granger cause X, Y is strictly exogenous to X. Granger causality tests can be performed within a Box-Jenkins ARIMA modeling framework or in the context of a traditional OLS regression analysis. For example, consider the following:

$$X_t = \alpha_0 + \alpha_1 X_{t-1} + \cdots + \alpha_k X_{t-p} + \beta_1 Y_{t-1} + \cdots + B_p Y_{t-p} + u_t. \quad (17)$$

Estimating this model and performing a block F test for the joint significance of the Y's tests if Y Granger causes X. It is important to recognize that Granger causality tests are tests for strong, not weak, exogeneity. Granger causality tests are thus not helpful in deciding if it is permissible to draw inferences about the parameters in a single-equation model. However, Granger causality tests are useful for deciding if a single equation model of Y where X is a right-hand-side variable will be useful for forecasting purposes. If Y does Granger cause X, then this needs to be taken into account. The intuition here is that the single-equation model for Y does not take account of the feedback from Y to X revealed by test results indicating that the former variable Granger causes the latter. An important general point is that analysts should not confuse tests for Granger causality with tests for weak exogeneity (i.e., parameter stability tests). Both are useful, but they are useful for different purposes.

(Non)Stationarity

Both traditional regression-based approaches to time series analysis and ARIMA modeling procedures require that the variables being analyzed be stationary. (Non)stationarity is also a principal consideration in analyses of cointegration. Until the mid-1980s, nonstationarity was assessed by two methods. First, researchers displayed their data in graphic form and looked to see if the series had an upward or downward trend. Second, following Box and Jenkins, analysts computed an autocorrelation function (ACF) for a series and inspected the results. An ACF is a series of correlations between a variable (Y_t) and itself at successive lags (i.e., Y_{t-1}, $Y_{t-2}, \ldots, Y_{t-k}$). The classic signature for a nonstationary series is a set of very stong correlations that decay very slowly as the lag length increases. If such a pattern was detected in the ACF, the series was judged to be nonstationary. Clearly, neither the graphic nor the ACF procedures constituted formal statistical tests.

Since the late 1970s, econometricians have developed a wide variety of formal statistical tests for nonstationarity. The most widely used such test is that of Dickey and Fuller. The basic Dickey-Fuller test statistic is computed from an OLS regression for the following model:

$$(1-L)Y_t = (\beta_1 - 1)Y_{t-1} + \epsilon_t. \quad (18)$$

The null hypothesis for the test is that the series is nonstationary, the basic null hypothesis being that it is generated by a random walk. If so, $\beta_1 - 1 = 0$. Additional parameters for a constant and/or a deterministic trend may be added to Eq. (18), depending on what specific assumptions are made about the data-generating process. In any event, rejection of the null hypothesis

prompts the inference that the series is stationary. A key point is that t distributions for the Dickey–Fuller test are nonstandard and, hence, special critical values must be employed. Also, as in any regression, inference is problematic if the ϵ's have nonzero correlations. If diagnostics suggest the presence of such correlations, lags of the dependent variable (which is differenced) are included in a respecified model, and the model parameters are reestimated. The resulting test is called an augmented Dickey–Fuller test.

Two points regarding (non)stationarity tests bear emphasis. First, structural breaks in otherwise stationary processes may falsely prompt the conclusion that a series is nonstationary in the sense of being generated by some type of stochastic trend data-generating process. Second, unit-root tests have low power against near-integrated and fractionally integrated alternatives. The result is that failure to reject the null hypothesis may lead the analyst to falsely conclude that β_1 in Eq. (18) equals 1.0, and the data-generating process is random walk. Recognition of this possibility has led some researchers to argue that alternative procedures should be employed to determine the order of integration.

Fractionally Integrated Processes

Work on "long-memory" processes relaxes the assumption that the differencing parameter d must have integer values. Analyses are done within the framework of an ARFIMA (autoregressive, fractionally integrated, moving average) model:

$$(1-L)^d Y_t = \frac{\theta(L)}{\phi(L)}\epsilon_t, \tag{19}$$

where Y_t is a time series variable, ϵ_t is a stochastic error, ϕ signifies an autoregressive parameter(s), θ signifies a moving average parameter(s), and d is the differencing parameter. The model thus resembles the conventional ARIMA model except that the differencing parameter d can take values along the real line from -0.5 to 1.0. Nonzero values of d signify a fractionally integrated process. When $0 < d < 0.5$, the process is stationary. However, when $0.5 \leq d < 1.0$, the process is nonstationary, but ultimately mean reverting. A key point is that d can be estimated from the data, and associated standard errors can be used for hypothesis testing purposes. As with conventional ARIMA models, rival ARFIMA models can be evaluated on the basis of various diagnostics, including model selection criteria such as the AIC and BIC. Work on fractionally integrated processes has increased in recent years, and some studies have generalized the concept of cointegration to consider fractionally cointegrated systems. In political science, a finding with potential theoretical significance is that many often-analyzed time series, including presidential approval, party identification, and economic evaluations, are nonstationary, fractionally integrated processes. Clarke and Lebo cite relevant literature.

Vector Autoregression

In reaction to the forecasting failures of traditional multiequation Cowles Commission models, Sims proposed a technique called VAR. Sims focused his critique on the "incredible" assumptions made in the specification of traditional models. Lacking adequate theoretical or empirical underpinnings, these assumptions were principally matters of convenience to ensure that model parameters could be identified. Traditional models were a system of structural equations that expressed endogenous variables as being (in part at least) a function of the current value of other endogenous variables. Sims proposed a reduced-form alternative whereby all endogenous variables are functions of their own lagged values as well as lagged values of other endogenous variables. Motivated by a desire to improve forecasting performance rather than to test economic theory, Sims contended that such a reduced-form specification could capture dynamic interrelationships among variables of interest. All that was needed was to "round up the usual suspects" (i.e., variables that theory and experience suggest are relevant to the forecasting exercise at hand) and include them in a VAR.

The following is an illustrative two-variable example of a VAR:

$$\begin{aligned} Y_t &= \beta_0 + \beta_1 Y_{t-1} + \cdots + \beta_p Y_{t-p} + \alpha_1 X_{t-1} \\ &\quad + \cdots + \alpha_p X_{t-p} + \varepsilon_t \\ X_t &= \gamma_0 + \gamma_1 X_{t-1} + \cdots + \gamma_p X_{t-p} + \lambda_1 Y_{t-1} \\ &\quad + \cdots + \lambda_t Y_{t-p} + \xi_t. \end{aligned} \tag{20}$$

Error terms in such a VAR model (ε_t, ξ_t) are assumed to be $\sim N(0, \sigma^2)$ and serially uncorrelated. Thus, each equation in the model may be estimated using OLS. If ε_t and ξ_t are contemporaneously correlated, seemingly unrelated regression provides no gains in efficiency because identical sets of predictor variables are in each equation. In addition, although the presence of interrelated lagged regressors produces collinearity, this is not a problem because there is no interest in inference on individual parameters. Assuming variables in the system are stationary, the only question concerns the appropriate lag length, p, for the variables in the system, and various procedures (block F tests and model selection criteria) may be employed for this purpose. Since the stationarity assumption may not obtain, econometricians have debated whether nonstationary variables should be used in a VAR. Enders reviews the

issue, usefully linking his discussion to Johansen's methodology of cointegration tests.

In Sim's original formulation, VAR is proposed as a forecasting tool. However, analysts also use VAR methods to investigate relationships among a set of interacting variables. To this end, a VAR is expressed as a vector moving average (VMA) system. A VMA representation allows one to trace the impact of a shock to one variable through time on other variables in the system via impulse response functions and forecast error variance decomposition. Such "innovation accounting" exercises are sensitive to assumptions about the overall flow of causality through the variables in the system. Varying the order of variables in the system enables the analyst to determine the sensitivity of innovation accounting results to such assumptions.

Despite increasing sophistication in the use of time series methods, and widespread availability of suitable software, political scientists have been slow to adopt VAR methods for applied work. In part, this reflects the discipline's continuing emphasis on inference rather than prediction. However, forecasting exercises also have eschewed VARS in favor of simple structural models or, occasionally, univariate ARIMA models.

ARCH Models

Political scientists are typically interested in modeling the mean of a time series variable. However, some analysts, (e.g., political economists studying exchange rates) are concerned with the volatility of a series. For this purpose a class of ARCH (autoregressive conditional heteroskedasticity) models pioneered by Engle are very useful. ARCH models express the conditional variance of stochastic errors as an ARMA process:

$$\epsilon_t = v_t \sqrt{\bar{h}_t} \tag{21}$$

$$h_t = \alpha_0 + \sum_{i=1}^{q} a_i \epsilon_{t-i}^2 + \sum_{i=1}^{p} \beta_i h_{t-i} \tag{22}$$

Here, v_t is $\sim N(0, 1)$, and so the conditional variance of ϵ_t is $E_{t-1}\epsilon_t^2 = h_t$. This basic GARCH (generalized ARCH) model has been modified in several ways. For example, ARCH-M models specify that the mean of a series is a function of its conditional variance (h_t). Threshold ARCH and exponential GARCH models account for asymmetries in the effects of positive and negative shocks, and integrated GARCH models consider situations of strong persistence in the conditional volatility of a series. ARCH models may also be extended to study how various events and conditions affect the conditional volatility of a series. Although most political science applications of ARCH models are found in work by political economists, some analysts are beginning to use these models to study volatility in presidential approval ratings and support for political parties.

The Future of Time Series Analysis: Linkages to Theory

Although there are many applications of time series methods in political science, it is likely that these techniques will become increasingly popular in the future. In part, this development will reflect the continued growth in time series databases relevant to political science research. Equally important is the growing recognition of the need for a closer articulation of theory and method. In this regard, there have been sporadic attempts, albeit no systematic intellectual movement, to link time series techniques directly to behavioral theories. To date, these efforts have occurred in other disciplines, such as economics. This situation is changing. Although there will always be a need for pure time series statistical tools, there is also a new appreciation among political scientists of the utility of linking time series techniques to formal models—what has been called the empirical implications of theoretical models (EITM) (see http://www.nsf.gov/sbe/ses/polisci/eitm_report/start.htm). Using EITM, political scientists can take a set of plausible facts or axioms, model them in a rigorous mathematical manner, and identify causal relations that explain empirical regularities over time. Of course, these transparent linkages between theory and testing procedures do not mean a theory is correct. Instead, political scientists who link formal models with time series techniques would satisfy a minimal requirement that theory and test are related. This linkage bears on important issues regarding falsification and the accumulation of scientific knowledge.

Time-Series–Cross-Section Data

Nathaniel Beck
New York University, New York, New York, USA

Glossary

contemporaneous correlation of the errors When errors for observations in a unit are correlated with errors for other units observed at the same time.
dynamic model States that effects of covariates occur over time rather than instantaneously.
feasible generalized least squares (FGLS) Generalized least squares in which parameters of the error process are estimated.
panel correct standard errors (PCSEs) Ordinary least squares standard errors corrected for panel heteroskedasticity and contemporaneous correlation of the errors.
panel heteroskedasticity Heteroskedasticity in which variance differs from unit to unit, but is constant within units.
pooling The assumption that all units follow the same specification with identical parameters.
spatial effects Effects when values for other units enter the specification for a given unit.
time-series–cross-section (TSCS) data Data observed at regular intervals on fixed units.

Time-series–cross-section data consist of repeated observations at fixed intervals on a group of fixed units in which the observed units comprise, in general, the entire population of such units. A common application is to the political economy of advanced industrial societies for which there are annual measures of political and economic phenomena in approximately 20 nations, but there are many other applications in political science, economics, and sociology.

Introduction

What Are Time-Series–Cross-Section Data?

There are many types of data for which there are repeated observations on the same units over time. Time-series–cross-section (TSCS) data are one type of such data. The units in TSCS data are of interest per se; in other types of data, the units studied are a sample from a population, and interest centers on inferences to that larger population.

Thus, in a study of how politics affects economic growth in advanced industrial societies, all advanced industrial societies are observed. There are no issues of inference to a larger population of nations. In resampling experiments, a new "Germany" will not be drawn from a large population of nations; the various unobserved characteristics of "Germany" remain constant over any sampling (thought) experiments. Many thought experiments will be of the form: "What would have happened if Germany had only right-wing governments?" As shall be seen, this is different from panel data based on sample surveys of individuals, in which there is no interest whatsoever in inferences conditional on a specific individual.

The repeated observations in TSCS data are at fixed intervals. For many political economy applications, this interval is annual, but it could be quarterly, monthly, or daily. The fixed intervals allow the analyst to know that, for example, the observation for unit 3 at time period 6 is perhaps related to the observation for unit 7 at time period 6. This allows analysts to model the dynamics of TSCS data as they would for simple time-series data, and allows for many of the methods and insights of the time-series analyst to be used by the TSCS analyst.

Time-series insights for TSCS data are only relevant if enough time points are observed. While there is no hard and fast rule as to how many time points need be observed, analysts clearly cannot use time-series insights and methods if each unit is observed only two or three times. TSCS data thus consist of repeated observations at fixed intervals on fixed units, with enough repeated observations to make time-series insight relevant.

Examples of TSCS Data

The paradigmatic political economy application, as exemplified by the work of Franzese, Garrett, and Iversen, examines economic policies or outcomes in 15–20 advanced industrial societies (members of the OECD) in the post-World War II period (often 1960–1990), using annual data. The dependent variable is either an economic outcome (e.g., growth, unemployment, or inflation) or a policy (e.g., budget deficit or rate of money growth), with the covariates being both economic and political indicators. The political indicators usually measure the strength of left parties in the government, the organization of labor, and various political rules in the country (such as the electoral system).

Economists undertake similar analyses. Pesaran, Shin, and Smith, for example, examined the consumption function in 24 advanced industrial societies observed annually over 32 years. The dependent variable was the level of national consumption, with independent variables being the level of national income and other economic indicators. In this model, interest centers on both short-term and long-run effects.

Related Types of Data

TSCS data appear similar to other types of data commonly used in the social and biomedical sciences; the notation for these data sets often appears identical. But there are fundamental differences between TSCS and related data sets, both theoretical and in terms of practical issues of estimation. In particular, panel data, which appear to be notationally equivalent to TSCS data, are analyzed very differently from TSCS data.

Panel data consist of repeated observations, at fixed intervals, on a set of units. The units are sampled from a larger population, and interest centers on inference to that population. Typically, the number of repeated observations is not large. The paradigmatic panel study is the Panel Study of Income Dynamics, which (in simplified version) surveys a large number of individuals each month for approximately one year. Thousands of respondents are sampled, but interest centers on adult Americans. In principle, subjects can be interviewed a large number of times, but in practice, they are only interviewed a few times, with two or three interviews being most typical.

It should also be noted that the TSCS model is related to Zellner's "seemingly unrelated regressions" (SUR) model. In that model, time-series data for a number of units are observed. While the parameters of each time-series model differ, it is assumed that the error processes for each series for the same time period are related. As shall be seen, this is just one variant of a TSCS model.

Both panel and TSCS data are special cases of hierarchical data. Here, data are observed on units that are tied together as subunits. The paradigmatic example is data on students who are tied together in classes that are tied together in schools; the students studied are randomly drawn from a larger population of interest. Both TSCS and panel data impose more structure on the data, since the same subject is observed at repeated intervals. While the notation in hierarchical data may indicate subject 1 in class 1 and subject 1 in class 2, there is no relationship between those subjects.

So far, it has been assumed that the models have a continuous dependent variable. But TSCS data can also have a binary (or other discrete) dependent variable. The common application is the study of conflict, in which nations (or pairs of nations) are observed annually; each year it is recorded whether a dyad was in conflict, with covariates being either continuous or dichotomous. Such data are particularly difficult to model and present many interesting estimation issues that go beyond the continuous case.

Plan of the Article

TSCS data can be seen as presenting either estimation issues or modeling issues. The former derive from an older tradition, and many estimation issues can be simplified with a more modern approach. Current research focuses on modeling issues, particularly the modeling of spatiality and heterogeneity.

The next section discusses the notation used and overviews basic TSCS models, while showing how they may be differentiated from their close cousins; the following section emphasizes the importance of preliminary graphical analysis. Then some estimation issues related to the cross-sectional and temporal properties of the data are treated; attention is paid to both "old fashioned" and more modern approaches. The last two sections cover the direct modeling of some properties of TSCS data and some current issues.

Notation and Related Models

The common notation and generic specification used in this article are set forth here, with further discussion of some assumptions implicit in that notation. Because the notations do not adequately distinguish TSCS from panel data, this issue is pursued further.

The Basic Model

It is assumed throughout that there is a single dependent variable that is explained by a vector of covariates, as well as, possibly, by the past history of that dependent variable and various possible combinations of the error process. Reciprocal causation is thus ruled out, and the covariates

are assumed to be exogenous to the variable that is being explained.

Let $y_{i,t}$ indicate the dependent variable, which is indexed by both unit i and time period t, where it is assumed that all observations $y_{i,t}$ and $y_{i',t}$ refer to the same time period and all observations $y_{i,t}$ and $y_{i,t'}$ refer to the same unit. For convenience, given the paradigmatic application to political economy, i can be thought of as a country and t as a year. Assume we have N countries observed for T years.

It is assumed that the relation between $y_{i,t}$ and the vector of covariates $\mathbf{x}_{i,t}$ is linear, although this assumption can be weakened in the usual ways of introducing nonlinearities while maintaining an additive model. Notationally, we have

$$y_{i,t} = \mathbf{x}_{i,t}\beta + \epsilon_{i,t}; \quad i = 1, \ldots, N; \quad t = 1, \ldots, T, \qquad (1)$$

where ϵ is an error process that may have complicated properties.

While the error process in Eq. (1) may allow for temporal observations to be related, Eq. (1), is "static," in that the exogenous variables have an immediate effect on y that lasts exactly one period. The covariates may be lagged without problem, but they still affect y for only one period.

Relationship to Other Models

TSCS vs Panel Data Models

TSCS models are often confused with panel data models because the notation for panel data models is identical to Eq. (1). But the differences between the two types of data, and the methods and models used for estimation, are large. The reason is that in TSCS models, whereas N, the number of units, is taken as fixed, T, the number of observations per unit, may be thought of as growing larger and larger. All asymptotic theory for TSCS data is in T, with N fixed. Although N may be large, in practice it is not; the most common political economy studies have $N = 20$ and very few studies have more than 100 units.

The situation is exactly the opposite for panel data models. In these models, T is taken as fixed, whereas N is usually large and asymptotics are in N. Thus, a common panel data structure may have thousands of respondents interviewed three or four times. Whereas the number of respondents sampled can be thought of as growing larger and larger, the number of interviews per respondent cannot change, and, in practice, is small (almost always under 10, with 3 being the most common number of "waves" of a panel).

This has enormous consequences both for how the two types of data are modeled and for the estimation of these models. In TSCS data, with usually 20 or more observations per unit, it is possible to think of richer time-series models for each unit (though clearly not of the richness of standard single time-series models, in which hundreds of time-series observations, often at very high frequency, are available). But in panels with only very few observations per unit, it is clearly impossible to model the temporal structure of the data in any detail. While TSCS and panel data models have interrelated observations for each unit, it is difficult to do more than provide some simple fixes for those interrelationships in panel data.

Because the units in panel data consist of a random sample of individuals from a larger population, it is usually assumed that observations of different individuals are independent of each other. But for TSCS data, there is great interest in modeling the interrelationship between observations of the different units. Panel data modelers usually assume no spatial effects (relationships across units) in their data.

Finally, panel data analysts assume that they observe a sample of units drawn from a larger population of units, with inferences to that larger population being of interest. TSCS analysts, on the other hand, usually observe the entire population of units, and so have no need to worry about inferences to a larger population.

The differences in asymptotics also have implications for how diversity between units is modeled. The simplest assumption is that each unit in Eq. (1) has its own intercept, a_i, adjoined to the specification, which leads to

$$y_{i,t} = \mathbf{x}_{i,t}\boldsymbol{\beta} + a_i + \epsilon_{i,t}; \quad i = 1, \ldots, N; \quad t = 1, \ldots, T. \quad (2)$$

In panel data, fixed effects cause enormous estimation difficulties related to the incidental parameters problem first discussed by Neymann and Scott. In brief, this problem is that the number of incidental parameters, a_i, grows asymptotically as N grows. The a_i, therefore, cannot be consistently estimated, because they are estimated using only three (or T) observations. The difficulties of fixed effects models for panel data have led to a whole series of complicated models in which the a_i are taken as random draws (random effects). Note, however, that for TSCS data, asymptotics are in T with N being fixed. Thus, there will always be N dummy variables in Eq. (2) and hence a_i can be consistently estimated, since each is estimated with T observations that can be thought of as growing larger and larger. One of the biggest specification and estimation problems for panel data is thus a simple issue for TSCS data.

Note that even if fixed effects were statistically feasible for panel data, it would still be of little interest to panel analysts because they care about the population, not the observed units. Noting that some particular unit, say K, is, on average, a_K higher than a baseline unit is therefore of no interest—the estimated fixed effects tell the panel analyst nothing about a population. TSCS analysts, however, find great interest in the estimates of the fixed effects. Say K refers to Germany; then a_K tells the analyst, for example, the average growth rate of Germany relative to a reference unit.

There are many other differences between TSCS and panel data models, all brought on by the small T and big N for panel data and the reverse for TSCS data.

Seemingly Unrelated Regressions

The Zellner seemingly unrelated regressions (SUR) model assumes that there are N time-series models, indexed by i, in which each time-series is observed over the same time period, $1, \ldots, T$. Thus, time-series models can be thought of for various sectors of the economy, observed quarterly over some time period. While the time series for each sector can be estimated separately (assuming that T is large enough), Zellner's insight was that each observation at any time point, t, is related to every other observation at t. This information could be exploited to improve estimation.

Formally, the SUR model assumes

$$y_{i,t} = \mathbf{x}_{i,t}\boldsymbol{\beta}_i + \epsilon_{i,t}; \quad i = 1, \ldots, N; \quad t = 1, \ldots, T, \qquad (3)$$

where the specifications for the different units may include different covariates (in notation, some elements of β_i may be constrained to be zero). As will be seen in the next section, the error process for the SUR model is similar to some of the error processes for TSCS models. The assumption of a single $\boldsymbol{\beta}$ relating the covariates to y in Eq. (1) is one of complete homogeneity of the units, the assumption of complete "pooling." The SUR model is thus a model of complete heterogeneity of the units, or "non-pooling." This distinction has many consequences.

It should be noted that the typical SUR application has a relatively large T because the time-series model for each unit must be estimated separately; $T > 100$ is not uncommon. Also, in many applications, the number of units is quite small (sometimes only 3). This must be borne in mind, since it has implications for estimation.

Other Assumptions

It is assumed that the data set is "rectangular," that is, that all countries are observed for the same time period $1, \ldots, T$, with the same beginning and ending dates, and no missing data in the interior of this period. It is completely trivial, though notationally cumbersome, to allow each country to have its own starting and ending period and to allow different countries to be observed for different lengths of time. It is critical that time period t in $y_{i,t}$ and $y_{i',t}$ refer to the same calendar period (year).

Preliminary Data Analysis

Although it is tempting to turn directly to econometric estimation, researchers should, as always, begin by examining the data using common summary statistics and graphical methods. But in addition to standard data inspection methods, TSCS data presents some unique possibilities. Given that the number of units is small, and that the researcher is knowledgeable about those units, box plots of the dependent variable, disaggregated by unit, can be most informative. The unit box plots are only informative if the number of observations per unit, T, is sufficiently large, but this should be the case for most data sets that will be analyzed using TSCS methods.

Researchers can examine the box plots of the dependent variable to see whether there are gross differences in the median value for different units; the width of each box can also be examined to see whether the variance of the dependent variable differs markedly by unit. The plot can also show whether there is some unit that differs radically from the preponderance of units. It can also show whether there is sufficient intra-unit variation to make TSCS analysis meaningful. Finally, the unit box plots can be most helpful in allowing the analyst to find and deal with outliers.

Figure 1 shows a box plot for TSCS data used by Franzese in his 2002 study of the political determinants of the government deficit (as a proportion of GDP) in developed democracies in the post-World War II era (with 3 outliers winsorized). First, it can be seen that all countries exihibit temporal variation in their deficit, indicating that the deficit is not purely a function of stable cross-sectional variables. The medians by country, although different, do not indicate that any country is dramatically different from the others. Finally, while the variation of deficit by country is not constant, there does not appear to be an enormous amount of country-to-country variation in the variation of deficits over time. But analysts might expect to find some panel heteroskedasticity when estimating models of government deficit. Plots like Fig. 1 should always be undertaken before more technical analysis is attempted. Researchers can also examine the impact of time on the dependent variable by producing box plots of the dependent variable disaggregated by year. Having done this, the researcher can then turn to estimation of the relevant models. Once a model is estimated, the model residuals can be graphed using a similar disaggregated box plot. Such a residual plot is invaluable in the refinement process.

Estimation Issues: Cross-Sectional

If the errors in Eq. (1) satisfy the Gauss-Markov assumptions, then it is optimal to estimate it by ordinary least squares (OLS). The Gauss-Markov assumptions about the errors are

$$\mathrm{Var}(\epsilon_{i,t}) = \sigma^2, \qquad (4)$$

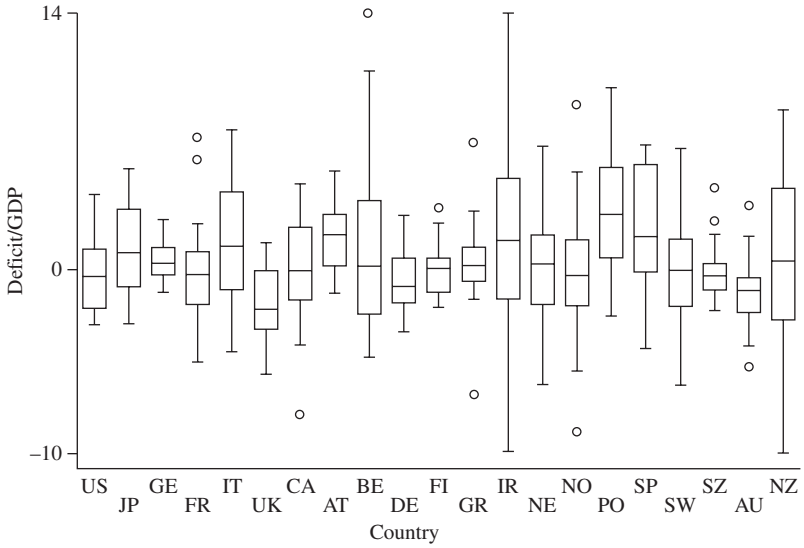

Figure 1 A box plot of government deficit (as percent of GDP) by country in post-World War II developed democracies.

$$\text{Cov}(\epsilon_{i,t}\epsilon_{i',t'}) = 0 \quad \text{if} \quad i \neq i', t \neq t'. \tag{5}$$

It is assumed throughout that the models contain a constant term so that $E(\epsilon_{i,t}) = 0$. It is also assumed throughout that the covariates are exogenous.

The traditional approach to TSCS data is based on the idea that the properties of TSCS data cast doubt on the Gauss-Markov assumptions in several ways, but that, given weaker assumptions about the error structure, Eq. (1) can be optimally estimated by feasible generalized least squares (FGLS). This approach is traditional in that it does not question the basic specification, Eq. (1). Rather, it simply regards the TSCS properties of the error process as a nuisance that causes difficulties for OLS. A more modern approach allows for the various features of TSCS data to enter the specification relating the covariates to the dependent variable.

More General Error Processes and FGLS

While the errors in TSCS models may violate the Gauss-Markov assumptions for all the reasons that error processes in any model may be complicated, there are some features of TSCS data that make the Gauss-Markov assumptions particularly suspect. These can be categorized as panel heteroskedasticity, contemporaneous correlation of the errors, and serial correlation of the errors. For this section, assume that there are no dynamics, so work with Eq. (1) will assume temporally independent errors. (This assumption is relaxed in the next section—the methods discussed there can easily be conjoined with the recommended approach from this section, and so there is no loss in postponing the issue of dynamics.) It is also possible to correct the standard errors for violations of the Gauss-Markov assumptions. This section concludes with a discussion of panel correct standard errors (PCSE) and a recommended methodology for dealing with violations of the Gauss-Markov assumptions that are related to cross-sectional issues. (The nomenclature using the term panel has unfortunately become standard; these are all TSCS, not panel data, issues.)

Panel Heteroskedasticity

The simplest complication of the error process retains independence across observations but allows for the error variance to vary from unit to unit. Panel heteroskedasticity thus maintains the independence of observations of the Gauss-Markov assumptions but relaxes the assumption in Eq. (4) by

$$\text{Var}(\epsilon_{i,t}) = \sigma_i^2. \tag{6}$$

Note that this form of heteroskedasticity allows for the spatial structure of TSCS data and is more restrictive than the general forms of heteroskedasticity studied in general linear models.

The presence of panel heteroskedastic errors means that OLS is no longer optimal and that the standard errors reported by OLS are no longer accurate. It is easy to test for panel heteroskedasticity via a likelihood ratio test. The null hypothesis for this test is that all of the σ_i^2 in Eq. (6) are identical, with the alternative hypothesis that at least one differs from the others. Let $\hat{\sigma}^2$ and $\hat{\sigma}_i^2$ be the maximum likelihood estimates of the homoskedastic and

panel heteroskedastic σ^2 in Eqs. (1) and (6) (these are estimated by the relevant sums of squared errors divided by either $N \times T$ or T). The likelihood ratio statistic is then

$$T\left(N \ln\hat{\sigma}^2 - \sum_{i=1}^{N} \ln\hat{\sigma}_i^2\right), \tag{7}$$

which is asymptotically distributed as chi-squared with $N-1$ degrees of freedom.

While the likelihood ratio test (or other common variants based on Lagrange multiplier methods) is useful for testing the null hypothesis of panel homoskedasticity, researchers should do more than simply perform this test. With TSCS data, it is possible to meaningfully estimate each of the σ_i^2. (It is not possible to pursue this investigation for simple cross-sectional data.) These $\hat{\sigma}_i^2$ can then be examined to see, for example, if only one particular unit has a particularly large error variance, that is, it does not fit the basic specification well. Such inspection of the estimated unit variances should always be combined with a more formal hypothesis testing strategy. Such inspection is invaluable if researchers are to make an informed tradeoff of the costs and benefits of alternative estimation strategies for panel heteroskedastic data.

If there is panel heteroskedasticity, Eq. (1) can be estimated by FGLS. This is equivalent to panel-weighted least squares, with observations for each unit being weighted by the inverse of the square root of $\hat{\sigma}_i^2$. This has the usual asymptotically optimal properties of FGLS.

Even if the likelihood ratio test indicates that the null hypothesis of panel homoskedasticity can be rejected, researchers should be careful in using FGLS that downweights observations on units that do not fit Eq. (1) well, while giving units that fit greater weight. Consequently, FGLS can easily mislead researchers into concluding that results based heavily on units for which Eq. (1) fits well apply to all units. Researchers should thus have a strong prior belief that Eq. (1) holds equally for all units before using FGLS to correct for panel heteroskedasticity. As shall be seen, it is easy to correct the OLS standard errors for panel heteroskedasticity without causing the problems inherent in panel-weighted least squares.

Contemporaneously Correlated Errors

Much attention has focused on estimating models in which the errors show both panel heteroskedasticity and contemporaneous correlation of the errors, that is,

$$\text{Cov}(\epsilon_{i,t}\epsilon_{i',t'}) = \begin{cases} \sigma_{i,j} & \text{if } t = t' \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

This assumes that at any given time, the error process for any given unit is related to the error process for other units, but that this linkage only occurs contemporaneously. The amount of correlation between units is unspecified, so there are many $[N(N-1)/2]$ extra parameters in this model.

Parks suggested that models with panel heteroskedastic and contemporaneously correlated errors could also be estimated by FGLS. While the estimation is complicated, the basic idea is that Eq. (1) is first estimated by OLS (which is consistent). The OLS residuals are then used to build up estimates of the contemporaneous covariance matrix and heteroskedasticity as in Eqs. (6) and (8), and finally observations are transformed by the inverse of the Cholesky decomposition of that estimated matrix. For this procedure to work, it is required that $T > N$.

But even if $T > N$, FGLS estimates $[N(N-1)]/2$ additional parameters that are not accounted for in the FGLS standard errors (because FGLS assumes that the error process parameters are known, not estimated). Monte Carlo evidence indicates that the FGLS standard errors in this case may be off by 50% or more unless T is much greater than N. For typical TSCS data, the FGLS correction for contemporaneously correlated errors should thus not be used.

As with panel heteroskedasticity, analysts can also examine the estimated contemporaneous correlation of the errors, computed from the OLS residuals. These estimates can be used to see if OLS might be highly inefficient. But even if the estimated contemporaneous correlations are high, the poor properties of the FGLS correction for contemporaneously correlated errors indicate that it should not be used. But high contemporaneous correlation of the residuals indicates that researchers should try to respecify their model.

Fortunately, it is still possible to use OLS, which is consistent, and then provide panel correct standard errors that are accurate indicators of the variability of OLS estimates even in the presence of panel heteroskedasticity and contemporaneous correlation of the errors. This allows researchers to avoid the serious problem that is common with TSCS data, incorrect OLS standard errors, without having to turn to the very problematic FGLS approaches.

Panel Correct Standard Errors

Beck and Katz showed that it is easy to correct the OLS standard errors for problems of panel heteroskedasticity and contemporaneous correlation of the errors. Unlike other corrections for heteroskedasticity, such as that of White, this method relies less heavily on asymptotic results, since with TSCS data it is possible to estimate the covariance matrix of the errors using T replicates of the OLS residuals.

The basic insight behind panel correct standard errors (PCSEs) is that, however complicated the error process,

the true sampling variance of the OLS estimators is given by

$$\text{Cov}\left(\hat{\boldsymbol{\beta}}\right) = (\mathbf{X}'\mathbf{X})^{-1}\{\mathbf{X}'\boldsymbol{\Omega}\mathbf{X}\}(\mathbf{X}'\mathbf{X})^{-1}, \tag{9}$$

where $\mathbf{X}$ is the data matrix built of all covariates (with data stacked by time period so that the first row of data is for unit 1, time period 1, followed by unit 2, time period 1, etc.) and $\boldsymbol{\Omega}$ is the true covariance matrix of the errors.

Under the Gauss-Markov assumptions, $\boldsymbol{\Omega}$ reduces to $\sigma^2 I$, which then yields the usual OLS standard errors. For TSCS data with contemporaneously correlated and panel heteroskedastic errors, however, $\boldsymbol{\Omega}$ does not reduce to this simple form. Rather, $\boldsymbol{\Omega}$ is a block diagonal matrix, with the contemporaneous covariances forming each block (and by assumption, each block is identical). Letting $\mathbf{E}$ denote the $T \times N$ matrix of the OLS residuals, $\boldsymbol{\Omega}$ can be estimated by

$$\hat{\boldsymbol{\Omega}} = \frac{(\mathbf{E}'\mathbf{E})}{T} \otimes \mathbf{I}_T, \tag{10}$$

where $\otimes$ is the Kronecker product. This estimate can then be substituted into Eq. (9) to produce a correct estimate of the variance-covariance matrix of the OLS estimates. Monte Carlo evidence indicates that standard errors computed from this matrix are quite accurate, usually being within a few percent of the true variation. Equally importantly, this accuracy is obtained with the typical Ts seen in common TSCS data sets (that is, PCSEs are reasonably accurate with 20 time points per unit, and are almost perfect with 50 time points per unit).

It should be stressed that the PCSEs correctly indicate sampling variation of the OLS $\hat{\boldsymbol{\beta}}$s. Because the $\hat{\boldsymbol{\beta}}$s are not themselves modified, PCSEs clearly do not remedy the possible inefficiency of OLS. If analysis indicates that this inefficiency is serious, then alternative methods must be sought. But, in practice, the inefficiency of OLS is often not severe, and it is possible to improve the basic specification [Eq. (1)] to model the causes of heteroskedasticity and contemporaneous correlation of the errors directly, leaving the resulting OLS estimates reasonably efficient.

Thus, current practice is to estimate TSCS models that may show panel heteroskedasticity and contemporaneous correlation of the errors using OLS and PCSEs. While OLS is not optimal, the FGLS "improvements" work out very poorly in practice. PCSEs, on the other hand, guard against incorrect estimates of sampling variability at essentially no cost.

Estimation Issues: Dynamics

As in single time-series models, it is unlikely that the observations in TSCS models will be temporally independent and show no dynamics. It is often the case that TSCS data sets are observed for a time period long enough that analysts can seriously think about modeling dynamics. Nevertheless, it is also often the case that such data sets are observed for a shorter time period, and at a lower frequency, than single time-series data sets. As a result, many of the refinements possible for the analysis of a long single time series are not available to most TSCS analysts. This section focuses on simple (first-order) models; analysts with richer time-series data can use most of the more sophisticated time-series methods as their data allow. This section examines only dynamic issues; as shall be seen, it is easy to combine the treatment of dynamics with the recommended PCSEs.

Serially Correlated Errors

The old-fashioned approach, corresponding to the FGLS approaches of the previous section, is to assume that dynamics manifest themselves as serially correlated errors that are an estimation nuisance. In this approach, analysts allow for first-order serial correlation of the errors and then use FGLS to correct for this problem. Serially correlated errors are assumed to follow

$$\epsilon_{i,t} = \rho\epsilon_{i,t-1} + \nu_{i,t}, \tag{11}$$

where the ν are a "white noise" (independent and identically distributed) process, and some suitable assumption must be made about the first observation for each unit.

A variety of tests exists for serially correlated errors. The Lagrange multiplier (LM) test is the easiest and also fits best with what is done below. The null hypothesis for the test is that $\rho = 0$ against the alternative that it is not zero. The LM test regresses the OLS residuals [of Eq. (1)] on their first-order lags and all of the covariates in the model. The null can be assessed by either examining the t-statistic on the coefficient of the lagged residual or by examining the statistic $N \times T \times R^2$, which has a chi-squared distribution with 1 degree of freedom and where R^2 is the uncentered squared correlation of the "auxiliary" regression.

If the null hypothesis of serial independence of the errors is rejected, standard FGLS methods can be used. These consist of running OLS on Eq. (1), computing the correlation of the residuals and lagged residuals and then taking a pseudo-difference of each observation (the observation minus $\hat{\rho}$ of the lag of that observation, where $\hat{\rho}$ is the estimated correlation of the errors). In this procedure, the first observation for each unit is lost. This procedure can be improved by using the Prais-Winsten method, which retains the first observation for each unit (suitably transformed) while taking pseudo-differences of all observations other than the first one for each unit. Because there are N first observations and T is usually

not large, the Prais-Winsten procedure is superior to the more commonly used pseudo-differences.

Lagged Dependent Variable Models

Although the FGLS correction for serially correlated errors has good statistical properties, it has largely been supplanted in single time-series analysis by more modern treatments. The serial correlated error approach sees the dynamics as a nuisance that impedes estimation; more modern approaches add the dynamics to the basic specification. This corrects some theoretical oddities in the serially correlated errors approach.

Note that for the paradigmatic political example, the serially correlated errors model assumes that the effect of unmeasured variables on growth persists over time (declining geometrically), but the measured variables (the covariates) have only an immediate and non-dynamic impact. This is odd, as the covariates are presumably of more theoretical interest than the unmeasured variables in the error term.

While there are a variety of specifications used in modern time-series analysis, the annual data and smallish T in typical TSCS data limit the richness of time-series models that can be used. It is therefore common to use a model that simply adjoins the first lag of y to the model, yielding

$$y_{i,t} = \phi y_{i,t-1} + \mathbf{x}_{i,t}\boldsymbol{\beta} + \epsilon_{i,t}; \quad i = 1, \ldots, N; \quad t = 1, \ldots, T. \tag{12}$$

Note that, as with the serially correlated errors model, a change in the error term has a persistent exponentially declining impact on y. But, in contradistinction to that model, a change in a covariate also has an effect that sets in over time (in the same exponential manner). This model also forces the analyst to explicitly recognize dynamics rather than thinking of those dynamics as simply a nuisance impeding estimation. [Eq. (12) could also include lags of exogenous variables, yielding a richer dynamic model without increasing estimation complexity. But the researcher should not expect that, with 20 or 30 years of annual data, it will be possible to distinguish between alternative dynamic models, so in many cases the simple lagged dependent variable model will be adequate.] This is not to say that Eq. (12) is always superior to the serially correlated errors model, but rather that, in general, it seems to be a better approach to modeling TSCS dynamics.

If the errors in Eq. (12) are serially uncorrelated, then it can be correctly estimated by OLS. If the errors are serially correlated, then OLS is inconsistent. Fortunately, it is easy to test for serially correlated errors using the same LM test as for the static model (adjoining the lag of y to the list of regressors in the auxiliary regression). The test statistic for whether the errors in Eq. (12) are uncorrelated is identical to that for Eq. (1).

It is interesting that for panel data, Eq. (12) with fixed effects causes very serious econometric problems. This is because with small T, the OLS estimate of ρ is biased downward, with the degree of bias inversely proportional to T. But this is much less of a problem in TSCS data, because T is almost always large enough to make this bias trivial.

It should also be noted that it is assumed that [in Eq. (12)] $\|\phi\| < 1$, that is, the model is stationary. Much recent research on single time series has focused on the nonstationary case, but little is known about nonstationary TSCS data. In many applications, including the paradigmatic political model, the dependent variable is a rate of growth, and hence very likely to be stationary. However, there will be models with a nonstationary dependent variable. Because the asymptotics of TSCS data are different than for single time series, the standard tests for nonstationarity may not be correct. Analysts estimating models with ϕ close to 1 should clearly worry about this issue. It may well be that a TSCS version of the "error correction" model espoused by Hendry *et al.* may be the appropriate model for nonstationary or near-nonstationary TSCS data.

This model assumes that in the short run there is some relationship between the covariates and y, which is modeled by $\Delta y_{i,t} = \Delta\mathbf{x}_{i,t}\boldsymbol{\beta} + \epsilon_{i,t}$. In addition, there is a long-run equilibrium between y and $\mathbf{x}$ modeled by $y_{i,e} = \mathbf{x}_{i,e}\boldsymbol{\gamma}$. When the system is out of equilibrium, y adjusts to that equilibrium at a rate of ϕ percent per year. Note that this is the single equation form of the error correction setup, in which the system returns to equilibrium by adjustments in y only. The error correction model is

$$\Delta y_{i,t} = \Delta\mathbf{x}_{i,t}\boldsymbol{\beta} - \phi\left(y_{i,t-1} - \mathbf{x}_{i,t-1}\boldsymbol{\gamma}\right) + \epsilon_{i,t}. \tag{13}$$

This can be estimated by OLS as long as the ϵ are stationary. While the typical N and T of TSCS data make the distribution of a Dickey-Fuller type statistic problematic, it will often be the case that the estimated serial correlation of the residuals is either so close to 1 or so far from 1 that nonstationarity (or stationarity) is obvious, regardless of any exact distribution of a test statistic. For the remainder of this article, stationarity is assumed, either of Eq. (12) or (13). Since Eq. (13) can be rewritten as a more complicated form of Eq. (12) (with levels and differences), for simplicity this article works only with Eq. (12), but everything should hold for the error correction formulation.

If Eq. (12) shows serially correlated errors, then the researcher must resort to complicated instrumental variable methods to estimate it. But if the LM test indicates that the null of uncorrelated errors cannot be rejected, OLS is the optimal estimation method. In practice, it is difficult to distinguish between a static equation with

serially correlated errors and the lagged dependent variable model. So, in many cases, the null hypothesis of serially independent errors will not be rejected and hence OLS can be used to estimate Eq. (12).

Instrumental variable estimation is itself problematic. Eq. (12) with serially correlated errors, can be rewritten as a model with uncorrelated errors but with more lags of both y and $\mathbf{x}$. Thus, if Eq. (12) shows serially correlated errors, it is surely worth examining (via LM tests) whether specifications with more lags of y or $\mathbf{x}$ result in serially uncorrelated errors.

This is particularly helpful to TSCS analysts, since they can then estimate dynamic models but use PCSEs, which are computed in the same manner as the static model. Consequently, while the old-fashioned procedure consists of testing for various error complications and then using FGLS to correct for these, the more modern approach estimates Eq. (12) with OLS and PCSEs and then tests whether the residuals are correlated, noting in practice that they seldom are. This simple estimation strategy allows analysts to focus on the important issue: the basic substantive specification. While all the usual issues surrounding choice of specification are present, TSCS data also present some unique issues that are discussed in the next section. But TSCS analysts will, of course, engage in all of the same specification searches and tests that are the stock and trade of regression analysts.

Specifying TSCS Models

Much of the debate in TSCS analysis has focused on how to estimate such models when the error structure is complicated. But, as has been seen, a simple estimation strategy is available. This leaves analysts to focus on the choice of specification. Here two strategies are considered: modeling heterogeneity and spatial issues. These are all done in the context of Eq. (12).

Heterogeneity

As noted, Eq. (12) implies complete pooling, meaning that all units have exactly the same relationship between the covariates and the dependent variable. (In this subsection, only heterogeneity in the mean function, that is, the relationship of the covariates to the expected value of the dependent variable, is considered.) Not only are the same covariates used for each unit, but also the coefficients on those covariates are assumed to be identical from unit to unit as well. (Note that for SUR, it is typically assumed that different covariates affect different units, since this is what gives SUR its power. But for TSCS models, it is almost invariably assumed that the covariates for all units are identical. This assumption is used here.)

The opposite of pooling is the completely unpooled model, in which each unit has its own set of coefficients. In dynamic form, this is

$$y_{i,t} = \phi_i y_{i,t-1} + \mathbf{x}_{i,t}\boldsymbol{\beta}_i + \epsilon_{i,t}; \;\; i = 1, \ldots, N; \;\; t = 1, \ldots, T. \tag{14}$$

If this specification is correct, then it is optimal to use unit-by-unit OLS. That is, it is optimal to run N separate OLS regressions, each on T observations (as always, assuming that specification tests show that this model is appropriate for each unit). This assumes that there is no relationship between the units and no possible information gains by imposing some degree of homogeneity on the coefficients (across the units). Analysts thus seem to be forced to choose between the assumption that the units are completely homogeneous or completely heterogeneous.

Assessing Heterogeneity

Because Eq. (12) is nested inside Eq. (14), it is easy to test which specification the data prefer. Taking as the null hypothesis that Eq. (12) is correct, a standard F-test comparing the sums of squared errors from the two specifications provides the best test between these two specifications.

But while this test is statistically straightforward, interpreting its results is less so. With a very large T, the researcher may end up rejecting the null of complete pooling even when the units are by and large homogeneous. There is less danger in accepting the null hypothesis due to a small T, since then unit-by-unit OLS will not be a feasible strategy.

It is also the case that some coefficients may be homogeneous while others may be heterogeneous. Eq. (14) uses up a substantial number of degrees of freedom. For example, it may be considered likely that ϕ, the speed of dynamic adjustment, is similar from unit to unit. Or we may be willing to allow the coefficients on controls that are not of theoretical interest to be homogeneous. Allowing for some coefficients to be homogeneous across units, while others are allowed to vary freely, can save many degrees of freedom and allow for efficient use of the data for the Ts typically seen in TSCS data. The researcher can easily modify the standard F-test to allow for the imposition of unit homogeneity in some coefficients.

The F-test approach may also mask another problem when most units are similar, but one is rather different from the others. With a large N, this heterogeneity may be missed; alternatively, one outlying unit may lead to the rejection of the pooled model, whereas the appropriate strategy is to estimate a pooled model on all but the outlying unit.

It is easy to assess whether there are one or a few outlying units via cross-validation. TSCS data present the analyst with a natural cross-validation strategy. The fully pooled model can be estimated leaving out one unit at a time, with the dependent variable for that omitted unit then being "predicted" based on the estimates that omitted that unit. While cross-validation is most commonly used for model selection, here the interest is in whether most units show low "prediction" error, with only one or a few showing high prediction error. If the units that have high prediction error are also those that appear different on theoretical grounds (e.g., geography, type of political or economic system), then the most sensible strategy would be to estimate the pooled model omitting the few units with high prediction error (of course, noting the change in "sample").

Estimation with Heterogeneity

There are attempts to steer an intermediate course between assuming complete pooling and no pooling whatsoever. These attempts all build on the classic work of Swamy, who proposed a "random coefficients model" (RCM) akin to Eq. (14), but in which the coefficients are joined by being draws from a normal distribution. He adjoined to Eq. (14) the assumption that $\boldsymbol{\beta}_i \sim N(\boldsymbol{\beta}, \boldsymbol{\Gamma})$, where $\boldsymbol{\Gamma}$, the amount of unit-to-unit variation in the unit coefficients, is a hyperparameter to be estimated. Swamy and Hsiao have proposed various FGLS methods for estimating this model. Smith, and more recently Western, have proposed estimating this model in a Bayesian or empirical Bayes context; recent advances in Markov chain Monte Carlo methods now make this feasible.

The model appears attractive. One particularly attractive feature is that the analyst can modify the assumption about how the coefficients are generated to allow them to vary systematically by unit specific covariates (z_i), which measure items that do not vary over time, such as the political system. This results in $\boldsymbol{\beta}_i \sim N(\boldsymbol{\beta} + \mathbf{z}\gamma, \boldsymbol{\Gamma})$, where both γ and $\boldsymbol{\Gamma}$ are parameters to be estimated.

Although this model appears to be an attractive position in between two implausible extremes, and the RCM has proven extremely useful in hierarchical modeling, its usefulness in TSCS data is less clear. It does appear clear that the FGLS estimator proposed by Swamy and Hsiao does not work well in practice. This is because in order to ensure the positive definiteness of a covariance matrix, it assumes that sampling variance is zero. With the typical T of a TSCS data set, this is often incorrect, and leads to very poor performance of the Swamy/Hsiao estimator. This is unfortunate, as this is the RCM estimator seen in most computer packages.

Monte Carlo evidence indicates that the fully pooled model estimated via OLS does quite well unless there is either a very large T or a large amount of diversity in the unit $\boldsymbol{\beta}_i$. With a large T, unit-by-unit OLS [Eq. (14)] performs quite well, though such an estimator performs poorly for moderately sized Ts often seen in TSCS data. Although empirical Bayes estimators also perform well for a smallish T or relatively homogeneous $\boldsymbol{\beta}_i$, pooled OLS is better. For large T, unit-by-unit OLS is as good as the more complicated techniques. While more research is necessary, at this moment it appears that researchers can simply do an F-test to discriminate between Eqs. (12) and (14) and then do either fully pooled OLS or unit-by-unit OLS. The Monte Carlo evidence indicates that fully pooled OLS might be superior, even when the F-test marginally prefers the unpooled model. Choosing between the two methods thus requires a bit of art, and choice should be informed by theory as well as simple statistical tests, cross-validation, and other examinations of the data.

Spatial Variables

The units in TSCS data are typically spatially related. Note that analysts using FGLS were worried about whether the error process of one unit was related to the error process of other units. Spatial econometrics is a very complex arena by itself; most analyses deal with issues where interrelated units are observed only once. Spatial issues are simpler to analyze in the TSCS context.

FGLS Estimation

For concreteness, consider the analysis of economic growth as a function of economic and political variables in the 20 or so advanced industrial societies. The contemporaneously correlated errors approach assumes that the "errors" in the growth equation for one country are related to the error terms for other countries. Note that the problem with using FGLS to correct for this is that the correlation matrix of the errors was left free, leaving FGLS to estimate an inordinately large number of parameters in that matrix. Spatial analysis can dramatically improve on this.

Spatial analysts assume that the relationship between countries is proportional to some measure of distance. Whereas geographers focus on physical distance, political economists might assume that the interrelationship between the economies in two countries varies with the amount of trade they engage in. Letting D_{ij} be a measure of the distance between two countries (whether geographic or economic), the spatial approach replaces the non-zero covariances in Eq. (8) by

$$\mathrm{Cov}(\epsilon_{i,t}\epsilon_{i',t'}) = \begin{cases} \nu D_{i,j} & \text{if } t = t' \\ 0 & \text{otherwise.} \end{cases} \tag{15}$$

This then reduces the problems of FGLS drastically. FGLS estimation of the unparameterized correlated errors model has approximately $N^2/2$ estimated parameters that are not accounted for in the FGLS equations. If this error correlation is parameterized using spatial

notions, the number of estimated parameters that FGLS does not account for is reduced to 1. Such an approach would make FGLS a very reasonable choice of estimator for treating spatial correlation in the error process. At that point, it would be better to estimate this model via maximum likelihood, since the analyst would then obtain an estimate and standard error for the spatial correlation parameters, ν. To test the null of no spatial correlation of the errors, the analyst would then simply test the null $\nu = 0$. It should be noted that while this approach is difficult for standard cross-sectional spatial data, it is much simpler in the TSCS case, because in the latter case T replicates of the error process are observed, whereas in the former case only one such replicate is observed.

Adding Spatial Variables to the Specification

Allowing for spatially correlated errors is an improvement on the traditional FGLS estimator for contemporaneously correlated errors. But spatial notions can also be used in a more modern context, where spatial variables are included in the specification. The assumption of spatially correlated errors is equivalent to the assumption that unmeasured variables that affect growth in one country also affect growth in other countries. In this model, only measured variables pertaining to the unit affect the growth of that unit; unmeasured variables pertaining to all units affects the growth of each unit. This is odd because it is presumably the measured variables that are of interest.

It thus seems reasonable that the economic growth of one country is affected by the growth experienced by its neighbors, with the effect declining with distance (either geographic or economic). Then the specification called the "spatial lag," that is, the spatially weighted sum of growth in all of the other countries can be considered. Because it seems reasonable that neighbors have an effect only with some time lag, it might reasonably be expected that this spatially lagged variable should also be lagged one year. Note that this makes estimation simple. If, however, the contemporaneous spatial lag was included, this would return to the same very complicated estimation problem of the cross-sectional spatial analyst, in which there are T observations on an N-variate vector instead of $N \times T$ observations on scalar dependent variables.

This leads to a spatial and temporally dynamic specification:

$$y_{i,t} = \phi y_{i,t-1} + \lambda \sum_{j \neq 1} w_j y_{j,t-1} + \mathbf{x}_{i,t}\boldsymbol{\beta} + \epsilon_{i,t}; \quad i = 1, \ldots, N; \quad t = 1, \ldots, T, \tag{16}$$

where the spatial weights, w_j, are defined *a priori* by the analyst. If the errors are temporally and spatially independent, this can be estimated by OLS and PCSEs. Such a procedure has been used informally by many TSCS modelers, who might, for example, include the lag of the trade-weighted average growth in all partner nations in their study. It is, of course, better to model spatial effects explicitly. This is an ongoing area of research in which much more study needs to be done, particularly of the appropriateness of using the temporally lagged spatial lag in the dynamic specification.

Current Issues

TSCS data present many interesting complications. The old-fashioned approach is to view these complications as nuisances that cause problems for OLS. The more modern approach is to add the TSCS features to the specification, explicitly modeling both dynamic and spatial features of the data. In many cases, this can be done via OLS with panel-corrected standard errors, and so leads to a relatively simple estimation problem.

So far, only TSCS data with a continuous dependent variable have been discussed. But there is often TSCS with a binary (or other discrete) dependent variable; the paradigmatic example is whether a pair of nations in conflict or not. While discussing this type of data is beyond the scope of this article, it should be noted that this is an extremely active area of research. There are at present two leading approaches for this type of data: correcting the error process in a generalized linear model setup, leading to Liang and Zeger's generalized estimating equation, and Beck, Katz and Tucker's event history approach (which is intimately related to the Markov switching model). But new breakthroughs in computational methods (Markov chain Monte Carlo) may allow for more direct modeling of binary TSCS data. At present, there is no definitive recommendation on how to model such data in general. But for the continuous case, OLS combined with panel corrected standard errors of a model that specifies the interesting features of TSCS data is the generally recommended method.

Time–Space Modeling

Donald G. Janelle
University of California, Santa Barbara, Santa Barbara, California, USA

Glossary

agent-based spatial models Models that simulate an agent's decisions and relationships to other agents through space and time based on the modeler's designated rules of agent behavior.

cellular automata A procedure for simulating dynamically changes in the characteristics of cells, arrayed usually as a grid to represent an environment (e.g., demographic transition in an urban neighborhood).

human extensibility The capability of a person or institution to exert influence beyond their current location and time (e.g., via telecommunications or through application of economic and political power).

time geography The study of the temporal dimensions of human spatial behavior and of the embeddedness of time in geographic patterns.

time–space compression The accelerated growth of events in a person's life and the intensified uses of space through time.

time–space convergence/divergence The rate (e.g., minutes per year) at which places (e.g., cities) move closer together or further apart as a result of technological changes or congestion factors that impact on the travel time or communication time between them.

time–space distanciation The spatiotemporal outreach of a social system to form larger organizational entities and agents of change.

time–space path A line of movement behavior of a person through time (usually represented as a single dimension of clock time on the vertical axis of a graph) and over space (usually represented on the horizontal axis as a single dimension of distance or as a geographic surface of two dimensions). The time–space path is a central feature of Torsten Hägerstrand's time geography model of society. Depending on the temporal scale, it may be a daily path or a lifeline.

time–space-prism A space that delimits the movement possibilities and activity choices of a person, usually based over a defined time period such as 24 hours.

This article discusses concepts and research methods that seek to merge time and space into an integrated time–space depiction of process. It reviews modeling frameworks used to represent time–space structures of human behavior, including the application of new tools that seek a more dynamic depiction of change and development. Most of the examples are drawn from the disciplines of human geography, regional science, and related fields.

Representing Time–Space Processes

Many significant societal issues are best understood and dealt with as time–space in nature. Examples include diffusion processes such as epidemics, which may be guided by complex patterns of human behavior, spatial structures of human contacts, facilities for movement, as well as the intrinsic temporal parameters of biological transfer among hosts and susceptible populations. Similarly, crime events in cities may exhibit temporal sequence, which may not be independent of spatial patterns and structures.

Although the term *process* implies some notion of continuity of change over time and space simultaneously, researchers have focused largely on one dimension or the other as opposed to treating time–space operationally as a single integrated framework. This is due, in part, to the scarcity of appropriate data resources and to the immaturity of methodological means to treat process in an explicit manner. Thus, for example, time series data on economic indicators are usually investigated for trends through time while ignoring patterns of change in such indicators over space. The temporal dimension is usually represented at highly

aggregate levels in space (e.g., the nation). The availability of data (especially from the census) has conditioned many images of landscape change to a series of snapshots 10 years apart. Examples include population density patterns or household income distributions within cities. Since the census and most customized social surveys typically focus on discrete points in time, social scientists have not had access to continuous data for study of processes in their full temporal–spatial contexts.

Early attempts to understand the changing character of geographic space over time often skirt data constraints by using spatial concepts to envision landscapes at different points in time. The identification of historical phases in the development of urban settlement systems is an example, typified by the idealized stage model proposed by Taaffe *et al*. in 1963 to account for the sequence and extent of transportation development and urban growth in West Africa. Although such approaches fall short of embracing a full understanding of how the world works, they are useful for generating hypotheses and suggesting approaches to empirical verification, thereby enhancing prospects for predictions of spatial patterns over time.

An interesting example of a time–space perspective to modeling is represented by the popular computer game, SimCity (Maxis Software, Division of Electronic Arts). SimCity simulates the development of an urban landscape based on a complex set of interdependent decisions by the player. This involves allocation of land resources to given activities in an attempt to satisfy both individual and community needs, the establishment of employment centers, and the raising of tax revenue. In turn, these decisions are embedded with both positive and negative spillover effects at neighborhood and regional levels—seen in terms of environmental impact, traffic flows, land values, criminal activity, and public assessment. Unforeseen events related to the economy, political sentiment, and natural forces add interest and test the robustness and resiliency of the city as it evolves in time and space. The graphic displays in SimCity capture the dynamics of change in space and time, allowing players to alter the scale of representation, explore different scenarios of social and economic change or land use design, and visualize information about the city's development in different data formats (e.g., as maps, trend lines, and tables).

Within a framework of simplified rules and impressive graphic display, SimCity captures much of what might be embraced in a time–space perspective on social and behavioral change. Game results may be explored in greater depth to describe and predict the evolution of networks and infrastructure over time, the diffusion of land uses, changes in population density, and implications for individual behavior. Although the modeling of game processes reflects understanding of the gaming environment, it would be presumptuous to claim equivalent specificity in the time and space attributes of social change. Data constraints and confidentiality issues in the treatment of information about people and firms usually preclude the same level of detail for modeling or analyzing human systems.

Scientific efforts to describe human behavior and organizational systems, explore relationships among variables across space and time, and predict outcomes as time–space patterns are constrained by the underlying complexities of the processes at work, the adequacy of theory and measurement tools, and the nature of standard data resources at the disposal of researchers. While recognizing these limitations, it is useful to highlight some of the methodologies that have been applied. Of the approaches most commonly used, diffusion and migration modeling and spatial point processes are discussed elsewhere in the encyclopedia. Time–geography, cellular automata simulations, and agent-based spatial models are introduced in the following section. This is followed by a review of time–space concepts that have yet to be incorporated in existing modeling frameworks and by discussion of technical developments that may alter standard methodologies for modeling time–space processes.

Time–Space Modeling Approaches

Statistical analysis, based mostly on regression techniques, is widely used to model trends in variable relationships across time in hopes of explaining values of a dependent variable by a set of independent variables. This methodology relies on historical data and is most appropriate in circumstances in which theoretical understanding within a knowledge domain is weak. In accounting for spatial variation in dependent variables at a point in time or for analysis of changes over a period of time across the spatial units of observation, these methods raise concerns regarding the dependency of results according to variability in sizes and shapes of spatial units, gaps in time between data points, and periods of measurement. Additional concerns about time series autocorrelation and spatial autocorrelation are dealt with successfully with econometric methods and local indicators of spatial association. Nonetheless, difficulties in treating simultaneously the assessment of temporal and spatial variation continue to limit applications of statistical methods in modeling.

As an alternative to statistical modeling, dynamic models may use simultaneous equations to describe systems based on theories that purport to capture functional and causal linkages in the flows of resources and changes over time. In these models, system dynamics are describable by a set of state variables (stocks), controls over rates of flows, and parameters of the system. A systems approach can be used to explore "what if" scenarios that give insight to system responses to changes in policies and different parameter values. The aggregate analytical

approach to dynamic modeling lends itself to predictive uses. However, needs for analytical or numerically intensive solutions, conditions of equilibrium, and other simplifying assumptions have tended to constrain the complexity and applicability of these models. These kinds of models have been used to explore the functioning of environmental systems and have also seen application in attempts to model the dynamics of regional economies.

A general critique of systems modeling is embraced in structuration theory, which argues for a more recursive link between independent human agencies and "the system" and for greater emphasis on the contextuality of human actions. Increasingly, researchers have turned to microlevel methods and concepts for describing and simulating time–space processes and to methods that allow for representation of human intention in making decisions. The following sections treat some of the approaches that are explicitly time–spatial in their formulation and that hold promise for representation of human agency. These include time geography and simulations based on cellular automata and agent-based modeling.

Time Geography

Torsten Hägerstrand's time geography model of society treats individual activity behavior explicitly as a time–space process and views individual behavior as the building block of larger social systems. In the time geography perspective, the activities and movement paths (or time–space paths) of individuals are subject to a set of constraints. These constraints link the individual to a broader system of social ties (couplings), controls over the use of space and facilities (authority), and differential access to the means of overcoming distance and to requirements for meeting personal needs for rest and nourishment (capabilities). Hägerstrand's motivation for casting human behavior in this way was to provide a method to assess the impact of policy decisions on the freedom of action that people have within regional or urban settings. The modeling approach recognizes that human activity choices of any kind have finite durations, are linked to prior activities, and condition future choices. At any given point along a time–space path, a person has a limited degree of freedom to make choices—represented by Hägerstrand as a time–space prism. The prism defines the outer boundaries of locations that a person can access given his or her level of mobility (speed of movement) and the amount of time at his or her disposal between any designated set of activities. Lenntorp provides the classic application of this approach, modeling the possibilities for residents to engage in different activities by means of public transportation in Karlstad, Sweden. Burns used it to model tradeoffs between time and space in the assessment of options for urban transportation planning. Although the time geography modeling approach has been slow in seeing wide application, researchers have linked it through geographic information systems (GIS) to the analysis and representation of time–space travel surveys and have used it to characterize human behavior as dynamic geographies and as a basis for modeling accessibility. Time geography modeling lends itself to linkages with other modeling approaches, including event history analysis, cohort studies of demographic and behavioral change, and agent-based spatial modeling.

Cellular Automata

Cellular models, including cellular automata (CA), provide simple representations of dynamic systems and have been especially popular for simulating environmental change at a range of geographical and temporal scales. CA are conceived typically as a grid of cells, with the character (state) of cells subject to a set of transition rules about the rates and likelihood of change over time. These rules usually include the effects of neighboring cells on each given cell (e.g., as in a contagion process, such as gentrification within the central region of cities). Implementation of the rules is used to generate a dynamic computer display of change over time. Thus, the elemental components of a CA model include the lattice of cells, a set of discrete states for cells, a specified neighborhood of surrounding cells, transition rules for cell transfer from one state to another, and a time step (e.g., 1 year) for updating the state status of all cells. Cell dynamics may be constrained further by introduction of external factors (e.g., by some measure of performance for the national economy) and by relaxation of assumptions about the homogeneity of cells. Thus, a CA model on urban land use transition might weight certain cells for housing value based on the expected amenity value of a cell's physical setting and the quality of neighboring houses. An early use of the CA approach was Tobler's dynamic depiction of land use change in the Detroit region. Clarke *et al*. offer a another example, and Batty *et al*. provide a general overview of the CA approach in the context of urban dynamics. Among the weaknesses of cellular models is the inability to reflect the role of complex decision making by human agents. However, cellular frameworks may be combined with Markov models, in which transition rules are treated probabilistically and may be conditioned by temporal lags in cell response. In addition, they can be combined within the framework of agent-based simulations that focus explicitly on the behavior of agents and the interdependency of such behavior on cell characteristics.

Agent-Based Spatial Modeling

Agent-based modeling (ABM) provides an attractive methodology for linking social and behavioral theory

within the explicit time–space context of the behavioral environment. The agents represent decision makers who act and interact with others in an environment according to rules of behavior and defined bases of motivation. The environments may be based on replication of an established behavioral setting (e.g., a market) and could be set forth within the framework of a CA model. Some of the underlying assumptions of these models (that the systems are dynamic and evolving and not in equilibrium) are congruent with real-world patterns of change. Within this framework, microlevel individual decisions may have effects at other scales; for example, consumer selection of housing within an area of a city for personal reasons could impact the composite urban structure of land values, demand for classrooms, commercial potential, and the spatial distribution of social needs both locally and regionally. Because these diverse impacts relate to the behavior of multiple decision makers, these models are frequently defined as multiagent systems (MAS). Gilbert and Troitzsch present a thorough introduction to agent modeling. ABM/MAS offer a way to imitate behavior within a dynamic modeling framework. Examples of applications in the time–space context include the modeling of pedestrian flows in business districts, intraurban household migration, and social segregation processes.

The ability to use "representative" data as opposed to empirically derived data sets and the ability to input theoretical constructs into the model of decision making by agents are intrinsically attractive given the difficulty in securing adequate data for exploration of many social science research questions. However, this flexibility also raises issues regarding the validity of models and the verification of model outputs and their interpretation. The use of realistic parameters, possibly derived from empirical investigation, is one way that researchers have attempted to deal with this issue. CA and ABM provide a means of assessing the current state of knowledge regarding time–space processes, they help reveal gaps in our understanding of behavior, and they have the potential to demonstrate how processes at one scale (the microscale) can impact in unexpected ways on patterns of human organization and resource use at more macroscales. Through systematic exploration of parameter values to determine a model's sensitivities to a range of plausible behaviors, it may be possible to enhance the acceptance of predictions based on data that are representative of real-world situations.

Merging Time and Space in Social–Behavioral Research

Social science theory treats time–space as an embedded structure of human social and economic systems. Four general concepts about such systems address explicitly their spatiotemporal attributes. For the most part, time–space modeling approaches have not attempted to include these concepts, but they represent significant challenges in attempts to capture and interpret the dynamic structures of human environments. These concepts are time–space convergence, human extensibility, time–space distanciation, and time–space compression. Collectively, these ideas relate to processes that alter the significance of space in the functioning of social and economic systems. Brief discussions of each of these concepts and their relationships to one another expose issues that have not been fully explored in time–space modeling methodologies.

Time–Space Convergence

Time–space convergence and the related concept of time–space divergence treat space as a product of human efforts to reduce the travel time and travel cost between places. For example, as a consequence of improved rail and highway infrastructure, Boston and New York City converged on each other at an average rate of 26 minutes per year between 1800 and 1960. Such measures may help in the interpretation of social and economic responses to reduced constraints on human interactions, but they also mask complexities that are inherent to convergence processes. For instance, measures will differ depending on access to modes of movement and to social class differences that may deny use of preferred (faster) modes to some. Thus, there exist multiple representations of time–space convergence for any single place or region. Among the multiple of places that make up urban systems, the variability of convergence rates characterizes a non-Euclidean geometry that complicates any simple visualization (e.g., a map) of results. Such formidable difficulties in establishing an empirical framework have no doubt impeded research on convergence/divergence processes.

Human Extensibility

Human extensibility is the reciprocal of time–space convergence. It describes how the relaxation of constraints on movement allows people to extend their presence beyond their current locations. The nature and degree of extensibility are unique to each individual or to general categories of people divided by social cleavages across income, class, and other attributes. Empirical work in this area has been extended by Paul Adams based on detailed surveys of daily behavior of individuals. The emergence of the Internet and of multiple global communication systems has sparked renewed interest in this concept. General issues relate to the connectedness of people within communities and to disconnections among communities versus broader

levels of regional and global consciousness. New methodologies are needed to expand empirical understanding of the extensibility processes in different behavioral situations.

Time–Space Distanciation

Time–space distanciation is a related process that merges time with space. Advanced by sociologist Anthony Giddens in relation to his structuration theory, this concept illustrates how convergence and extensibility processes go beyond the context of individuals and places to shape the emergent organization of entire social systems, one example being the intensified globalization of economic activity.

Time–Space Compression

Time–space compression is another dimension to the collapse of space through time. David Harvey pioneered this idea based on the intensification of events per unit of time and per unit of space. It links a process of accumulation in the Marxian sense with the daily lives of people, with the appreciation of some places over others, and with the resulting enlargement in disparities among regions. This notion adds the dimension of experiential meaning associated with the annihilation of space through time.

The concepts of convergence, extensibility, distanciation, and compression are all central to understanding the time–space context of human activities and the systems in which they take place. They offer insight on how the individual fits within the broader system of time–space structures. The challenge for researchers is to incorporate these ideas within more formal modeling frameworks, be they agent-based models, time geography, or dynamic systems approaches.

Developments in Spatiotemporal Representation and Modeling

Two developments stand out with regard to their likely future impact on advances in time–space modeling for the social and behavioral sciences: the emergence of new data visualization technologies and the growth of on-demand, real-time information systems that use technologies that know where they are at any point in time [i.e., location-based services (LBSs) that link individuals within a framework of georeferenced information about the world around them].

Visualization

Advances in graphical visualization methods offer ways to explore representations of time–space processes. Video capture of simulations or graphical animations of changing geographical patterns (dynamic maps) are expected to refine capabilities for time–space modeling. For instance, slowing down or speeding up processes may facilitate pattern detection. Animations at different resolutions of time and space may expose process linkages at multiple scales. Other options include the ability to explore possible causal linkages among processes both as lagged and nonlagged time series across different spatial scales. Embedding these capabilities within a GIS offers yet additional scope to application of analytical modeling methods. Peuquet explores some of the computational and data modeling issues that relate to efforts of integrating space and time within GIS software environments. In addition, new tools of interactive spatial data analysis are becoming more sensitive to the needs of time–space analysis.

Continuous Data Capture in Space and Time

Real-time capture of information at the level of the individual person or for specific locations is based on the locational awareness of new communication technologies that are linked with geographically referenced information systems. The merging of the laptop computer, personal digital assistant, Internet, database, and telephone capabilities into personal, wearable, wireless information utilities increases the scope for new types of human behavior and for new research methodologies in the social and behavioral sciences. It is an open question as to what new forms of behavior might emerge or what LBS functions government or business might provide. Nonetheless, it is likely that LBS technologies will influence the spatial and temporal organization of society, offering opportunities for new forms of retailing, work activity, governance, emergency care delivery, services for the blind and deaf, criminal behavior, and search-and-find methods.

From the perspective of science, these technologies offer options for sensing processes as they occur, sampling human behavior in a time–space framework, carrying out dynamic calculations and mappings, and analyzing information as it is collected. The capabilities to retrieve information based on where one is at any given time or to target information to respondents based on where they are open possibilities for dynamic modeling of time–space attributes of social and behavioral processes. These new tools may substantially alter the methods of primary data capture in field research. The real-time recording of time–space activity diaries for respondents provides a basis for testing the theoretical foundations of time geography modeling. Linking of such data with computational capabilities could yield new methods for evaluating ABM simulations. Of course, new data mining

and visualization tools will be needed to exploit these potentials. At the same time, these capabilities may burden the ethical foundations of behavioral research with issues regarding the protection of individual privacy and autonomy from unwanted surveillance and from the time–space profiling of individuals or regions. Time–space modeling is entering an exciting era of potential and challenges.

Total Survey Error

Tom W. Smith
University of Chicago, Chicago, Illinois, USA

Glossary

bias/systematic error An error that creates a difference between the measured and true overall mean values.
context effects Differences in measurements resulting from the order and content of prior items.
interviewer effects Differences in measurements resulting from differences in the characteristics or interviewing behaviors of those conducting an interview.
mode effects Differences in measurements resulting from method of administration (e.g., in person, by telephone, self-completion).
nonresponse Failure to respond to or participate in a survey (unit or survey nonresponse) or to answer a question in a survey (item nonresponse).
response option effects Differences in measurements resulting from the content, number, or order of the answer categories to closed-ended questions.
variance/variable error A random error with no expected effect on the overall mean values.

Total survey error is the sum of two components: (1) variance, or variable error, which is random and has no expected impact on mean values, and (2) bias, or systematic error, which is directional and alters mean estimates. Variable error consists of sampling and nonsampling (collection and processing) errors. Collection errors are further broken down into errors associated with mode, instrument, interviewer, and respondent. Processing errors consist of errors related to coding, data entry, data transfer, and documentation. Systematic errors also consist of sampling and nonsampling errors. Sampling errors may relate to the sample frame, selection, or statistical inference. Nonsampling errors consist of nonobservational and observational errors. The former results from either noncoverage or nonresponse and the latter results from errors in collection, processing, and analysis. As with variable errors, collection errors are related to mode, instrument, interviewer, and respondent, and processing errors are related to coding, data entry, data transfer, and documentation. Analysis errors can be conceptual, statistical, or presentational.

Introduction

Total survey error sums up all of the myriad ways in which measurement can be wrong. As Judith Lessler has noted, total survey error is "the difference between its actual (true) value for the full target population and the value estimated from the survey." Total survey error comes in two varieties: (1) variance, or variable error, which is random and has no expected impact on mean values, and (2) bias, or systematic error, which is directional and alters mean estimates. Total survey error is the sum of these two components.

The concept of total survey error goes back at least to the 1940s; the term was in general use by the 1960s and is now frequently invoked in general discussions of survey error. As Fig. 1 illustrates, total survey error has many components. Each component must be considered to understand the total error structure of a survey.

Variable Error

Looking at variable error first, the most well-understood and frequently discussed source of error is sampling variance, which is the variability in estimates that results from using a random subset of observations to represent all units in the population. Sampling error is usually overemphasized because it is the only component of total survey error that can be readily quantified into confidence intervals and levels of statistical significance. It is also usually

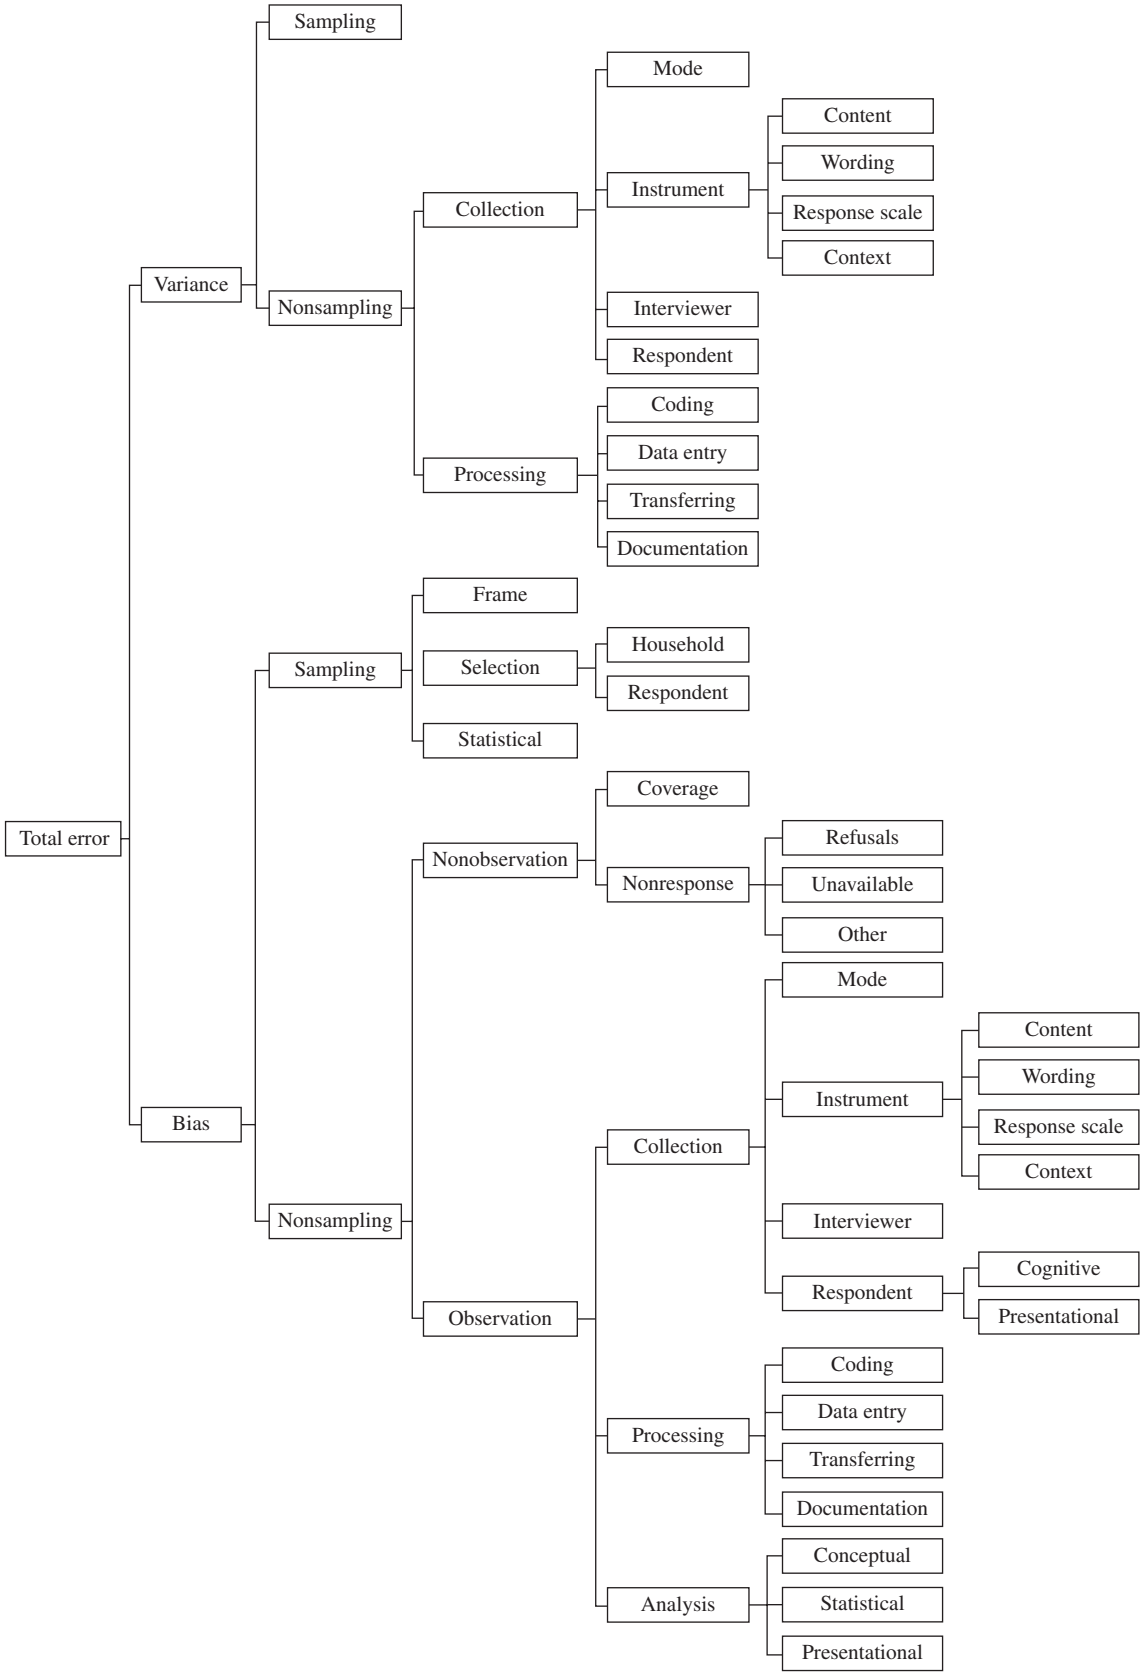

Figure 1 Total survey error.

misreported because estimates of sampling error commonly ignore both the design effects associated with nonsimple random samples and the variable-by-variable differences in sampling variance associated with marginal distributions and clustering.

The other major component of variable error is nonsampling variability, which consists of collection and processing errors. The main aspects of collection error concern differences resulting from mode of administration, instrument format, interviewer, and respondent. Mode of administration differs in three major ways: format (audio, visual, mixed), presenter (interviewer administered, self-administered, mixed), and technology (none/in person, paper, telephone, computer, mixed). Each of these elements can be combined to form a particular method of surveying. For example, using an audio format, interviewer-administered survey with no technology would be the traditional, face-to-face interview—the paper-and-pencil interview (PAPI). Another method would be the visual format, self-administered, and computer-driven interview—the CASI (computer-assisted, self-interview). Each of the many mode variants has unique measurement aspects and error profiles, depending on differences in factors such as the literacy and eyesight and hearing capabilities of the respondents, load capacity, and personal vs. nonpersonal interaction.

In many ways, the survey instrument (i.e., the questionnaire) is the heart of the survey. First, content (i.e., what type of information is being collected) is crucial. For example, a better developed index with more items will produce a more reliable measurement, compared to a less reliable scale. Second, the wording of specific items will affect measurement reliability (but, as discussed later, question wording differences are more likely to be associated with systematic than with variable error). Third, the choice of response scale affects variability. For example, much rounding occurs in many count estimates, and when a "101° feeling thermometer" scale is used, almost all responses are limited to "temperatures" (numerical rankings or ratings) divisible by 10 or 25 (e.g. 40 or 75). Finally, the ordering of questions creates context effects by which earlier items affect the responses to later items. This is usually related to bias, but when order is randomized to minimize context effects (as is often done in computer-assisted interviews), then the order effects essentially become part of the survey variance.

Interviewers also introduce random error. They may unintentionally go to the wrong household, select the wrong respondent in the household, use the wrong version of the questionnaire, etc. Also, almost 30% of the time, interviewers do not ask a question exactly as it is written. The frequency of interviewer mistakes depends in large part on the level of training, experience, and supervision. Of course, error also comes from respondents. They will mishear or misread questions and misspeak or mismark responses. These inadvertent errors will increase when respondents' interest and motivation are low, when there are cognitive, language, or other impediments, and in other circumstances (e.g., when there are time pressures or distractions during the interview).

Processing errors occur when data are being transferred or transformed. Such errors can be minimized by instituting and enforcing quality-control procedures. Coding of open-ended material can be enhanced by the development of detailed, comprehensive coding schemes and close supervision. In particular, items can be coded more than once by different coders and intercoder reliability measures can be calculated. Similarly, data entry errors can be measured and minimized by double-entry verification. Likewise, when transferring data, such as transcribing recorded interviews or converting from data collection programs to data analysis programs, careful cross-checking is needed. Finally, solid documentation is needed to avoid mistakes. Question wordings may be paraphrased or misreported, codes may be mislabeled, and wild punches or unexplained values may show up in the final data set.

Bias, or Systematic Error

Turning to bias, or systematic error, there is also a sampling component. First, the sample frame (i.e., the list or enumeration of elements in the population) may either omit or double count units. For example, the U.S. Census both misses people (especially African-Americans and immigrants) and counts others twice (especially people with more than one residence), and samples based on the census reflect these limitations. Second, certain housing units, such as new dwellings, secondary units (e.g., basement apartments in what appears to be a single-family dwelling), and remote dwellings, tend to be missed in the field. Likewise, within housing units, certain individuals, such as boarders, tend to be underrepresented and some respondent selection methods fail to work in an unbiased manner (e.g., the last/next birthday method overrepresents those who answer the sample-screening questions). Third, various statistical sampling errors occur. Routinely, the power of samples is overestimated because design effects are not taken into consideration. Also, systematic sampling can turn out to be correlated with various attributes of the target population. For example, in one study, both the experimental form and respondent selection were linked by systematic sampling in such a way that older household members were disproportionately assigned to one experimental version of the questionnaire, thus failing to randomize respondents to both experimental forms.

Nonsampling error comes from both nonobservational and observational errors. The first type of

nonobservational error is coverage error, in which a distinct segment of the target population is not included in sample. For example, in the United States, preelection random-digit-dialing (RDD) polls want to generalize to the voting population, but systematically exclude all voters not living in households with telephones. Likewise, samples of businesses often underrepresent smaller firms. The second type of nonobservational error consists of nonresponse (units are included in the sample, but are not successfully interviewed). Nonresponse has three main causes: refusal to participate, failure to contact because people are away from home (e.g., working or on vacation), and all other reasons (such as illness and mental and/or physical handicaps).

Observational error includes collection, processing, and analysis errors. As with variable error, collection error is related to mode, instrument, interviewer, and respondent. Mode affects population coverage. Underrepresentation of the deaf and poor occurs in telephone surveys, and of the blind and illiterate, in mail surveys. Mode also affects the volume and quality of information gathered. Open-ended questions get shorter, less complete answers on telephone surveys, compared to in-person interviews. Bias also is associated with the instrument. Content, or the range of information covered, obviously determines what is collected. One example of content error is when questions presenting only one side of an issue are included, such as is commonly done in what is known as advocacy polling. A second example is specification error, in which one or more essential variable is omitted so that models cannot be adequately constructed and are therefore misspecified.

Various problematic aspects of question wordings can distort questions. These include questions that are too long and complex, are double-barreled, include double negatives, use loaded terms, and contain words that are not widely understood. For example, the following item on the Holocaust is both complex and uses a double negative: "As you know, the term 'holocaust' usually refers to the killing of millions of Jews in Nazi death camps during World War II. Does it seem possible or does it seem impossible to you that the Nazi extermination of the Jews never happened?" After being presented with this statement in a national U.S. RDD poll in 1992, 22% of respondents said it was possible that the Holocaust never happened, 65% said that it was impossible that it never happened, and 12% were unsure. Subsequent research, however, demonstrated that many people had been confused by the wording and that Holocaust doubters were actually about 2% of the population, not 22%. Error from question wording also occurs when terms are not understood in a consistent manner.

The response scales offered also create problems. Some formats, such as magnitude measurement scaling, are difficult to follow, leaving many, especially the least educated, unable to express an opinion. Even widely used and simple scales can cause error. The 10-point scalometer has no clear midpoint and many people wrongly select point 5 on the 1–10 scale in a failed attempt to place themselves in the middle. Context, or the order of items in a survey, also influences responses in a number of quite different ways. Prior questions may activate certain topics and make them more accessible (and thus more influential) when later questions are asked. Or they may create a contrast effect under which the prior content is excluded from later consideration under a nonrepetition rule. A norm of evenhandedness may be created that makes people answer later questions in a manner consistent with earlier questions. For example, during the Cold War, Americans, after being asked if American reporters should be allowed to report the news in Russia, were much more likely to say that Russian reporters should be allowed to cover stories in the United States, compared to when the questions about Russian reporters were asked first. Even survey introductions can influence the data quality of the subsequent questions.

Although social science scholars hope that interviewers merely collect information, in actuality, interviewers also affect what information is reported. First, the mere presence of an interviewer usually magnifies social desirability effects, so that there is more underreporting of sensitive behaviors to interviewers than when self-completion is used. Second, basic characteristics of interviewers influence responses. For example, Whites express more support for racial equality and integration when interviewed by Blacks than when interviewed by Whites. Third, interviewers may have points of view that they convey to respondents, leading interviewers to interpret responses, especially to open-ended questions, in light of their beliefs.

Much collection error originates from respondents. Some problems are cognitive. Even given the best of intentions, people are fallible sources. Reports of past behaviors may be distorted due to forgetting the incidents or misdating them. Minor events will often be forgotten, and major events will frequently be recalled as occurring more recently than was actually the case. Of course, respondents do not always have the best of intentions. People tend to underreport behaviors that reflect badly on themselves (e.g., drug use and criminal records) and to overreport positive behaviors (e.g., voting and giving to charities).

Systematic error occurs during the processing of data. One source of error relates to the different ways in which data may be coded. A study of social change in Detroit initially found large changes in respondents' answers to the same open-ended question asked and coded several decades apart. However, when the original open-ended responses from the earlier survey were recoded by the same coders who coded the latter survey, the differences virtually disappeared, indicating that the change had been

in coding protocols and execution, not in the attitudes of Detroiters. Although data-entry errors are more often random, they can seriously bias results. For example, at one point in time, no residents of Hartford, Connecticut were being called for jury duty; it was discovered that the new database of residents had been formatted such that the "d" in "Hartford" fell in a field indicating that the listee was dead. Errors can also occur when data are transferred. Examples include incorrect recoding, misnamed variables, and misspecified data field locations. Sometimes loss can occur without any error being introduced. For example, 20 vocabulary items were asked on a Gallup survey in the 1950s and a summary scale was created. The summary scale data still survive, but the 20 individual variables have been lost. Later surveys included 10 of the vocabulary items, but they cannot be compared to the 20-item summary scale.

Wrong or incomplete documentation can lead to error. For example, documentation on the 1967 Political Participation Study (PPS) indicated that one of the group memberships asked about was "church-affiliated groups." Therefore, when the group membership battery was later used in the General Social Surveys (GSSs), religious groups were one of the 16 groups presented to respondents. However, it was later discovered that church-affiliated groups had not been explicitly asked about on the earlier survey, but that the designation had been pulled out of an "other-specify" item. Because the GSS explicitly asked about religious groups, it got many more mentions than had appeared in the PPS; this was merely an artifact of different data collection procedures that resulted from unclear documentation.

Most discussions of total survey error stop at the data-processing stage. But data do not speak for themselves. Data "speak" when they are analyzed, and the analysis is reported by researchers. Considerable error is often introduced at this final stage. Models may be misspecified, not only by leaving crucial variables out of the survey, but also by omitting such variables from the analysis, even when they are collected. All sorts of statistical and computational errors occur during analysis. For example, in one analysis of a model explaining levels of gun violence, a 1 percentage point increase from a base incidence level of about 1% was misdescribed as a 1% increase, rather than as a 100% increase. Even when a quantitative analysis is done impeccably, distortion can occur in the write-up. Common problems include the use of jargon, unclear writing, the overemphasis and exaggeration of results, inaccurate descriptions, and incomplete documentation. Although each of the many sources of total survey error can be discussed individually, they constantly interact with one another in complex ways. For example, poorly trained interviewers are more likely to make mistakes with complex questionnaires, the race of the interviewer can interact with the race of respondents to create response effects, long, burdensome questionnaires are more likely to create fatigue among elderly respondents, and response scales using full rankings are harder to do over the phone than in person. In fact, no stage of a survey is really separate from the other stages, and most survey error results from, or is shaped by, interactions between the various components of a survey.

Conclusion

Conducting surveys often seems easy—and it is easy, if the job is done poorly. The pseudo-motto of one survey firm, "Price, Speed, Quality: Pick Two," makes the choice clear. Surveys are complex measurement tools that depend on a combination of many skills, including mathematics, creative writing, logistics, accounting, motivation, persuasion, and theorizing. Total survey error is both a means of keeping the survey researcher aware of the myriad ways in which error invades the data and a research agenda for identifying and minimizing those errors.

What is needed is what was called for in 1984 by the National Academy of Sciences' Panel on Survey Measurement of Subjective Phenomena, "a systematic long-term study of all phases of the survey process . . . [to] develop error profiles and models of total survey error." But at present, our knowledge of the error structure in general is limited, and the relative contribution of various error components in a particular survey is mostly incalculable. Today, the survey researcher's task and challenge is less that of an engineer (applying well-established formulas to well-measured physical parameters), and more that of an artisan (applying knowledge based on both science and experience to incompletely understood factors). The survey researcher draws on the existing scientific literature, and undertakes careful development work (e.g., pretesting) to make the best possible decisions about study design, sample size, question wording, interviewer training, and all the other components of surveys, without having complete information on the exact nature and relative magnitude of the error associated with each component of a survey. In finding the right balance, the survey researcher must avoid what Robert Groves called the "tyranny of the measurable." As Groves noted in *Survey Errors and Survey Costs*, "Errors that elude simple empirical estimation are often ignored in survey statistics practice. . . . The art of survey design consists of judging the importance of unmeasurable sources of error relative to the measured."

Tourism Statistics

Stephen L. J. Smith
University of Waterloo, Waterloo, Ontario, Canada

Antonio Massieu
World Tourism Organization, Madrid, Spain

Glossary

domestic tourism Tourism that occurs within the visitor's country of residence.
international tourism Tourism that occurs when a visitor travels to a country other than that of his/her usual residence.
tourism The set of activities engaged in by persons temporarily away from their usual environment for a period of not more than one year, and for a broad range of leisure, business, religious, health, and personal reasons, excluding the pursuit of remuneration from within the place visited or long-term change of residence.
tourism product A good or service that would be produced only in a substantially reduced volume or would virtually cease to be produced at all in the absence of tourism.
tourism industry An industry that produces a tourism product.
visitor A person temporarily away from his/her usual environment for a period of not more than one year whose primary purpose of travel is not the pursuit of remuneration from within the place(s) visited. The person may be engaged in any of the broad range of activities listed above in the definition for tourism. If the person does not stay away from his/her usual residence over night, the visitor is a "same-day visitor"; if he/she stays away overnight, the person is a "tourist."

The development of consistent measures of tourism has challenged statisticians and economists since the 1930s. The challenges arise, in part, from the nature of tourism as an economic activity. Although tourism is often referred to as an industry, it is fundamentally different than conventional industries and these differences complicate the measurement of tourism. Further, the development of measures of tourism consistent among nations has required extensive negotiations among national statistical agencies and international organizations to reach a consensus on definitions of tourism and related concepts. These concepts then had to be operationalized through new analytical tools. International agreement on core definitions and measurement techniques has now been achieved in principle. The tasks facing tourism statisticians are to apply and extend the concepts and tools that have been developed.

The Challenge of Measuring Tourism

The Journey to a Common Definition of Tourism

As many social phenomena, tourism can be defined in numerous ways. The definitions not only reflect the different uses to which their authors wish to put their definition, they also reflect fundamentally different attitudes to tourism. For 200 years, some social commentators have imbued "tourism" with an invidious connotation, as something unworthy of those with refined tastes. However, most contemporary social scientists work with less judgmental perspectives.

One of the more common perspectives can be characterized as "demand-side" because it focuses on tourism as a human experience. Pearce, for example, wrote "tourism may be thought of as the relationships and phenomena arising out of the journeys and temporary stays of people travelling primarily for leisure or recreational purposes." Leiper proposed a more expansive

demand-side definition: "[t]ourism comprises the ideas and opinions people hold that shape their decision about going on trips, about where to go (and where not to go) and what to do or not do, about how to relate to other tourists, locals, and service personnel. And it is all about behavioral manifestations of those ideas and opinions."

McIntosh, Goeldner, and Ritchie incorporated elements of the supply side (the businesses serving tourists) when they defined tourism as "the science, art, and business of attracting and transporting visitors, accommodating them, and graciously catering to their needs and want." Jafar proposed an even more intellectually comprehensive definition when he argued that "[t]ourism is the study of man away from his usual habitat, of the industry that responds to his needs, and of the impacts that both he and the industry have on the host's socio-cultural, economic, and physical environments."

Cohen side-stepped the task of defining tourism by defining a tourist: "Tourism is a fuzzy concept—the boundaries between the universe of tourist and non-tourist roles are vague . . . [a] 'tourist' is a voluntary, temporary traveller, travelling in the expectation of pleasure from the novelty and change experienced on a relatively long and non-recurrent round-trip."

These examples illustrate the divergence in academic approaches to defining tourism. Unfortunately, not only do these examples fail to represent a consensus on the nature of tourism, they do not provide a solid conceptual foundation on which to build reliable and accurate measurement tools. However, statisticians in national agencies and international organizations have also been debating the nature of tourism, particularly in the context of international measurement. Their interests arise from two related needs: (1) the need to accurately and consistently measure the magnitude of international tourism flows and (2) the need to analyze the structure and magnitude of tourism in national economies.

The work of these experts covers more than a half century, beginning in 1937 with the Committee of Statistical Experts of the League of Nations. The committee defined "international tourist" as anyone visiting a country other than his/her usual residence for more than 24 hours, with the exception of workers, migrants, commuters, students, and en route travellers (e.g., persons from one country passing through an airport in another country on their way to a third country). Little was done with this definition for the next two decades, however, as a result of the demise of the League of Nations and World War II.

After the war, international tourism grew rapidly, driven by a curiosity among many people to see more of the world, rising discretionary incomes, and improved modes of commercial transportation. In 1950, the International Union of Official Travel Organizations (IUOTO)—the precursor to the World Tourism Organization—expanded the 1937 definition by including students on tours. IUOTO also proposed a definition for "international excursionists" (an individual visiting a country other than his/her residence for pleasure on a same-day trip) and "transit travellers" (travellers en route through a second country on their way to a third). A few years later, in 1953, the UN Statistical Commission modified the IUOTO definition by specifying a maximum duration of six months for a tourism trip. A decade later, the 1963 UN Conference on International Travel and Tourism drew a distinction between "tourists" (those who stayed away for 24 hours or more) and "excursionists" or "day visitors" (for persons who stayed away from for less than 24 hours). The combination of "tourists" and "excursionist" were collectively called "visitors." In 1978, a conference hosted by the WTO, the U.N. Conference of Trade and Development, the Conference of European Statisticians, the East Caribbean Common Market, and the Caribbean Community ratified these basic definitions, although they called for the use of "excursionist" to cover both same-day visitors and "in-transit travellers."

The IUOTO definition, in this modified form, became an operational standard for over a decade. In practice, however, it did not adequately address other core concepts and had little impact on promoting harmonization of tourism statistics among nations. The next major step forward occurred in 1991 at WTO-sponsored conference in Ottawa, Canada, on tourism statistics. The Ottawa Conference achieved agreement on a number of important definitions and extended the maximum time for a trip to be considered as a tourism trip to one year. It also provided the foundation for harmonizing international tourism statistics and the development of an analytical framework to make the measurement of tourism consistent with those of other industries (the framework was to become known as the Tourism Satellite Account or TSA).

Another WTO conference on tourism statistics was held at Nice, France, in 1999 to report on progress in measuring the contribution of tourism to national economies. The delegates from 160 nations at that conference endorsed a number of key conventions proposed by the WTO related to TSAs. There were some technical differences, though, between the WTO recommendations and a set of conventions proposed by the OECD. The WTO and OECD resolved these differences in the months following the 1999 conference and, in 2000, the U.N. Statistical Commission approved a joint submission by the WTO, OECD, and Eurostat that represents a new international standard in tourism statistics.

Why Is Tourism Difficult to Measure?

Tourism is something that people do rather than something that businesses produce. This is an important

distinction when one tries to measure the magnitude of tourism as an industry because industries are defined by the products they make. For example, the motor vehicle industry is the set of businesses that produce motor vehicles; the corn industry is composed of farms that grow corn. In the case of tourism, though, there is no single characteristic product that could be classified as "the tourism product." Instead, tourism is associated with a variety of commodities, primarily services. Measurement of tourism necessarily involves measurement of the production and use of many fundamentally different commodities produced by many different types of businesses.

As noted, those commodities tend to be services, and the measurement of the production and consumption of services is difficult. Services are intangible; they cannot be stored and inventoried. The production of services typically is intrinsically tied to their consumption. For example, the provision of overnight accommodation in a hotel to a guest does not occur until a guest checks in and spend the night; and if that room-night is not sold, it is lost forever.

Not only does tourism cover a wide range of products, the businesses providing those products tend to be small or medium-sized enterprises that are widely dispersed throughout rural areas, small towns, and cities. Collectively, the tourist clientele of those businesses make billions of individual transactions—most fairly small—over the course of a year. Moreover, most of these businesses typically serve both visitors and nonvisitors. The development of a statistical infrastructure that can provide accurate and reliable coverage of this large, diffuse, and complex environment clearly is challenging.

Definition of Tourism and Related Concepts

Tourism and Its Forms

The history of efforts by national and international statistical agencies to reach agreement on a definition of tourism culminated in the World Tourism's Organization definition (endorsed by the U.N. Statistical Commission in 1993):

> *The set of activities engaged in by persons temporarily away from their usual environment for a period of not more than one year, and for a broad range of leisure, business, religious, health, and personal reasons, excluding the pursuit of remuneration from within the place visited or long-term change of residence.*

This represents the starting point for collecting, reporting, and analyzing tourism statistics. Tourism occurs in six different forms, three that can be considered fundamental and three that are combinations of the fundamental forms.

Domestic: A visit by a resident of a country totally within the border of that country.

Inbound: A visit by a resident of another country into a specified country.

Outbound: A visit by a resident of one country to another country.

Internal: The combination of domestic and inbound tourism.

National: The combination of domestic and outbound tourism.

International: The combination of inbound and outbound tourism.

Related Concepts

Two other concepts are core to measuring tourism: tourism product and tourism industry. The basic notion of product and industry are adapted from those used by Systems of National Accounts (SNA), and the U.N.'s International Standard Industrial Classification system and the Central Product Code. The reasons for this are to ensure the definitions and measures of tourism are consistent with those used by conventional industries. Although tourism is a demand-side concept—something that people do rather than something businesses produce—it still has to be conceptualized in a way that linkages can be made to the broader international systems of industrial statistics.

Tourism Product: A good or service that would be produced only in a substantially reduced volume or would virtually cease to be produced at all in the absence of tourism.

Tourism Industry: An industry that produces tourism products.

The application of these definitions is not as straightforward as they may appear. Tourism products are used by both visitors and nonvisitors. For example, not everyone who stays in a hotel, travels by airplane, rents a car, or dines in a restaurant is a visitor. Moreover, tourism products can be produced by nontourism industries. Some retail department stores or grocery stores also operate restaurants or dining counters. Certain tourism industries produce tourism services that are not their characteristic product: hotels provide food service operations and may sell tour packages. Airlines and rail companies provide food services.

Some tourism industries sell nontourism products. Hotels sell fax and long-distance telephone services to their guests as well as dry cleaning or laundry services. Restaurants may sell clothing and nonfood gift items. Some nontourism industries produce commodities routinely purchased by visitors: travel books, food and

beverages from retail stores, sunscreen lotion, crafts, and clothing.

In brief, tourism industries produce both tourism and nontourism products. Nontourism industries produce tourism and nontourism products. Visitors consume nontourism products and nonvisitors consume tourism products. The measurement of tourism requires data sources and analytical tools that allow analysts to separate out the portions of the tourism-related production and consumption of tourism products and nontourism products from the nontourism activity. The analytical framework by which this happens is known as the Tourism Satellite Account.

Tourism Satellite Accounts (TSA)

Objectives and Logic of TSAs

A Satellite Account is a term developed by the United Nations to refer to an extension of the SNA (hence, a "satellite" of the SNA) to measure the size of economic sectors that are not defined as industries in national accounts. Tourism, for example, is an amalgam of industries such as transportation, accommodation, food and beverage services, recreation and entertainment, and travel agencies.

Tourism is a unique phenomenon because it is defined in terms of a certain type of consumer, a "visitor." Visitors buy goods and services, both tourism and nontourism. The key from a measurement standpoint is to associate visitors' purchases to the total supply of these goods and services within a country.

However, visitor consumption is not restricted to a set of predefined goods and services produced by a predefined set of industries. What makes tourism special is not what is purchased but the temporary situation in which the consumer finds himself/herself. He/she is outside his/her usual environment, traveling for a purpose other than the exercise of an activity remunerated from within the place(s) visited. This is the characteristic that distinguishes visitors from other consumers.

The TSA is a new statistical instrument that brings together these diverse aspects of tourism by providing a tourism dimension to the framework of an SNA. It permits the separate measurement of the demand and supply sides of tourism within an integrated system (the SNA) that describes the production and demand aspects of the whole economy.

Structure of TSAs

Tables

The methodological design for the elaboration of the TSA is a set of definitions and classifications integrated into tables and organized in a logical, consistent way. It allows the examination of the whole economic magnitude of tourism in both its aspects of demand and supply. In principle, there are 10 key tables that constitute a TSA:

Tables 1, 2, and 3: Visitor final consumption expenditure in cash, by product, and form (as described above) of tourism.

Table 4: Internal tourism consumption, by product and form of tourism.

Table 5: Production accounts of tourism industries and other industries.

Table 6: Domestic supply and internal tourism consumption, by product.

Table 7: Employment in tourism industries.

Table 8: Gross fixed capital formation of tourism industries and other industries.

Table 9: Tourism collective consumption, by functions and level of government.

Table 10: Nonmonetary indicators such as employment and numbers of visitors.

Aggregates

TSAs support the measurement of so-called "aggregates" or macroeconomic indicators such as tourism consumption, tourism value-added, tourism GDP, tourism employment, and tourism gross fixed capital formation. These aggregates are not the most important feature of the TSA, whose primary objective is to provide detailed and analytical information on all aspects of tourism, particularly the composition of visitor consumption, the productive activities most concerned by the activities of visitors, and relationships between tourism and other productive activities. Nevertheless, these aggregates are often politically important because they are measures of the quantitative importance of tourism in a country. The importance of credible measures of the magnitude of tourism in a national economy should not be underestimated.

Uses of TSA

The development of TSAs has been fueled by the recognition that they can:

- Improve knowledge of tourism's importance relative to overall economic activity in a given country;
- Provide an instrument for designing more efficient policies relating to tourism and its potential for job creation; and
- Create awareness among the players directly and indirectly involved with tourism of the economic importance of this activity and, by extension, the role of tourism in all industries producing the myriad goods and services demanded by visitors.

These needs are met by the TSA insofar as it provides (for an entire country and over a period of one year) an articulated framework of economic information that serves the interests of both political decision-makers and entrepreneurial decision-makers. Australia, Canada, Dominican Republic, Ecuador, Mexico, Spain, Sweden, and United States are countries with an established TSA.

Types and Sources of Tourism Statistics

Governments, entrepreneurs, and analysts usually do not have adequate information for designing sound tourism policies and business strategies, and for evaluating their effectiveness and efficiency. This chronic shortage of information on the role of tourism in national economies worldwide is partly due to the "horizontal" nature of tourism—the fact that tourism is an aspect of many different industries. The challenge of compiling and disseminating information from so many different types of businesses requires many different quantitative and qualitative sources.

The demand for tourism statistics continues to grow worldwide. There is also increasing demand for reliability, accuracy, precision, and timeliness in tourism statistics. Some actual or potential statistical sources are tourism-driven, such as tourism expenditure surveys, arrival and departure counts at national borders, records of overnight stays, and occupancy rates in accommodation enterprises. However, the full measurement of tourism economic impacts and the development of TSAs requires data from general economic statistical sources as well as administrative sources such as air traffic regulation authorities and tax records.

Internationally comparable tourism data should be based on certain common key indicators related to the different forms of tourism and certain tourism industries.

Inbound Tourism

Arrivals are a basic measure and are not necessarily equal to the number of different persons traveling. When a person visits the same country several times a year, each visit by the same person is counted as a separate arrival. If a person visits several countries during the course of a single trip, his/her arrival in each country is recorded separately. Arrivals associated with inbound tourism equals arrivals by international visitors to the economic territory of the country of reference and include both tourists and same-day nonresident visitors.

Data on arrivals may be obtained from different sources. In some cases, data are obtained from border statistics derived from administrative records (police, immigration, traffic counts, and other type of controls) as well as border surveys. In other cases, data are obtained from registrations at tourism accommodation establishments.

Statistics on *overnight stays* refer to the number of nights spent by nonresident tourists in hotels and similar establishments, or in all types of tourism accommodation establishments. If one person travels to a country and spends five nights there, that makes five tourist overnight stays (or person-nights).

Average length of stay refers to the average number of nights spent by tourists (overnight visitors) in all types of tourism accommodation establishments.

Tourism expenditure data are obtained from the item "travel receipts" of the Balance of Payments (BOP) of each country and corresponds to the expenditure of nonresident visitors (tourists and same-day visitors) within the economic activity of the country of reference. BOP data typically are collected either by a central bank or a nation's official statistical agency.

Domestic Tourism

Domestic *overnight stays* is the number of nights by resident tourists in hotels and similar establishments, or in all types of tourism accommodation establishments, and may be obtained either by household surveys or from records of accommodation establishments. *Same-day visits* typically are estimated from household surveys.

Outbound Tourism

Departures associated with outbound tourism correspond to the departures of resident tourists outside the economic territory of the country of reference.

Tourism expenditure data in other countries are obtained from the item "travel expenditure" of the BOP of a country and correspond to the "expenditure of resident visitors (tourists and same-day visitors)" outside the economic territory of the country of reference. Alternative sources, in principle, include border surveys and currency control forms. However, the current level of practice with respect to these sources does not support international comparison of data; only BOP data are comparable.

Tourism Industries

One of the most basic statistics related to tourism industries is the *number of establishments* within each tourism industry. This information may be compiled from business registration or tax data. Many different characteristics of businesses in each tourism industry are possible, but some of the most common are those related to the

accommodation industry. The *number of rooms and bedplaces* data refers to the capacity in hotels and similar establishments for providing temporary accommodation to visitors.

Occupancy rate refers to the relationship between available capacity and the extent to which it is used. This rate may refer either to use of rooms or of beds. Occupancy rate is based on the number of overnight stays of both resident and nonresident tourists.

Employment estimates are difficult to develop because of the high percentage of part-time or seasonal jobs in tourism industries. Several different measures can be developed. "Full-time equivalent jobs" (FTEs) are a statistical compilation of part-time and temporary jobs as well as full-time and permanent jobs into a statistical estimate of full-time equivalent jobs. Thus, FTE employment numbers are lower than the number of persons actually employed in tourism. *Jobs* or *positions* refer to specific positions within an employer, which often are associated with a particular job description. A job/position may be held by more than one person over the course of a year as a result of employee turnover. *Employees* refers to the number of different individuals that are employed in a tourism industry over a year, regardless of the number of hours per week or weeks per year worked. Employment data may be obtained from surveys or censuses of enterprises or statistically estimated from payroll data and average pay rates by occupation.

Glossary

centroid An area representing a zone that is treated as a node connected to transportation networks. All trips originating from a zone are assumed to start from its centroid and end at the centroid of the destination zone.
destination The terminal end of a trip.
origin The beginning end of a trip.
origin-to-destination trip table A table that shows the frequency of trips made in the area, typically per day, between each pair of origin and destination zones.
trip The movement made to engage in activities at another location in urban area. An individual's day may contain several trips, e.g., a morning commute trip from home to work, a trip from the office to a nearby restaurant and a trip back to the office during the lunch break, a trip to return home after work, an evening trip to a movie theater, and a trip back home.
trip chain A closed sequence formed by the series of trips made by an individual that starts and ends at the same place.

Transportation research is concerned with the movement of both people and goods. This article, however, focuses on the measurement of people's movements in time and space, primarily within an urban area. First, the history of travel surveys is briefly summarized. Early surveys of car trips, traditional large-scale household surveys, and enhancements recently made to them are discussed next, followed by sections concerned with reporting errors in travel surveys, application of time-use survey methods that is believed to reduce trip reporting error, and multi-day surveys. The article concludes with a discussion on the application of information technology to travel surveys.

Measuring Travel Patterns

Survey methods to measure the characteristics of trips made by individuals have evolved in several stages. Surveys in the first stage were concerned only with trips made by the automobile. The unit of sampling was the trip, and no consideration was given to the fact that an individual often makes several trips in a day and their attributes are interrelated. In the second stage, large-scale household travel surveys were conducted to collect information on all trips made by household members (typically age 5 and older) on the survey day. In the third stage, various improvements were made to survey instruments and administration methods to reduce non-response, under-reporting of trips, and other reporting errors in household travel surveys. Also initiated in this stage were extension of the survey period to multiple days, application of methodologies in time-use surveys, and the use of computer-aided telephone interviews (CATI) to retrieve survey responses. Currently, the development of transportation survey methods may be viewed as in its fourth stage, in which global positioning systems (GPS), mobile communications systems, and other new technologies are being applied to obtain more accurate and complete information of individuals' trajectories in time and space.

Many different types of surveys exist. For example, traffic detectors permanently installed on roadways continuously provide traffic counts. Or a traffic counter with a rubber tube may be placed on the roadside to obtain traffic counts data at different locations on a rotational basis. These may be viewed as forms of surveys. Another form of survey is the transit on-board survey in which transit passengers are sampled. Certain techniques are used to obtain data on the use of parking facilities or to obtain the distribution of vehicle speeds.

Roadside Origin-Destination Studies

Passenger travel demand forecasting methods in their early forms can be found prior to World War II. In a 1927 study in Cleveland, for example, linear extrapolation was used to produce forecasts, and a 1926 Boston study adopted a gravity model that depicted the flow of people between a pair of geographical zones analogous to Newton's law of gravity.

Because motorization created a vast need for road building, early studies focused on auto trips. Roadside interviews were used to obtain information on origin-destination, purpose, and vehicle occupancy (the number of individuals in the vehicle). Most typically, vehicles were stopped by the police at a survey station and questions were asked to obtain this information. Alternatively, a questionnaire to be completed and mailed back was handed out to the driver. In yet another method, the license plate numbers of vehicles passing a survey station were recorded, and a questionnaire was mailed to the registered owner of each vehicle identified.

The information used for transportation planning in these early days primarily came from the origin-to-destination trip table developed from the data produced by such surveys. Later, however, the need to study the factors that influenced travel behavior was recognized, which led to the development of large-scale household travel surveys and full-fledged travel demand forecasting procedures after World War II.

Household Travel Surveys

Individuals often have means of travel other than the automobile, and planners may aim to develop a transportation system in which the automobile and public transit are well balanced. This calls for the knowledge of each individual's travel, regardless of the mode used.

The U.S. Bureau of Public Roads (BPR) published a manual for home interview travel surveys in 1944, and household-based origin-destination travel surveys were conducted in seven urban areas. Also in the 1940s, the approach of developing transportation plans based on the relationships among transportation, socio-demographics, and land use was recognized. In the San Juan study initiated in 1948, for example, models were developed to estimate the number of trips generated in an area based on land use information. Following this, major home interview surveys were conducted in Detroit and Chicago in 1955 and 1956, respectively.

In these surveys, households were sampled on the basis of residence, and were approached without advance notice. Random sampling or cluster sampling was in general adopted. In the interview, information on the trips of the day before was collected from all household members at least five years old. High sampling rates (approximately 5%) were adopted in the early studies. Information on the household and its members as well as the attributes of trips made by the household members on the survey day was collected in these travel surveys. Typical member attributes on which information was collected included age, sex, employment, and driver's license holding. Household characteristics of interest were household size (the number of household members living together), housing type and ownership, the number of vehicles owned or available, and household income.

In planning analysis, the data from a travel survey are often supplemented with data on land use and transportation networks. The former comprise population, population density, the number of employees by industry, the number of housing units by type, average household size, average number of vehicles per household, median income, and other indicators of the characteristics of respective geographical zones. Transportation network data typically comprise zone-to-zone (or centroid-to-centroid) travel times obtained using network models for all relevant pairs of zones, often evaluated for different periods (e.g., morning peak, off-peak, afternoon peak, and evening). For public transit, network data contain attributes of transit trips, e.g., transit fare, waiting time, and number of transfers.

Because transportation planning at the time was primarily concerned with road building, travel surveys were primarily concerned with motorized trips, i.e., those made by automobile, taxi, bus, or rail. For example, the 1955 and 1965 household travel surveys in the Detroit metropolitan area excluded walk and bicycle trips; it was only in the 1980 survey that these non-motorized trips were addressed.

It is important to note that the treatment of absent households can result in systematic bias if they are not properly handled. Although non-response due to absence at the time of contact, either by visiting or by placing a telephone call, may not introduce any systematic bias in general, this is not the case with a travel survey. That household members are absent implies that they are making trips, which is the subject of the survey. If absent households were not included in the sample, that would imply a tendency of excluding households with higher propensities to make trips. It is therefore critically important that repeated call backs are made to ensure that the absent households are included in the sample.

Enhanced Household Travel Surveys

Although home interview surveys are a highly desirable means of survey administration, they are costly and are

becoming increasingly difficult to conduct, as urban residents have become less cooperative in recent years. Other problems being recognized are trip underreporting and response inaccuracies. Since approximately 1980, new types of survey instruments and alternative methods of survey administration have been experimented with. Notable is the use of CATI; adoption of travel diaries, memory joggers, and other instruments for improved quality of trip reporting; adoption of multi-day survey periods; and application of time-use survey methods. Around the same time, the sample size had decreased to 2000–10,000 households, with an average in the beginning of 1990s of about 2500 households.

The method of contact had also changed. Instead of the retrospective surveys with cold contact as used in the earlier days, prospective respondents were first recruited by the telephone. The typical procedure can be described as follows:

1. Recruiting by the telephone or mail.
2. Notification of the survey date; delivery of a letter describing the purpose of the survey, travel diaries, memory joggers, and other survey instruments.
3. Retrieval of responses through CATI.

The questionnaires used in earlier self-administered travel surveys were similar to the worksheets used by interviewers to record responses in home interviews. More recent questionnaires are more "respondent friendly," often taking on the form of a pocket-size diary.

Despite these efforts, several problems persist. Although there are reports of improved trip reporting due to the improved questionnaire design, underreporting of trips is far from being eliminated. The effectiveness of travel diaries or memory joggers is not conclusive. Moreover, CATI presents its own problems with household travel surveys, because retrieving trip information from all household members requires quite lengthy interviews for larger households, often requiring several telephone interviews. This leads to systematic non-response when larger households are underrepresented in the sample. Furthermore, because it is not always possible to interview every household member, especially for a large household, travel information tends to be offered through proxies, compromising its quality. Consequently, responses tend to be less accurate, and chances of trip underreporting tend to increase for larger households or for household members who tend not to be at home. The effectiveness of alternative administration methods, including mail surveys (mail-out mail-back, or drop-off mail-back), is being evaluated.

Another problem is the difficulty when using random digit dialing in determining whether a telephone number is eligible when there is no answer. Determining whether a number is eligible is crucial to avoid systematic non-response biases, but it increases the cost of survey. In addition, telephone-based travel surveys are subject to general problems, including the presence of households without a telephone, call screening by an answering machine, and the more recent practice of screening calls using the caller ID.

On the other hand, one of the advantages of telephone-based surveys is easy call backs, which aid in reducing systematic non-response biases. Another advantage is that CATI facilitates the dialogue between the respondent and the interviewer. This is important in travel surveys because the definition of trip is quite involved and the definition of trip purposes can be confusing; a well-trained interviewer can aid the respondent in providing travel information and thus contribute to its quality. CATI is also effective when the survey questionnaire involves complex branching or customization. The latter is often adopted in stated-preferences surveys where the respondent is asked to indicate his or her preference under a hypothetical scenario. Responses to earlier questions in an interview may be used to customize the scenario and make it seem more realistic for the respondent.

Trip Reporting Errors

It has been found that short trips, walk and bicycle trips, trips that neither start from nor end at the home base (called non-home-based trips), trips made for work-related businesses, and trips back to home (home trips) tend to be underreported with the survey instruments and administration methods that have been adopted in household travel surveys. On the other hand, commute trips to work (work trips) and trips made by motorized modes tend to be reported well.

A comparison of the entries in an activity diary and the answers to a travel survey questionnaire has indicated that short movements and brief excursions out of the home tend not to be recognized as trips. In addition, the definition of the trip is difficult to convey, and the respondent may not clearly understand which trips should be reported in the survey.

For example, consider a case in which a commuter does grocery shopping at a supermarket on the way back home from work. In this case, the journey from work to home is composed of two trips: a shopping trip from the workplace to the supermarket, and a trip from the supermarket to home. Consider, next, a case in which the commuter picks up a newspaper from a vending machine located at a shopping center. It is unlikely in this case that the respondent will break up the movement from work to home into two segments and report them as two trips. But should the movement be reported as two trips? Unfortunately, the answer is not obvious.

How the respondent is expected to report such movements as jogging, walking the dog, or pleasure driving is also ambiguous. In these movements, there are no clear destinations, making them difficult to report in the survey. Again, how these movements should be reported is often not well spelled out in the survey. Finally, and to make the matter more confusing, movements within the same premise, e.g., a shopping mall or a college campus, are not considered as trips. In this case, the respondent is not supposed to report movements as trips at all.

Given a reported trip, the next question is how accurately its attributes are reported. The most noticeable reporting errors are associated with departure and arrival times, which tend to be rounded to the nearest quarters of an hour, i.e., 00, 15, 30, or 45 minutes. For example, in a nationwide survey conducted in the United States in 1990, 36.2% of trips were reported to have started at exact hours, 27.8% at 30 minutes, 9.2% at 15 minutes, and 8.7% at 15 minutes past hours. Only 18.1% of the trips were reported to have started at other minutes. The duration of a trip tends to be rounded in a similar manner. On the other hand, a study in which the movement of vehicles was recorded using GPS devices shows that trip starting times are distributed uniformly from 00 to 59 minutes.

Another attribute of the trip that is difficult to report is the destination location. The respondent does not always know his destination by its street address. Rather, it may be reported as "McDonald on Anderson Street." When such a description does not offer sufficient information to geo-code the location, the respondent must be contacted to retrieve adequate levels of information.

Application of Time-Use Survey Methods

Time-use surveys have been conducted since the early 20th century to collect information on individuals' activities. A standard scheme for activity classification has been developed, and a large-scale international study of time use was carried out in the late 1960s. The first time-use study in the transportation planning area dates back to the mid-1940s, but it was in the 1990s that time-use survey methods were adopted in travel surveys with the purposes of improving the accuracy of trip reporting and obtaining data that may be used to probe into the mechanism of trip making.

Travel surveys that adopted time-use survey methods differ from time-use surveys themselves in that information on in-home activities is not always collected exhaustively. For example, in one travel survey, the respondent was requested to report only those in-home activities that exceeded 30 minutes in duration. Another travel survey, on the other hand, asked the respondent to report those in-home activities that substitute for out-of-home activities (e.g., watching television at home instead of going to a movie theater).

The anticipation that trip underreporting can be reduced by applying time-use survey methods is based on the belief that activities are easier to recall than trips. Namely, "What did you do next?" is easier to answer accurately than "Where did you go next?" because activities are continuous in time and are therefore easier to trace back and recall, while trips are intermittent and difficult to recall exhaustively.

In one example that illustrates the extent of trip underreporting, results of two time-use surveys, conducted in the Netherlands and California, were tabulated. The two surveys adopted different schemes of data collection. The survey in the Netherlands was based on a time-interval method in which the representative activity was asked for each of 144 15-minute intervals of the day. The survey in California was based on activity episodes, with the respondent prompted to report activity by activity as they were pursued. Despite the difference in their data collection methods, these two surveys offered consistent time-use figures for such basic activities as sleeping and having meals. The episode-based California data contained more reported trips (3.046) than the interval-based Dutch data (2.484). The average number of unreported trips, estimated based on activity location codes, was 2.130 for California and 2.455 for the Netherlands, with the total number of trips estimated as 5.176 and 4.939, respectively. It is evident that trips tend to be underreported, and that a substantial number of unreported trips can be captured using time-use data.

Multi-Day Surveys and Other Applications

Some trips, like commute trips, are repeated regularly day to day; others are not. People do not repeat exactly the same travel pattern every day. Knowing daily variations in an individual's travel patterns is important in some contexts. For example, the statement that "20% of commuters use public transport" may imply that every commuter has a 20% chance of using public transit on a given day, or that a fixed 20% of the commuter population uses public transit every day. One-day data do not offer enough information to determine which is the case. But this question is important if one wishes to determine who are the beneficiaries of subsidies for public transit, or to determine the target of effective marketing to promote public transit use.

Multi-day surveys are needed to determine how variable are day-to-day travel patterns. Likewise, multi-week surveys are needed to evaluate the variability in travel

from week to week, and probably panel surveys to assess seasonal variations. Most travel surveys are concerned with just one day, which is often taken as a "typical" weekday (Tuesday, Wednesday, and Thursday) in an autumn month. There have been only several multi-day surveys for survey durations of up to one week, and a few surveys with survey durations of several weeks, reported in the literature on travel behavior analysis. The primary reason for the rarity of multi-day surveys is presumably the increased respondent burden, and the decline in response accuracy as a consequence. For example, the number of trips reported by the respondent gradually declines toward the end of the survey period in a weekly survey, then jumped up on the very last day of the survey.

Day-to-day variations in daily travel create problems when one wishes to measure change in travel patterns over time, e.g., in order to evaluate the effect on travel of a planning measure such as the opening of a bypass. Day-to-day variations in travel patterns make this comparison less reliable. Higher levels of precision may be achieved by increasing the length of the survey period in the before and after periods, by increasing the sample size, or both. Little research has been done on this subject in the travel behavior research field.

There are cases in which random sampling is impractical or inefficient as a means of collecting data on travel behavior. For example, suppose one wishes to study how people choose between private automobiles and public transit for commuting, but the fraction of commuters who use public transit is very small. In such a case, random sampling of households would yield only a small number of transit users, increasing the total number of samples required to achieve a desired level of accuracy. An alternative is to over-sample transit users by adopting non-random sampling schemes, e.g., by distributing questionnaires to the riders at railway stations or in buses or trains. This is called choice-based sampling because sampling is done based on the choices made by the sample individuals (i.e., to ride a bus or a train). The resulting choice-based sample contains obvious bias, which can be corrected by applying appropriately defined weights for parameter estimation.

A situation often encountered in transportation planning is the need to estimate demand for non-existent transportation services, e.g., a proposed subway line. In this case, data showing the use of the subway are not available simply because it does not yet exist. In such a case, a survey may be conducted that solicits the respondent to answer hypothetical questions that assume the presence of the subway line. For example, the respondent may be asked "Suppose you must visit the city hall, and there are the following two ways of traveling: (1) walk 8 minutes to the subway station, ride the subway for 15 minutes, then walk 5 minutes to the city hall, with a subway fare of $1.20, or (2) drive your car for 20 minutes, and park at a parking lot next to the city hall, and pay $3.50 for parking. Which one would you prefer?" Such a survey is called a stated-preference survey because the data it produces reflect "stated," as opposed to "revealed," preferences. The resulting data are most often used to develop mathematical models to explain the choices, which are in turn used to estimate demand for non-existent transportation services.

Information Technologies in Travel Surveys

Advances in information and computer technologies (ICT) have made it possible to trace the trajectory of a person or a vehicle in time and space with levels of accuracy that were unthinkable in the past. Much of the information associated with trips that has been collected through household travel surveys can now be obtained automatically using new technologies. In one experiment, a GPS device was installed on a passenger vehicle, and the position information was transmitted from the GPS unit to the experiment headquarters every second. In addition, supplementary information (driver, accompanying travelers, and the purpose of travel) was entered into a hand-held computer for each trip made using the vehicle. The results of the survey were compared with data obtained from conventional household travel surveys. Likewise, study results to determine the location of the holder of a cellular phone based on the intensities of its radio waves received at three or more communications stations have been accumulated.

Studies have shown that GPS devices, cellular phones, hand-held computers, and other ICT devices facilitate acquisition of accurate information on time and location. Attributes of trips such as beginning and ending time, origin and destination locations, and routes can then be inferred with high levels of accuracy that traditional household travel surveys cannot possibly attain. Combined with supplementary interviews of the travelers, most, if not all, information that has been provided by conventional surveys can be obtained with the new types of surveys that deploy ICT devises. Although there are technical problems that need be resolved (e.g., disruption of radio waves by high-rise buildings), it is likely that new forms of travel surveys that do not rely on respondents' retrospective reporting of trips will be prevalent in the near future.

Treatment Effects

Charles S. Reichardt
University of Denver, Denver, Colorado, USA

Glossary

before–after quasi-experiment A comparison of outcomes before and after a treatment is introduced.
between-participant design A comparison of participants who receive different treatments.
correlational design A between-participant quasi-experiment in which the treatment is a continuous rather than discrete variable.
interrupted time series quasi-experiment A comparison of a time series of observations before a treatment is introduced with the continuation of that time series of observations after the treatment is introduced.
nonequivalent group quasi-experiment A comparison of participants who receive different treatments in which the participants are not assigned to the treatments at random.
quasi-experiment A comparison in which different treatments are not assigned at random.
randomized experiment A comparison in which different treatments are assigned at random.
regression-discontinuity quasi-experiment A comparison in which participants are assigned to treatments using a cutoff score on a quantitative assignment variable.
threat to internal validity An alternative to the treatment as an explanation for an observed outcome difference.
treatment effect The difference between what happens after a treatment is administered and what would have happened if the treatment had not been administered, but everything else had been the same.
within-participant design A comparison in which each participant receives all the different treatments.

A treatment effect is the difference between what would have happened if a treatment had been implemented and what would have happened if the treatment had not been implemented, but everything else had been the same. Such a comparison is called the ideal comparison. Unfortunately, the ideal comparison cannot be obtained in practice. In any comparison that can be obtained in practice, every thing else cannot have been the same. Whatever else is not the same is called a threat to validity. A threat to validity can cause a difference in the observed outcomes and therefore either masquerade as a treatment effect when none is present or bias the estimate of a treatment effect when it is present. One of the critical tasks in estimating treatment effects is to take account of threats to validity. This article describes different types of comparisons, the primary threats to validity for each comparison, and the categories of threats to validity that must be addressed when estimating treatment effects.

Types of Comparisons

A treatment is an intervention such as a medical treatment, job training program, or remedial reading course. Comparisons that are drawn to estimate treatment effects involve two or more treatment conditions. To simplify the discussion, the simplest case is considered first in which there are only two treatment conditions. A treatment is implemented in one of the two conditions (the treatment condition) and either no treatment or an alternative treatment is implemented in the other condition (the comparison condition). For example, a novel medical treatment could be compared either to the absence of medical treatment or to a standard medical treatment. Also for convenience, the participants in a study are referred to as individuals and assumed to be humans, although the participants could be other animals and either individuals or groups of individuals.

It is customary to distinguish between two broad categories of comparisons (or research designs): randomized experiments and quasi-experiments. In randomized experiments, the treatment conditions are assigned at

random. Quasi-experimental comparisons are implemented without the benefit of random assignment.

It is also customary to distinguish between comparisons that are drawn "between" participants and those drawn "within" participants. In between-participant designs, some participants receive the treatment condition, whereas the other participants receive the comparison condition. The treatment effect is estimated by comparing the performances of these two groups of participants on an outcome variable. In within-participant designs, each participant receives both the treatment and the comparison conditions. The treatment effect is estimated by comparing each participant's performance in the treatment condition to that same participant's performance in the comparison condition. In both types of comparisons, the difference between the treatment conditions is called the independent variable. The outcome variable is called the dependent variable.

Between-participant comparisons can be either randomized experiments or quasi-experiments. The same is true for within-participant comparisons.

Between-Participant Randomized Experiments

In a between-participant randomized experiment, individuals are randomly assigned to treatment conditions. After the different treatments have been administered to the groups, a posttreatment, outcome measure is assessed. Effects of the treatment are estimated based on differences between the groups on the outcome measures. For example, in a series of classic studies of conformity by Solomon Asch in the 1950s, individuals were randomly assigned either to a treatment condition in which peer pressure was exerted or to a comparison condition without peer pressure. Peer pressure caused the treatment group to make far more errors on a subsequent perceptual task than the comparison group.

One of the primary threats to validity in a randomized between-participant experiment is "random selection differences." Because the treatment effect is estimated by comparing the performances of different individuals in the two treatment conditions, observed differences in outcomes could be due to differences in the composition of the two groups (i.e., random selection differences) as well as to the effects of the treatment. Statistical inference is the classic means of distinguishing between these two sources of effects. A statistical significance test reveals whether the observed outcome difference between the groups is larger than would be expected due to random selection differences (or to other random effects) alone. Alternatively, a confidence interval estimates the size of the treatment effect within a range of scores that takes account of uncertainty due to the effects of random differences.

Threats to validity due to nonrandom differences can also arise in between-group randomized experiments. Two of the most common such threats are local history and differential attrition. Local history arises when external events differentially affect the two treatment groups. Differential attrition means that different types of individuals in the two treatment groups fail to complete either the prescribed treatment protocols or the outcome measurements. Randomized experiments conducted under laboratory conditions can often minimize local history through careful implementation of controls such as experimental isolation from outside forces, and differential attrition can often be minimized by using short time intervals between the treatment and outcome measurement. Randomized experiments in the field should try to implement the same controls but often cannot avoid these problems even then.

Randomized experiments do not require that pretreatment measures be collected on the participants. However, pretreatment measures can help diagnose and take account of differential attrition. Pretreatment measures can also be used to increase the precision of treatment effect estimates and to assess how the effect of the treatment varies across individuals.

Within-Participant Randomized Experiments

In a within-participant randomized experiment, each participant receives all of the different treatment conditions. The treatment effect is assessed by comparing the performance of each individual under each of the different treatment conditions. For example, a series of studies by Benton Underwood and associates in the 1960s assessed the effects of massed versus distributed practice on learning by having participants study a list of words. Target words were repeated three times in the list and were randomly assigned to presentation in either massed fashion (i.e., the repetitions of a target word appeared one right after the other in the list) or distributed fashion (i.e., filler words appeared between repetitions of a target word). Following the presentation of the list, participants were asked to recall the words. The differences in the numbers of massed and distributed words that were recalled by each participant were averaged across the participants. The mean difference between the number of massed and distributed words that were recalled reflects the effect of massed versus distributed practice.

A threat to validity in within-participant studies arises when different materials (e.g., different words) are used in the different treatment conditions (e.g., the massed versus

distributed practice conditions), which could cause differences in outcomes (e.g., differences in the number of massed and distributed words that are recalled). In within-participant randomized experiments, the materials are assigned to the different treatment conditions at random. Therefore, a threat to validity due to using different materials in different treatment conditions can be addressed by the classic statistical procedures of confidence intervals and statistical significance tests.

Another threat to validity, called practice effects, can arise because of the ordering in which participants are exposed to the different treatment conditions (e.g., the ordering of massed and distributed words within a list). Participants can become more skilled as they perform a task, or they can become tired or bored as a task continues. To the extent that the materials for one treatment condition come earlier in time than the materials for the other condition, practice effects can bias the estimate of the treatment effect.

Practice effects can be controlled by counterbalancing the order of presentation. If the different treatments are repeated only a few times for each individual, the ordering of the treatments can be varied randomly across individuals. If the different treatments are repeated a large number of times for each individual, the order of the repetitions can be randomized for each individual. Another alternative is to order the treatment (A) and comparison (B) conditions in repeating ABBA sequences over time.

A final threat to validity is called transfer or carryover effects, which arise when the effect of a treatment condition depends on the condition that preceded it. For example, if the treatments being compared are different medications, the effect of the medication administered second could vary depending on the medication administered first. The effects of the first medication might not have worn off before the second medication is taken, so a drug interaction occurs. Also, the first medication might cure the illness, so the second medication can have no ameliorative effect.

When transfer effects are plausible, a between-participant design is usually preferred over a within-participant design. Otherwise, within-participant designs tend to be preferable because (i) participants serve as their own comparison condition, which increases statistical precision, and (ii) within-participant designs tend to be less expensive to implement.

Between-Participant Quasi-Experiments

The most common between-participant quasi-experiments are nonequivalent group designs, correlational designs, and regression-discontinuity designs.

Nonequivalent Group Designs

In a between-participant randomized experiment, participants are assigned to treatment conditions at random. A nonequivalent group design is identical to a between-participant randomized experiment except that individuals are not assigned to the treatment conditions at random. For example, individuals might be assigned to treatment conditions by self-selection or based on convenience for administrators.

With or without random assignment, different individuals will be in the different treatment groups, and these group differences (i.e., selection differences) may produce a difference in the outcome measures that would be mistaken for a treatment effect. The advantage of random assignment to treatments is not that it removes selection differences but that it makes selection differences random, which means that they can easily be taken into account using the classic methods of statistical inference. Without random assignment, selection differences are unlikely to be random, and it is much more difficult to be convinced that they have been taken into account properly.

Taking account of the biasing effects of nonrandom selection differences requires a pretreatment measure. In most cases, the best pretreatment measure is one that is operationally identical to the posttreatment measure. A number of statistical methods have been proposed for analyzing data from nonequivalent group designs so as to take account of the effects of nonrandom selection differences. The analysis strategies all use a pretreatment measure to model the effects of the nonrandom selection differences, but in most situations it is not clear which, if any, of the statistical methods are likely to produce credible estimates of treatment effects.

Implementing additional design features is the preferred approach for separating the effects of nonrandom selection differences from the effects of the treatment. Useful design elaborations include multiple comparison groups (including cohort comparison groups), dependent measures that are affected by selection differences but not by the treatment, and pretreatment measures collected at more than one point in time prior to the treatment. However, no matter the approach, the nonequivalent group design rarely produces as credible an estimate of the treatment effect as randomized experiments.

Correlational Designs

So far, it has been assumed that the independent variable is discrete. That is, it has been assumed that a discrete treatment is compared to a discrete comparison condition. Alternatively, the amount of a treatment can vary continuously rather than discretely. For example, the effects

of smoking could be assessed by comparing smokers to nonsmokers (so the treatment is a discrete variable) or by comparing individuals who smoke different amounts (so the treatment is a continuous variable). A design in which the level of the treatment varies continuously and nonrandomly is called a correlational design. Correlational designs are the counterpart to nonequivalent group designs, when the treatment is a continuous rather than a discrete variable.

As in nonequivalent group designs, a primary threat to validity in correlational designs is nonrandom selection differences. Different types of individuals tend to get different amounts of the treatment and these selection differences can bias the estimate of the treatment effect. The most common way to take account of the biasing effects of selection differences in correlational designs is to measure the sources of selection differences and control for their effects statistically. As in nonequivalent group designs, however, it is difficult to be convinced that adequate statistical controls have been applied.

In addition to selection differences, other threats to the validity of between-participant randomized experiments are also threats to the validity of correlational and nonequivalent group designs. These threats can be addressed in similar ways in the different types of between-participant designs. The primary advantage of correlational and nonequivalent group designs is that they often can be implemented when randomized designs cannot, especially in field settings

Regression-Discontinuity Designs

In a regression-discontinuity design, participants are assigned to discrete treatment conditions using a quantitative assignment variable (QAV). The participants are measured on the QAV before the treatments are introduced and assigned to treatment conditions according to a cutoff score on the QAV. All participants with QAV scores above the cutoff score are assigned to one of the treatment conditions, whereas all participants with QAV scores below the cutoff score are assigned to the other treatment condition. The treatments are then introduced and an outcome measurement is obtained on each participant.

Figure 1 is a scatterplot of data from a hypothetical regression-discontinuity design. The outcome measure is plotted on the vertical axis and the quantitative assignment variable is plotted on the horizontal axis. The vertical line indicates the cutoff score on the QAV. Individuals with QAV scores above the cutoff are placed in the experimental group, and their scores are represented by X's in Fig. 1. Individuals with QAV scores below the cutoff are placed in the comparison group, and their scores are represented by O's in Fig. 1.

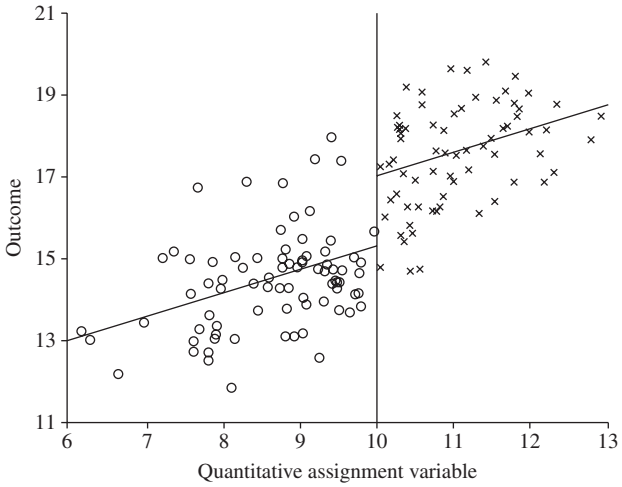

Figure 1 Data from a hypothetical example of a regression-discontinuity design.

In essence, the data from a regression-discontinuity design are analyzed in the following fashion. The scores on the outcome measure are regressed onto the QAV scores separately in each treatment condition and the two regression lines are compared. In Fig. 1, the regression lines are the two sloping lines fit through the data scatters in each group. A treatment effect is evidenced to the extent the two regression lines are not the same. If the treatment effect is a constant for all participants, a vertical displacement in the regression lines would occur at the cutoff point on the QAV. An upward displacement of the treatment group's regression line compared to the comparison group's regression line means that the treatment increases the scores on the outcome variable. Conversely, a downward displacement means that the treatment reduces the outcome scores. If the effect of the treatment interacts with the QAV score, the regression lines are not only displaced upward or downward compared to each other but also differ in slope. Figure 1 reveals a positive effect of the treatment because the regression line in the treatment groups is shifted upward compared to the regression line in the comparison group. However, there is no treatment effect interaction because the regression lines are parallel.

To obtain an unbiased estimate of the treatment effect, the regression lines in the two treatment groups must be fit correctly. For example, if the true regression surface is a straight line, a straight-line regression is the correct model to fit. However, if the true regression surface is curvilinear, a straight-line regression model is likely to produce a biased estimate of the treatment effect: A curvilinear regression model would be required. A curvilinear regression model can be fit in a variety of ways. The most common approach is to add polynomial terms to the regression equation. However, neither this

approach nor any other is likely to produce as credible estimates of effects as are produced in randomized experiments. In addition, the regression-discontinuity design requires far more participants (at least 2.7 times more in common cases) to have the same statistical power as a between-participant randomized experiment.

One of the primary advantages of the regression-discontinuity design is that it can sometimes be implemented in situations in which a randomized experiment cannot be used. In this regard, the regression-discontinuity design is likely to be particularly attractive to program administrators and staff because, unlike in between-group randomized experiments, the QAV can be used to assign participants to treatment conditions based on measures of need or merit. When it can be implemented, a randomized experiment is likely to be superior to a regression-discontinuity design. However, a regression-discontinuity design is likely to produce far more credible results than nonequivalent group or correlational designs. The primary drawback is that the regression-discontinuity design can be implemented in fewer settings than nonequivalent group or correlational designs.

Within-Participant Quasi-Experiments

Within-participant quasi-experiments most often take one of two forms: before–after designs and interrupted time series designs.

Before–After Designs

As the name suggests, in a before–after design, participants are observed on the same variable both before and after a treatment is implemented. The difference between the two measures is used to estimate the treatment effect. A before–after design is often particularly easy to implement, but it is also usually susceptible to severe bias from threats to validity.

Six threats to validity are often plausible in before–after designs. First, a maturation threat to validity occurs when changes from before to after the treatment are introduced because the participants grow older, more experienced, more fatigued, and so on. Second, a history effect occurs when an external event, which occurs between the times of the before and after measurements, causes a difference in the outcomes. Third, a testing effect arises when the mere measurement of the before observation causes a change in the after observation. Fourth, an effect due to instrumentation arises when the variable being measured before the treatment is introduced differs from the variable being measured after the treatment intervention, and this change alters the before–after difference that is observed. Fifth, attrition arises when some of the participants measured before the treatment is introduced are not assessed after the treatment is introduced. Sixth, a regression artifact can arise, for example, if the "before" measurement is obtained when the participants seek treatment because they are experiencing unusually severe problems and these problems would diminish, even without treatment, by the time of the "after" measurement.

A before–after design can produce credible results if few threats to validity are likely to be operating, such as in a learning experiment in which the content matter is unlikely to be learned in any way other than from the treatment intervention. However, such circumstances are relatively rare. The credibility of a before–after design is often improved by adding a before–after comparison using participants who do not receive the treatment. However, adding such a comparison simply converts the before–after design into a nonequivalent group design, which, as previously noted, still tends to be inferentially weak. The primary advantage of the before–after design is that it is easy to implement. However, in most circumstances, alternative designs are preferable.

Interrupted Time Series Designs

An interrupted time series design is an extension of a before–after design in which additional observations are added at points in time both before and after the treatment is implemented. That is, observations on the same variable are collected at several points in time before the treatment is introduced, the treatment is then introduced, and observations on the same variable are collected at several additional time points. Figure 2 is a plot of data from a hypothetical interrupted time series design. The outcome measure is plotted on the vertical axis and time is plotted on the horizontal axis. The vertical line in the middle indicates the time at which the treatment was introduced.

In essence, the data from an interrupted time series design are analyzed in the following fashion. A regression line is fit to the time series data that precede the treatment, and a separate regression line is fit to the time series data that follow the treatment. In Fig. 2, the regression lines are the two sloping lines fit through the two time series of data. These two regression lines are compared, and shifts in one regression line compared to the other are used to estimate the treatment effect. If the treatment effect is constant over time, an upward or downward displacement in the two regression lines should occur. An upward displacement in the "after" regression line compared to the "before" regression line means the treatment increases the scores on the outcome variable. Conversely, a downward displacement means the treatment reduces

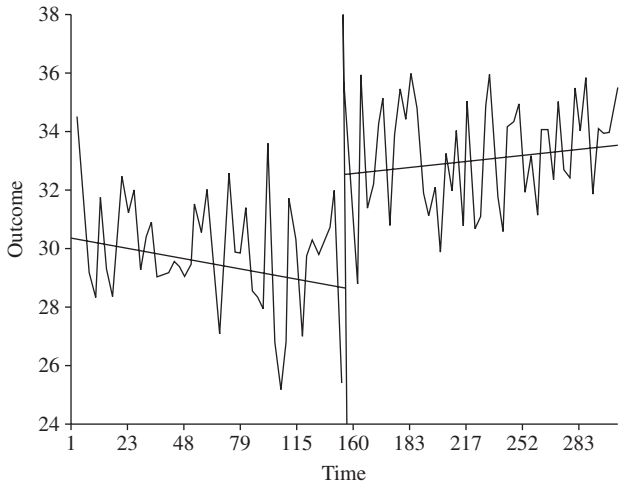

Figure 2 Data from a hypothetical example of an interrupted time series design.

the scores on the outcome variable. If the effect of the treatment varies over time, the regression lines are not only displaced upward or downward compared to each other but also shifted in slope. Figure 2 evidences a positive effect of the treatment because the "after" regression line is displaced upward compared to the "before" regression line. In addition, the effect of the treatment varies over time because the regression lines have different slopes.

Compared to the simple before–after design, the interrupted time series design tends to diminish the plausibility of the threats to validity of maturation, testing, (non-treatment-related) attrition, and regression artifacts. However, the interrupted time series design can still be susceptible to the threats to validity of history and instrumentation. The plausibility of these threats can often be reduced by adding a time series of observations collected on participants who are influenced by the same effects of history and instrumentation but who do not receive the treatment. The data in the comparison time series are analyzed in the same fashion as the data in the treatment time series. A treatment effect is evidenced to the extent the estimate of the treatment effect in the treatment condition time series differs from the estimate of the "treatment" effect in the comparison condition time series. Treatment-related attrition can also be a threat to validity and can usually be assessed by collecting additional data on the degree to which participants did not complete the study.

In some circumstances, such as in behavioral assessments in clinical psychology, interrupted time series designs are implemented with a single participant. In addition, the design is often easy to implement using archival data. An advantage of the interrupted time series design is that it can reveal how the effect of a treatment varies over time. Another advantage is that interrupted time series designs often produce relatively credible estimates of treatment effect. The obvious disadvantage is that data must be obtained over more time periods than in other designs.

Factorial Designs and Treatment Interactions

So far, this article has considered designs with only a single (either discrete or continuous) independent variable. Any of the designs described previously could be implemented (although sometimes only with substantial complications) so as to assess the effects of two different independent variables. For example, a researcher could assess the effects of (i) the independent variable of ingesting caffeine versus not ingesting caffeine and (ii) the independent variable of sleep deprivation versus no sleep deprivation. In what are called factorial designs, participants would be assigned to the four treatment combinations that are generated by these two independent variables. That is, participants would be assigned to the four conditions of (i) caffeine and sleep deprivation, (ii) caffeine and no sleep deprivation, (iii) no caffeine and sleep deprivation, and (iv) no caffeine and no sleep deprivation.

In such a factorial design, three different treatment effects can be estimated. First, the researcher can estimate the effect of caffeine versus no caffeine. Second, the researcher can estimate the effect of sleep deprivation versus no sleep deprivation. These two effects are called main effects. Third, the researcher can estimate the effect of the interaction between caffeine and sleep deprivation. If an interaction effect is present, it means that the effect of caffeine versus no caffeine is different under the condition of sleep deprivation than under the condition of no sleep deprivation.

Four Categories of Threats to Validity

Threats to validity are often partitioned into categories. This section describes the categories of threats to validity developed in a highly influential series of works by Donald Campbell, Julian Stanley, Thomas Cook, and William Shadish that have been published from 1957 to the present.

Statistical Conclusion Validity

Statistical conclusion validity concerns the proper use of statistical procedures in analyzing data. Typical threats to statistical conclusion validity are violating the

assumptions of statistical procedures such as the independence of observations, accepting the null hypothesis, having low statistical power, and increasing the chance of a type I error by data fishing.

Internal Validity

Threats to internal validity are alternatives to the treatment that could explain the observed outcome difference. Most of the threats to validity described in this article (e.g., selection differences, history, and maturation) are instances of threats to internal validity.

Construct Validity

Construct validity concerns the identification of the causes, effects, settings, and participants that are present in a study. For example, a medication might have an effect not because its putative active ingredients are absorbed into the bloodstream but because of its placebo effects. In this case, the cause would be misidentified if its effects were attributed to the absorption of the medication's active ingredients rather than to a placebo effect. Assessing the causal chain by which a treatment has its effects (i.e., determining the variables that mediate an effect) can reduce such misattributions. Alternatively, a cause can be misspecified when the treatment is implemented with less strength or integrity than intended. Manipulation checks are often used, especially in laboratory studies, to assess whether treatments are implemented as planned.

External Validity

External validity concerns the extent to which the results from a study can be generalized to other treatments, outcome variables, settings, and populations of participants. Useful generalization can sometimes be accomplished by identifying the causal mediators of an effect because similar causal mediators often produce similar effects. Generalizations can also be accomplished by identifying the moderators of an effect. When the size of a treatment effect varies with a characteristic of the participants, for example, that characteristic is said to moderate the effect. Moderators can be identified based on variation in the size of treatment effects within a study. Moderators can also be identified via meta-analysis, which is the quantitative synthesis of results from multiple studies. After a moderator has been identified, generalizations can often be made via extrapolation or interpolation.

Maximizing Validity

In many cases, changes made to strengthen one type of validity serve to weaken another type. For example, randomized experiments typically have superior internal validity compared to quasi-experiments, but randomized experiments often can be implemented only using volunteer participants, which tends to make generalizing to nonvolunteers more difficult. In general, limited resources mean that researchers should focus their attention on those types of validity that are judged to be most important in the given circumstances.

Conclusions

Estimating the size of treatment effects is often thought to be more august than "mere" measurement, perhaps because the noble goal of testing theories is done far more often by estimating treatment effects than by simply measuring, for example, public opinions. However, in fact, assessing a treatment effect is nothing more than measurement. The distal goal of a randomized experiment, for example, may be to test a theory, but measuring a treatment effect is always the proximal goal.

What distinguishes the measurement of treatment effects from other forms of measurement is the nature of the attribute that is being measured. A treatment effect is defined as the difference between what would have happened if a treatment had been implemented and what would have happened if the treatment had not been implemented but everything else had been the same. If one side of this comparison is obtained, the other cannot be, if everything else were the same. This impossibility raises unique problems for the measurement of effects.

Many types of designs can be used in place of the ideal but impossible comparison that defines a treatment effect. Each is subject to threats to internal validity. Which design is best depends on the circumstances. Some designs tend to be easier to implement. Others tend to be stronger in terms of internal validity. Yet others tend to offset relative inferiority in internal validity with greater strength in other forms of validity. Nonetheless, internal validity is of particular importance in estimating effects because it is concerned with how closely the comparison used in practice matches the ideal comparison that defines a treatment effect, which is the distinguishing feature of the measurement of effect sizes.

Internal validity is usually stronger in randomized experiment than in quasi-experiments. In quasi-experiments, threats to internal validity can be addressed with statistical procedures but are often better addressed by adding design features. The fundamental challenge for the researcher is determining which threats to internal validity are most plausible and which design features are likely to control them most effectively.

Type I and Type II Error

Alesha E. Doan
California Polytechnic State University, San Luis Obispo, California, USA

Glossary

alternative hypothesis An expectation or prediction that is tested; also referred to as the research hypothesis.
coefficient An unknown but fixed parameter estimated in a regression equation. The coefficient refers to the intercept coefficient and slope coefficient.
dependent variable A variable that is influenced or caused by another variable.
***F* test** An overall test of significance that can be used in a multiple regression equation. The test determines whether all of the slope coefficients simultaneously equal zero. The test is based on an analysis of the total sum of squares, which encompasses the explained sum of squares and the residual sum of squares.
independent variable A variable that influences or causes another variable.
null hypothesis A statement that is the opposite of the alternative hypothesis, stating that there is not a relationship between the independent and dependent variables.
***p* value** The exact level of significance; or, the exact probability of committing a type I error.
***t* statistic** A test of significance that uses the sample results to determine the accuracy of the null hypothesis (e.g., whether the null hypothesis should be accepted or rejected).
type I error Accepting the alternative hypothesis when the null hypothesis is true.
type II error Accepting the null hypothesis when the alternative hypothesis is true.

Committing a type I error or a type II error refers to the probability of erroneously rejecting the null hypothesis or, conversely, accepting the null hypothesis in error. When testing hypotheses, researchers are faced with a dilemma—attempting to minimize the risk of committing a type I error increases the probability of committing a type II error. The opposite relationship holds as well: minimizing the risk of type II error leads to an increased probability of committing a type I error. Both errors present unique problems for the investigator and can result in serious consequences for statistical inferences.

Introduction

Explanation of Type I Error and Type II Error

The goal of conducting research is often to test relationships between two or more variables (dependent variable, Y_i, and explanatory variable(s), X_i) within a sample and draw inferences to a larger population. Investigators set up competing research hypotheses and use statistical analysis to determine if there is empirical support in favor of one hypothesis over the other. Two hypotheses are derived, the null hypothesis, which is often notated as H_0, and the alternative hypothesis, notated as H_a. In empirical research, the null hypothesis typically tests the relationship H_0: $\beta_2 = 0$, which indicates that the slope coefficient is zero, or stated differently, there is no relationship between Y_i and X_i. The alternative hypothesis can be stated in a variety of forms, usually depending on theoretical expectations or prior empirical research. However, for simplicity, the following alternative hypothesis will be used H_a: $\beta_2 \neq 0$. The alternative hypothesis states that the slope coefficient is not equal to zero.

Unfortunately, as with all statistical analysis, a degree of uncertainty exists. An investigator is always confronted with the possibility of accepting the null or alternative hypothesis in error. If a researcher finds empirical support for the alternative hypothesis, thus rejecting the null hypothesis when in fact the null hypothesis is correct, the researcher has committed a type I error.

Alternatively, if a researcher accepts the null hypothesis when the alternative hypothesis is actually correct, then he or she has committed a type II error. Historically, researchers have predominantly focused on type I error; however, both types of errors can be costly.

Significance of Committing a Type I versus a Type II Error

Depending on the purpose of the research, the cost of committing a type I or type II error can be great, because it leads to drawing incorrect inferences and conclusions that can have potentially severe consequences for society. Although the hypothesis has been simplified, the following example highlights the significance of committing a type II error. Early medical trials assessing the benefits of using hormone replacement therapy (HRT) in postmenopausal women concluded that the use of HRT did not pose significant harm to women (H_0: HRT is not detrimental to a woman's health). Based on these studies, physicians routinely prescribed HRT for postmenopausal women. Unfortunately, subsequent research determined that HRT posed significant risks for women, such as an increased likelihood of developing breast cancer, coronary heart disease, and stroke. Clearly, a type II error had been committed in the early studies. Researchers had erroneously accepted the null hypothesis when in fact the alternative hypothesis (H_a: HRT is detrimental to a woman's health) was correct. In this case, committing a type II error resulted in thousands of postmenopausal women being exposed to serious health problems resulting from the use of HRT. The cost of making a type I or type II error is significant and can result in serious consequences for both researchers and society.

Article Overview

The remainder of this article explores how type I and type II errors arise in research. First, the symbols that are used throughout the article are explained, including a summary table. The next section examines the initial decision-making process regarding the formation of hypothesis. More specifically, attention is given to the reasons for setting up a null and alternative hypothesis. The issues pertaining to determining a level of statistical significance in research are explored (e.g., what is the relative advantage of using alpha (α), a probability value (p value), or confidence intervals), and the relationship between significance levels and type I and type II errors is discussed. The following sections review common misperceptions of type I and type II errors as well as some strategies for minimizing both types of errors. The article concludes with a discussion of the trade-offs between type I and type II errors.

Table I Symbols Used

α	The Greek letter alpha, used to represent a type I error.
β	The Greek letter beta, used to represent a type II error.
β_2	The slope coefficient in a regression analysis.
H_0	The null hypothesis.
H_a	The alternative hypothesis.
X_i	The independent variable in an analysis.
Y_i	The dependent variable used in an analysis.
N	The sample size of a study.
F test	An overall test of significance; used to determine if multiple slope coefficients simultaneously equal zero.
p value	The level of significance.
t statistic	A test of significance.
TSS	The total sum of squares; the total variation of the actual Y values about their sample mean.
ESS	The explained sum of squares; the variation of Y that is explained by the regression line.
RSS	The residual sum of squares; the unexplained variation of the Y values in the regression line.

Definition of Symbols

The symbols and notation used throughout this article mirror the conventional, standard Greek symbols and notation widely used in statistical textbooks and articles. Table I lists and defines all the symbols used in this article.

The Formation of Hypotheses

Generating Hypotheses

In empirical research, an investigator generates an expectation or set of expectations to test via statistical analysis. The expectations emerge from an exploration of existing theoretical or empirical work on the given topic, or from a combination of the two. The expectation is stated as a hypothesis, which is simply a statement to be tested. The generation and testing of hypotheses is a process that aids a researcher in making rational decisions about the veracity of the effects being investigated.

Importantly, the hypotheses must be established prior to the actual empirical testing, otherwise the work runs the risk of being *post hoc* and circular in reasoning. If a researcher engages in "data mining" (e.g., generating his or her expectations to match the results of the empirical analysis), then the researcher is guilty of foregoing the scientific method, thus largely invalidating the p values from that specific empirical test. *Post hoc* studies are not considered valid and should be avoided.

The Alternative or Research Hypothesis

The alternative (also referred to as the research) hypothesis is the expectation a researcher is interested in investigating. Typically, the alternative hypothesis will naturally emerge from the particular area under investigation. An alternative hypothesis may, for example, test whether the slope coefficient (β) is not zero (H_a: $\beta_2 \neq 0$), or it may test whether a relationship exists between the dependent variable (Y_i) and the independent variable (X_i). In this case, the alternative hypothesis is a two-sided hypothesis, indicating that the direction of the relationship is not known. Typically a two-sided hypothesis occurs when a researcher does not have sound *a priori* or theoretical expectations about the nature of the relationship. Conversely, in the presence of strong theory or *a priori* research, the alternative hypothesis can be specified according to a direction, in which case it takes on the following forms: H_a: $\beta_2 > 0$ or H_a: $\beta_2 < 0$.

The Null Hypothesis

The null hypothesis is set up to reflect the opposite statement from the alternative hypothesis and can take on multiple forms. For example, the null hypothesis may state that a relationship does not exist between the dependent (Y_i) and independent (X_i) variable. Or, the slope coefficient is expected to be zero (H_0: $\beta_2 = 0$). The null hypothesis is actually the hypothesis that is tested, not the alternative hypothesis. If the empirical testing does not produce any evidence for the alternative hypothesis, then the researcher fails to reject the null hypothesis. Similarly, if evidence is found in support of the alternative hypothesis, then the researcher fails to accept the null hypothesis. Importantly, because most empirical research is based on a sample rather than the true population, the alternative hypothesis (and likewise, the null hypothesis) is not "proved." A possibility always exists that more empirical tests, based on another sample, will yield different results, or another null hypothesis exists that is just as compatible with the empirical evidence. Therefore, a researcher is simply stating that based on the current sample evidence, there is reason to either accept or fail to accept the null hypothesis.

Determining Significance Levels

Choosing a Level of Significance

After generating the research and null hypothesis, a level of significance (α) must be established in order to determine the point at which a researcher will either accept or reject the null hypothesis. Essentially, hypothesis testing hinges on the level of significance chosen by the researcher. The level of significance is simply the probability of committing an error and the investigator—prior to the empirical analysis—sets it. In other words, the level of significance is the probability of committing a type I error. Of course, the more stringent a researcher is in setting the significance level (e.g., 0.05, 0.01, 0.001), the less likely the conclusions will be incorrect. Although the level of significance can be set by the investigator, in social science research, α is conventionally set at 1%, 5%, and occasionally at 10%. However, the α level is flexible and usually depends on several factors, such as the type and purpose of the research under investigation, the sample size, and the costs associated with drawing incorrect conclusions.

Relationship between α and Type I and Type II Errors

The α level is critically linked to the probability of committing a type I or type II error. Unfortunately, trying to reduce type I error (typically represented by α) leads to an increased probability of committing a type II error (typically represented by β). Type I and type II errors are inversely related and cannot be simultaneously minimized. Recall that type I error occurs when a researcher falsely rejects the null hypothesis. In other words, he or she found a false positive relationship. Conversely, a type II error exists when the null hypothesis is falsely accepted. The researcher's evidence suggests that there is not a significant effect, but in the population the effect is significant. In both cases, the researcher's sample has failed, either erroneously indicating an effect or no effect, respectively, in the population. Table II contains a summary table defining type I and type II errors.

By setting the α level, a researcher is actually setting the parameters for committing a mistake. In other words, α determines how much risk an investigator is willing to accept in his or her research. For example, by setting α at 5%, a researcher is accepting the chance of committing a mistake one in 20 times. Stated differently, a researcher will reject the null hypothesis when it is actually correct one in 20 times. Historically, statisticians have advocated for reducing the probability of type I error over type II error by setting α at a low level.

As a researcher attempts to mitigate against type I error, he or she increases the risk of committing a type II error. However, whereas the α level is determined in advance by a researcher, the β error rate is much more difficult to determine. In order to set β, a researcher

Table II Decision Analysis

Test decision	*H_0 is true*	*H_0 is false*
Reject H_0	Type I error	No error committed
Accept H_0	No error committed	Type II error

would have to know the distribution of the alternative hypothesis, which is rarely known. Consequently, the concept of power can be used to reduce the probability of committing a type II error.

Power refers to the probability of not committing a type II error. Stated differently, power is the likelihood that a test will reject the null hypothesis when it is truly false; it is determined by taking $1 - \beta$. Power can be strengthened by increasing the sample size of the study. In fact, consideration to type II error should be given at the initial stage of research design, when the investigator assesses how large of a sample is needed to detect any potentially significant effects.

Alternatives to α: *P* Value and Confidence Intervals

Instead of setting the α level, which is often arbitrary or done out of convention, a researcher can use a test statistic (e.g., the t statistic) to find the p value. The p value is the probability value; it provides the exact probability of committing a type I error (the p value is also referred to as the observed or exact level of significance). More specifically, the p value is defined as the lowest significance level at which the null hypothesis can be rejected. Using the test statistic, a researcher can locate the exact probability of obtaining that test statistic by looking on the appropriate statistical table. As the value of the test statistic increases, the p value decreases, allowing a researcher to reject the null hypothesis with greater assurance.

Another option in lieu of relying on α is to use a confidence interval approach to hypothesis testing. Confidence intervals can be constructed around point estimates using the standard error of the estimate. Confidence intervals indicate the probability that the true population coefficient is contained in the range of estimated values from the empirical analysis. The width of a confidence interval is proportional to the standard error of the estimator. For example, the larger the standard error of the estimate, the larger the confidence interval, and therefore the less certain the researcher can be that the true value of the unknown parameter has been accurately estimated.

The null hypothesis is frequently set up as an empirical straw man because the objective of empirical research is to find support for the alternative hypothesis (hence the conventional wisdom that null findings are not newsworthy findings). The null hypothesis may reflect a fairly absurd scenario that is actually used to dramatize the significance of empirical findings. Consequently, some econometricians argue for the use of confidence intervals, which focus attention on the magnitude of the coefficients (findings) rather than on the rejection of the null hypothesis. According to De Long and Lang (1992) "if all or almost all null hypotheses are false, there is little point in concentrating on whether or not an estimate is indistinguishable from its predicted value under the null" (p. 1257).

Both of these options present alternatives to simply choosing a level of significance. The p value yields an exact probability of committing a type I error, which provides the researcher with enough information to decide whether or not to reject the null hypothesis based on the given p value. Using confidence intervals differs in approach by concentrating on the magnitude of the findings rather than the probability of committing a type I error. Every approach to hypothesis testing—using α, p values, or confidence intervals—contains some amount of trade-offs. Ultimately, a researcher must decide which approach, or combination thereof, suits his or her research style.

Minimizing Type I and Type II Errors

Common Misperceptions

Conventional statistical wisdom often suggests that in order to reduce the likelihood of committing a type I or type II error, a researcher should increase the sample size of the empirical study. Greater confidence is typically attributed to the findings from studies that have a large sample size. This assertion, however, is only partially correct and can lead to inaccurate interpretations of research results.

Increasing the sample size will in fact reduce the probability of committing a type II error. In a smaller sample, detecting treatment effects is much more difficult compared to a larger sample. For example, consider two identical studies with varying sample sizes. The first study has a sample size of 25 ($N = 25$), whereas the second study has a sample size of 250 ($N = 250$). Using the same level of significance, the treatment effect in the first study would have to be three times larger than the treatment effect in the second study in order to be detected. This disparity results from the formula used to derive statistical significance, which contains the sample size in the denominator of the formula. Consequently, increasing the sample size will reduce the probability of committing a type II error, but not a type I error. Rather, reducing the α level is the only way to reduce the probability of committing a type I error.

Reducing the Probability of Committing a Type I Error

The probability of committing a type I error can dramatically increase when testing for multiple hypotheses. Indeed, when relying on the t statistic for multiple comparisons, the α level will become inflated,

leading to a greater propensity for a type I error. Essentially, the problem occurs because as the sample size increases, the value of the range increases at a faster rate than the value of the standard deviation. The t statistic, while accounting for the standard deviation in the formula, does not consider the larger increase in range in relation to the standard deviation. Consequently, when used in multiple comparisons, the t test will inflate the α level, thus leading to a greater risk of committing a type I error.

Although a perfect solution does not exist, there are several measures a researcher can take to mitigate the risk of committing a type I error. Two major approaches include using ordered p values or employing a comparison of normally distributed means. The easiest ordered p value approach is based on the first-order Bonferroni inequality. Simply stated, the Bonferroni technique takes into account the number of hypotheses being tested and adjusts the p value accordingly. For example, if three hypotheses are being tested, the p value is adjusted downward by dividing the p value by three (e.g., 0.05/3). The new p value becomes 0.02, based on the rules of probability. The Bonferroni adjustment should only be applied if the hypotheses are assumed to be independent; if they are interrelated, the Bonferroni adjustment is too severe.

Similarly, several comparisons of normally distributed means techniques exist. Three of the more common techniques are the Scheffe, Tukey, and Dunnett methods. Each of these techniques differs slightly in its approach according to the specific means contrasts under investigation. Despite their variations, they share several elements. First, they are particularly designed to deal with comparison of means; second, they assume normally distributed observations; and third, they are premised on the joint distribution of all observations. In the end, these approaches enable a researcher to decrease the likelihood of committing a type I error.

Reducing the Probability of Committing a Type II Error

As discussed previously, the most straightforward—although not always feasible—way to decrease the probability of committing a type II error is simply to increase the sample size. If increasing the sample size is not practical, then Fisher's ANOVA procedure can be employed. ANOVA is the analysis of variance, which is a study of the total sum of squares (TSS) in a regression analysis. The TSS is a combination of the explained sum of squares (ESS) and the residual sum of squares (RSS). ANOVA can be used to calculate an F ratio (assuming the disturbances are normally distributed). The F ratio follows the F distribution and provides a test of the null hypothesis (H_0: $\beta_2 = 0$). Fisher's test minimizes the probability of a type II error; however, the trade-off is that it increases the chance of making a type I error.

Conclusion: The Trade-off between the Two Errors

Type I and type II errors present unique problems to a researcher. Unfortunately, there is not a cure-all solution for preventing either error; moreover, reducing the probability of one of the errors increases the probability of committing the other type of error. Although a researcher can take several measures to lower type I error, or alternatively, a type II error, empirical research always contains an element of uncertainty, which means that neither type of error can be completely avoided.

Type I error has historically been the primary concern for researchers. In the presence of a type I error, statistical significance becomes attributed to findings when in reality no effect exists. Researchers are generally adverse to committing this type of error; consequently, they tend to take a conservative approach, preferring to err on the side of committing a type II error. The major drawback to exclusively emphasizing type I error over type II error is simply overlooking interesting findings. Typically, once statistical relationships are discovered, more studies follow that confirm, build upon, or challenge the original findings. In other words, scientific research is cumulative; therefore, false positives are revealed in subsequent studies. Unfortunately, in the presence of a type II error, the line of inquiry is often discarded, because in most fields of research, a premium is placed on statistically significant results. If a type II error has been committed and that particular line of inquiry is not pursued further, the scientific community may miss valuable information.

Ultimately, the scientist must decide which type of error is more problematic to his or her research. Essentially, the investigator is confronted with the question of what type of error is more costly. The answer to this question depends on the purpose of the research as well as the potential implications in the presence of a false positive (type I error) or false negative (type II error) findings.

Typology Construction, Methods and Issues

Kenneth D. Bailey
University of California, Los Angeles, California, USA

Glossary

classification The grouping of entities by similarity.
constructed type A qualitative type used to compare empirical cases.
ideal type A qualitative type with accentuated dimensions.
monothetic type A type in which all members are identical on all characteristics.
polythetic type A type in which all members are similar, but not identical.
reduction The process of reducing the number of types in a typology.
substruction The process of identifying and expanding the underlying dimensions of a type in order to form a full typology.
taxonomy An empirical typology used in biology and related fields.
three-level model An expanded measurement model recognizing the conceptual, empirical, and indicator or document levels.
typology A multidimensional classification, generally conceptual rather than empirical.

A typology is an array or complete set of types. It is a multidimensional classification. Typology construction is part of the more general process of constructing and utilizing classification schemes of various sorts. The use of types is endemic in everyday speech. It is common to speak of types of birds, types of trees, and so forth. Traditional typologies were generally qualitatively derived. They often remained conceptual, without empirical referents. More recently, typologies have been quantitatively derived through the computerized statistical analysis of empirical specimens. This approach has incorporated a variety of techniques, variously called cluster analysis, numerical taxonomy, or pattern recognition.

Classification

If classification in general, and typology construction in particular, has such a great value for social theory and measurement, it seems logical that scholars would devote special effort to its development and explication. Sadly, this is generally not the case. Typology construction is often taken for granted, if not neglected. Most of the literature on typology construction in social science is quite old. Much like the foundation of a building, the typological foundation of social measurement is often out of view, and thus easily out of mind. This is unfortunate, because social theory and measurement are often no stronger than their typological underpinning. If the latter is weak, so is the former. Yet ironically, something as important as typology can often become seemingly invisible, not only to the lay public, but even to many scholars as well. Terms such as typology, substruction, reduction, or classification elicit little name recognition. The only concept that many people seem to recognize is that of "sorting," a term that ironically is generally absent from the formal lexicon of typology construction. Many people have a drawer in their kitchen for sorting silverware into spoons, forks, and knives, and this seems to be about the extent of their awareness of classification principles and procedures. Social scientists often recognize the concepts of "ideal types" and "polar types," but this may represent the extent of their awareness of typological principles and procedures as well.

Basic Definitions

Classification

Classification is the generic process for grouping entities by similarity. The goal is to make each cell of the classification as similar as possible (to minimize within

group variance). This may involve maximizing between-group variance, by maximizing the distance between each cell. The individual cell or category within the larger classification is called a class. The term "classification" is used to refer both to the process and the result of the process, as in "The classification process produced an excellent classification." An adequate classification must be simultaneously mutually exclusive and exhaustive. In other words, the classification must provide a place (but only one place) for every individual in the sample.

Typology

A typology is a multidimensional classification. The term "typology" is often reserved for classification schemes that are verbal, or said to be conceptual, theoretical, or "heuristic," as opposed to empirical. A single cell of a full typology is called a type. Types can include both heuristic and empirical types. Heuristic types are conceptually derived, and thus may lack empirical examples. Empirical types are constructed entirely through empirical data analysis, and thus may lack precise conceptualization.

Taxonomy

A taxonomy is an empirical classification, generally associated with the field of biology. A single cell of the taxonomy is known as a taxon.

Numerical Taxonomy

The process of generating an empirical classification schema quantitatively is called numerical taxonomy. One generally begins with a set of empirical cases believed to have certain similarities. Then various algorithms are selected to mathematically group the empirical data according to similarity. Numerical taxonomy is virtually always a computerized analytic procedure. Although not limited to biology, numerical taxonomy was largely developed within biology, and is often associated with it.

Cluster Analysis

This procedure is similar to numerical taxonomy, and in fact the two terms are often used interchangeably. Cluster analysis also refers to a variety of techniques for quantitatively grouping data by similarity, generally (but not universally) on the computer. The term cluster analysis is not as closely associated with biology as is numerical taxonomy. Cluster analysis techniques are used by researchers in a wide variety of disciplines, including sociology, anthropology, psychology, and education.

Divisive Methods

These are methods which begin by treating the entire original sample as one cluster and then successively dividing it until the desired set of clusters is reached. Divisive methods are generally (but not always) computerized.

Agglomerative Methods

Agglomerative methods are the converse of divisive methods. They begin by treating each of the N cases in the original sample as N different clusters. Then these N clusters are successively agglomerated into a smaller number of classes. Although noncomputerized agglomerative methods do exist, most agglomerative methods fall under the rubric of either numerical taxonomy or cluster analysis. They generally proceed by utilizing some quantitative, computerized algorithm to iteratively generate the desired set of clusters M, where $1 < M < N$. Both agglomerative and divisive methods use algorithms or quantitative rules that dictate how clusters are formed. Though these are generally utilized in the form of "canned" computer programs, there may be decisions that researchers have to make in using them, concerning such things as the level of similarity required for adding an additional case to a preexisting cluster or even the desired number of clusters.

Identification

Conceptual verbal typologies and empirically derived concrete taxonomies represent different dimensions. Typologies may be purely conceptual, while taxonomies may be purely empirical. Each of these alternatives may prove sufficient for some research purposes, depending upon the researcher's particular goals. A verbal typology may suffice for heuristic purposes, or for explicating certain theoretical notions. Conversely, a taxonomy may be sufficient if one desires primarily an empirical description of cases and does not desire further theoretical analysis. However, in many instances the researcher may not be satisfied with either a purely verbal typology or with a computer-generated empirical mathematical taxonomy. If a researcher has constructed a purely verbal or conceptual typology, he or she may wish to find empirical cases to fit one or more of the verbal type cells. This process of finding empirical cases to fill in the cells of verbal typologies is called identification.

Qualitative Typologies

The typological tradition has a long history in social science, especially in sociology. Here, types were often viewed as multidimensional concepts, or constructs.

Often these types were utilized individually or in pairs, without the benefit of a full typology. Such a verbal type was generally seen as a set of correlated variables or dimensions that were somehow "connected" to each other. For example, "student athlete" is a multidimensional type concept comprising five separate but intercorrelated dimensions: (1) university affiliation; (2) sex; (3) age; (4) nationality; and (5) amateur standing.

The Ideal Type

Perhaps the most famous type concept is Weber's ideal type. This frustrating concept has proven to be both valuable and confusing, as scholars have argued over exactly what it is, and how to utilize it. As defined by Weber, the type concept is exaggerated on one or more of its basic dimensions, generally to the point that it cannot be found empirically (at least in its most exaggerated form). Weber states explicitly that the ideal type is a utopia. However, he also specifies that a given ideal type should be used as a criterion point to measure the degree to which a specific empirical case diverges from it. For example, Weber says that a researcher can begin with the ideal type of "city economy," and then study the degree to which the economy of an actual city departs from this ideal type.

Weber's strategy is actually ingenious, which explains all the acclaim that it has received. However, it is also unfortunately vulnerable to misinterpretation, which explains the criticism it has received, generally from critics who simply failed to understand its underlying logic and its proper use. Critics have seized upon Weber's comments that the ideal type is a utopia that "cannot be found empirically anywhere in reality." Critics have misconstrued this to mean that the ideal type is "imaginary" or hypothetical and thus lacking a fixed position in typological space. This is not true. To say that an ideal type is a utopia does not mean that it is imaginary or lacks a fixed location in typological space. It simply means that it occupies such an extreme position in the typology that examples of it will rarely (or ever) be found empirically. Critics charge that since the ideal type is imaginary, it can be placed anywhere the researcher desires, thus rendering it useless as a comparative tool. This is not a fair representation of the ideal type. The ideal type cannot be moved or revised at will, but instead occupies a firmly fixed position or location in typological space. In reality, types that are similar to the ideal type can be routinely found empirically, but without the perfection of the ideal type.

A contemporary example is the system currently in use for grading collectible United States coins. MS-70 is the highest, or perfect grade. It is the equivalent of the ideal type. It is a utopia as Weber stated, but it is certainly not imaginary, as critics have charged. It is very real and clearly defined in a multidimensional state, but it is simply difficult to attain as it represents perfection. It is, however, very valuable for grading coins of lesser grade. The MS-70 demonstrates what a perfect specimen would look like, and thus documents the degree of imperfection of the coin being graded. Coins grading around MS-60 or MC-62 are abundant, but the ideal type coin of MS-70 is rarely if ever found.

What Weber was doing by comparing all empirical cases with a single ideal type was effectively reducing the entire typology (which might have contained hundreds of individual types), down to a single type for comparative purposes. In Weber's precomputer era, a large typology was entirely too unwieldy to use efficiently. For example, if a researcher devised a 10-dimensional typology, the minimum size of this typology (if all dimensions were merely dichotomies) would be 1024 cells. If some or all of the dimensions contained more than two categories, the typology could be much larger, encompassing thousands of cells. Problems with using such an unwieldy typology for studying actual empirical cases are not limited to the number of cells, but stem from the number of dimensions as well. If a researcher wants to use a ten-dimensional typology, he or she is greatly constrained by the fact that only two dimensions at a time can be represented on a two-dimensional sheet of paper.

Fortunately, at this point Weber's ideal type emerges as a valuable compromise. Weber offered a single cell for the typology, generally one that was the most visible (often the most extreme) on each of the dimensions comprising the typology. The researcher was now spared the complexity of attempting to work with thousands of types. He or she could simply identify each empirical case, measure the degree that it departed from the ideal type on each dimension, and specify the theoretical typological cell corresponding to this case.

Constructed Types

An alternative to the ideal type is the constructed type, as popularized by McKinney. The constructed type is also a single type (like the ideal type, but without the mystery and confusion of the ideal type). As defined by McKinney, the constructed type is a purposive combination of a set of criteria with empirical referents. Although these criteria may be accentuated, they are generally not as extreme as an ideal type. While not an average, the constructed type is designed to be more central than the ideal type. This means that it is nearer in value to the empirical cases it is being compared with, thus facilitating measurement. The constructed type is designed to serve as a basis for the comparison of empirical cases.

Polar Types

A typologist who is reluctant to depend on a single ideal type may choose to add additional types, but without

going to the full typology. One popular strategy is the use of polar types. These types represent both extremes of the correlated dimensions comprising the type concept. That is, one of these would generally be the ideal type, and the other would be its polar opposite. One advantage of this strategy is that it mirrors the common practice of reducing empirical reality into simple dichotomies, rather than continuous dimensions. Common polar type pairs are gemeinschaft/gesellschaft, local/cosmopolitan, and rural/urban. This strategy could be further extended by choosing four types, such as the four corners of the typology, or by utilizing one or both of the diagonals of the typology.

Ethnographic Types

In addition to ideal, constructed, and polar types, another form of qualitative type is the ethnographic type. "Heuristic types" such as ideal and constructed types are generally deductively derived without empirical data analysis. In contrast, ethnographic types, while qualitatively produced, tend to be inductively derived through ethnographic analysis of empirical data (so called "grounded theory"). The standard procedure is for ethnographers to conduct field research on a particular group and to derive empirical type concepts that serve as descriptive labels for the varieties of social phenomena observed. A complicating factor, though, is that there are often two separate sets of qualitatively derived empirical types. One set is generated by the outside observer (ethnographer) while the other set is derived by the inside group members themselves. The existence of two parallel sets of types from the same phenomenon is an indication (at least to some degree) of an existing "insider–outsider" distinction.

Insider types tend to be more specific and more favorable than outsider labels. For example, among the labels that transients use to describe themselves are "bindle stiff" and "fruit tramp." These type concepts are generally unknown to the lay public, who tend to use alternative and more stigmatized labels such as "bum" or "wino." Note that like classical heuristic types, ethnographic types represent a purposive selection of types (the ones evident in the analysis) rather than a full typology.

Reduction

The use of ideal and constructed types for the identification and comparison of empirical cases can be seen as a rudimentary form of reduction. Lazarsfeld introduced the dual procedures of reduction and substruction of typologies. Reduction is the process of reducing the complexity of an unmanageable typology. Lazarsfeld introduced three forms of typological reduction—functional, pragmatic, and arbitrary numerical. All three forms of reduction assume that a full typology (for example, of 1024 cells) exists, but that the researcher desires to reduce the size and complexity of the typology.

Functional reduction is similar to the process we described for the ideal type, but does not entail prior specification of a criterion type such as an ideal or constructed type. With functional reduction, one first specifies the full typology, then seeks to identify empirical cases for the respective cells. Cells for which empirical examples can be found are retained, while the remainder (null cells) are removed from the typology. The second form of reduction is pragmatic reduction. This consists of collapsing together a number of contiguous cells in the typology. While having the advantage of reducing the total number of cells, it has the disadvantage of increasing the within-cell heterogeneity of the new aggregated type.

Lazarsfeld's third form of reduction is arbitrary numerical reduction. This is essentially an unequal-weighting scheme whereby two or more distinct and unequal types are rendered equal, and thus one or more becomes redundant and can be removed from the typology. In elaborating this strategy, Lazarsfeld presented each dimension of the type as a dichotomy, so that binary coding could be used. Thus, in a type of three dimensions, each of the three could be coded as either present (1) or absent (0) in a particular study. This yields eight possible code patterns from (0,0,0) to (1,1,1). Lazarsfeld's basic strategy entails setting some of these patterns equal through unequal weighting. For example, paraphrasing Lazarsfeld, imagine that we are constructing an index of residential housing attractiveness based on three dimensions—central heat, a fireplace, and a swimming pool. A home possessing all three of these would be the most attractive, and would be coded (1,1,1), while a home lacking all of these would be least attractive, and would be coded (0,0,0). Arbitrary numerical reduction, as the name implies, is both arbitrary and numerical. It entails specifying (somewhat arbitrarily) unequal weightings. For example, we could say that central heat is more important than the other two factors, so that a home with central heat, but lacking the other two, is equally attractive to a home lacking central heat, but possessing both a fireplace and a swimming pool. In coded form, $(1,0,0) = (0,1,1)$. This means that the original eight three-dimensional types have now been reduced to seven.

A huge typology that is theoretically rich is nonetheless of little use if it remains too complex to be used efficiently. At first glance it might seem that this was chiefly a problem for typologists such as Weber working in a time before computers. Now, typologists can let the computer deal with the complexity of a large typology, without the need for the drastic reduction of types. In reality, though, this is a gross oversimplification. Although the computer certainly stores more types than any device available in

Weber's time, computers have not effectively dealt with the monumental problems of interpreting the complex data. Thus, while computers may store a typology of multiple dimensions, they are not yet able to present them all simultaneously in a format that researchers can easily comprehend and interpret.

A researcher might construct a 10-dimensional typology, yet when he or she is ready to print it, the reality remains that the paper that the results are printed on remains intractably two-dimensional. The 10 dimensions cannot be presented simultaneously, but are generally printed two at a time. That is, dimensions one and two are printed, then dimensions one and three, and so forth. The worry is that the holistic nature of the full typology is almost totally lost. With no way to present the congruence of all dimensions simultaneously, the typologist can only view a piecemeal two by two presentation. This loses most of the holistic richness and complexity of the typology.

Thus, ironically, the need for reduction remains almost as strong in the computer era as it was in the precomputer era of Weber's time. Now, more dimensions can be stored, but they still cannot be simultaneously viewed and interpreted. In reality, rather than printing the *N*-dimensional typology two dimensions at a time, it may still be better to reduce the full typology to a few key types, each which can be viewed holistically, with its full complexity intact.

Substruction

Substruction is the opposite of reduction, and was also explicated by Lazarsfeld. Many times the literature does not present a full multidimensional typology, and so there may be no pressing need for reduction. However, the opposite problem may arise. That is, a writer may present a complex type such as "gemeinschaft" or "cosmopolitan," without adequately specifying all of its underlying dimensions. It may be evident to the reader that the type is multidimensional rather than unidimensional, but he or she may not know exactly what the latent dimensions are. The process of substruction entails identifying the underlying dimensions so that other relevant types, or even the full typology, may be constructed. This process of extending the complete property space and the resulting complete typology from one or a few multidimensional types is called substruction. Barton provided an example of substruction. He began with four types of social norms—folkways, mores, laws, and customs. He performed a substruction that identified three underlying dimensions of norms—"how originated," "how enforced," and "strength of group feeling." These intercorrelated dimensions were subsequently extended and combined to form a full property space.

Quantitative Typologies

Quantitative typologies differ in significant ways from their qualitative counterparts. They generally have different names, being referred to as taxa or clusters rather than as types. Quantitative types are almost exclusively derived through the analysis of empirical data and tend to be inductive. While it would be possible to construct a quantitative "heuristic" type by applying an algorithm to conceptual dimensions rather than to empirical data, this approach is rare or nonexistent. The chief goal of quantitative typologists, whether they term their efforts quantitative typology, numerical taxonomy cluster analysis, or some other label, is to take some empirical data set and group all the cases into categories that maximize the internal similarity of each group.

Q- versus R-Analysis

A major distinction in quantitative taxonomy is whether one is seeking to group objects (Q-analysis) or variables (R-analysis). The usual procedure is to begin the quantitative analysis with a basic data matrix in which the rows list data for objects, and the columns list data for variables. The basic data matrix is shown in the work of Bailey. The internal scores of the data matrix are the same whether one inspects rows or columns, and they represent the matrix of scores on each of *M* variables for the sample of *N* objects (persons, animals, plants, and so forth). In sociology and most of the other social sciences, it is customary to conduct R-analysis by correlating pairs of columns in the data matrix. This yields a set of R-correlation coefficient among variables. For example, variables 1 and 3 may exhibit a correlation of 0.67, while variables 2 and 6 have a correlation coefficient of 0.42, and so forth. In biology and related fields it is customary to use Q-correlations for numerical taxonomy and cluster analysis. The procedure is essentially the same except that correlation coefficients are computed for pairs of rows rather than pairs of columns. This yields Q-correlations between objects.

Most quantitative algorithms used in numerical taxonomy and cluster analysis are quite robust, enabling them to accommodate a variety of data. These include Q- and R-similarity coefficients for all levels of data measurement (ratio, interval, ordinal and nominal data and binary-coded data, as well as distance coefficients. However, due to degrees of freedom issues, Q- and R-analyses generally require somewhat different kinds of data sets. Specifically R-analysis is best with a large sample of objects (*N*) and a smaller set of variables (*M*). The converse is true for Q-analysis. It requires a small sample of objects (*N*) and a larger set of variables (*M*).

Thus, the fact that R-analysis predominates in sociology and Q-analysis predominates in biology is not merely

the result of whimsy or tradition. There are sound methodological reasons for this. In sociology and in related fields such as political science and policy studies, there is an increasing emphasis on the use of large national samples of individuals. If one is using a sample of 10,000 cases, it is virtually impossible to measure a larger number of variables (more than 10,000) for each of the individuals. Thus, the researcher has more objects than variables, making the analysis most appropriate for R-correlations. The converse is often true in biology or medicine, and sometimes in psychology and other fields as well. Here, it may be difficult to find more than a few rare specimens, but if binary coding is used, it may be possible to code data for a large number of characteristics (perhaps hundreds) each case. Data of this sort is conducive to the use of Q-analysis. Thus, the majority of quantitative analyses cluster objects via Q-analysis, but a few cluster variables via R-analysis.

Quantitative empirical methods generally cannot form full typologies. However, they can attempt to group the sample of specimens as well as possible on the basis of similarity. Ideally, all clusters or taxa would be tight, meaning that the individuals within each cluster were highly similar if not identical. That is, internal cluster variance or distance would be minimized. Further there will be maximum distance between clusters, so that there are no overlapping clusters, and no arbitrary decisions need to be made regarding when one cluster ends and another cluster begins.

Quantitative typologists need to make at least four main decisions. These are: the type of analysis (Q or R), whether the analysis is agglomerative or divisive (as discussed previously), what kind of coefficient to use (similarity or distance), and if an agglomerative method is chosen, the type of nucleus formation need to be decided. The basic decision is whether one chooses the most similar pair as the nucleus for one cluster, or the most dissimilar pair as the nuclei for two different clusters, or some variation of these basic strategies.

A Typology of Types

Figure 1 shows a typology of types. Row 1 shows the qualitative typologies, previously discussed. These can be divided into qualitative heuristic (Cell 1) and qualitative empirical types (Cell 2). The heuristic types are generally conceptual or theoretical in nature and are derived deductively prior to empirical investigation. These include the ideal type, the constructed type, and polar types. These may or may not have clear empirical referents. Types that are said to be purely theoretical, and to lack empirical referents, still may be valuable for heuristic purposes. However, if they are used empirically, they are vulnerable to charges of improper reification.

	Heuristic	Empirical
Qualitative	Ideal Type 1	Ethnographic Type 2
Quantitative	Rare or Nonexistent 3	Clusters or Taxa 4

Figure 1 A typology of types. From *Encyclopedia of Soc* 2E 4V, by, 5, Macmillan Library Reference, © 2000, Macmillan Library Reference. Reprinted by permission of The Gale Group.

The types of Cell 2 are inductively derived through ethnographic research. Outsider types may be imposed by external researchers or by the lay public, while insider types are generated and used by the insider participants themselves. The qualitative types of both Cell 1 and Cell 2 generally represent selected types, rather than the full typology. Thus, they can be viewed as examples of functional reduction, as described above.

Quantitatively derived types are found almost exclusively in Cell 4 (quantitative–empirical). Examples of Cell 3 (quantitative–heuristic) are rare if not nonexistent in the typological literature. About the only way they could be generated would be to take purely conceptual, nonempirical categories and process them through quantitative algorithms. The rationale for such analysis, and the value of the subsequent types, is unclear. The prospects for such activity in Cell 3 are low. In contrast, Cell 4 (quantitative empirical) is the site of a great deal of activity. A wide variety of cluster and numerical taxonomy techniques, both agglomerative and divisive, are available for constructing clusters and taxa in Cell 4. Such clusters and taxa generally do not represent a full typology, but rather can be seen as examples of pragmatic reduction. They are equivalent to the set of types that can be found by collapsing multiple contiguous cells to make a single new cell that is more parsimonious, but also more heterogeneous, than the prior types. The clusters and taxa of Cell 4 represent the maximum amount of intratype similarity that can be quantitatively achieved from the given sample of empirical cases.

Monothetic Types

The great advantage of constructing types that are purely theoretical is that they can be made entirely monothetic. Monothetic types are fully homogeneous. There is no internal variation within a monothetic type. In statistical terms, this would be represented by an example where all cases in the particular type possesses the mean value on all dimensions. Thus, the internal variance is zero.

Imagine a typology formed from 10 binary-coded characteristics, when each of the 10 is coded 1 if present and 0 if absent. The full typology will consist of 1024 cells or types. Each of these is monothetic, as a case cannot

occupy a given cell unless it possesses all of the characteristics represented by that cell. In order for a typology to be monothetic, the possession of a unique set of features must be both necessary and sufficient for identifying cases as belonging to a particular cell in the typology. Each specific characteristic is necessary, and the set alone is sufficient. Before a case can be identified with a particular type, it must possess all of the characteristics of that type, but no others. Thus, all of the cases in a given monothetic type are identical in all ways (at least in all the ways that were specified and measured).

Polythetic Types

Polythetic types are more eclectic and heterogeneous than monothetic types. While monothetic types display no within-type variance, polythetic types may display such internal variation, because not all cases within a given type are completely identical. Thus, compared to the pure internal homogeneity of monothetic types, polythetic types can be characterized as pragmatic or practical approximations to pure monotheticism. In a polythetic type, the cases are selected to display the greatest possible degree of similarity. That is, the internal variance of a polythetic type is not zero (as in a monothetic type), but is minimized. In a polythetic type, no single characteristic is either necessary or sufficient. For example, in the 10-dimensional typology comprising 1024 monothetic types, the cases in each type will all be identical on all 10 characteristics. In contrast, in a polythetic type based on the same dimensions, it might turn out that none of the pairs of cases identified for the type share all 10 characteristics, however, they might each have 9 of the 10 characteristics, but not the other one. For example, Case 1 might possess characteristics 1 through 9, while Case 2 possesses characteristics 2–10. These eight characteristics (2 through 9) are held in common by each case. However, in addition, Case 1 possesses characteristic 1 (which Case 2 lacks), while Case 2 possesses characteristic 10 (which Case 1 lacks). In a polythetic type, each specimen possesses a large number (but not necessarily all) of the characteristics, and each property is possessed by a large number of specimens (but necessarily all). A special case of the polythetic types is called fully polythetic. A type is termed full polythetic if no single property is held in common by every individual in the type.

A purely verbal quantitative type, constructed without analysis of empirical data, can be constructed to be monothetic if the full typology is constructed. The 10-dimensional typology of 1024 cells is monothetic as long as all 1024 cells are retained and the typology is not reduced. The monothetic typology is mutually exclusive and exhaustive. If a sample of empirical specimens is coded for the 10 characteristics, each specimen can be identified with some cell in the typology, although there may be many null cells (if the ample size is less than 1024, and there may be no cell with more than one specimen).

The three types of reduction discussed previously have different ramifications for monotheticism. It is assumed that the full multidimensional typology is monothetic. Functional reduction can maintain monethicism by only retaining the cells for which empirical cases are identified. Functional reduction will also ensure that the types remain mutually exclusive. Further, the reduced typology can still be considered exhaustive for the given sample. However, if a new sample is chosen for the identification of empirical specimens, the researcher may find that some type needed to identify a specimen has been deleted in the course of functional reduction. In this case, the typology remains monothetic, but it is inadequate because it is no longer exhaustive and is of no use for identifying the specimen in question. The two other types of reduction, pragmatic and arbitrary numerical, reduce the number of types by converting monothetic types into polythetic types. This is done by putting specimens in a single cell that previously would have occupied separate cells in the full monothetic typology. These forms of reduction enable the typology to remain both mutually exclusive and exhaustive, while relinquishing its monotheticism.

Returning to Fig. 1, it is clear that the qualitative types of Row 1 are monothetic. Both the heuristic types of Cell 1 and the ethnographic types of Cell 2 retain their monotheticism, even though in most cases they do not represent a full typology. In some cases, a full typology may have been constructed and then reduced, but in most cases the typology was only partially constructed, with other types remaining latent having never been constructed. The reduction is equivalent to functional reduction, as null cells are simply not included in the typology. The cells that remain are not collapsed or compromised in any way, so their full monothetic status is maintained.

In Row 2 of Fig. 1, examples of Cell 3 are virtually nonexistent. If any did exist, they would probably be polythetic. Virtually all of the examples of Cell 4 (and there are many) are polythetic. It would be possible to construct a monothetic type through cluster analysis or numerical taxonomy, but this would be a rare even using a special data set. The polythetic clusters of Cell 4 (and of Cell 3 if any existed) are the equivalent of reduced typologies produced through pragmatic or arbitrary numerical reduction. That is, they represent a reduced number of types from a full typology, with the remaining types being polythetic, and being more heterogeneous than monothetic types would have been.

To summarize Fig. 1 by rows, qualitative types (Row 1, Cells 1 and 2) are generally monothetic, while quantitative types (Row 2, Cells 3 and 4) tend to be polythetic. To summarize Fig. 1 by columns, heuristic types (Column 1,

Cells 1 and 3) tend to be deductively derived, while empirical types (Column 2, Cells 2 and 4) are inductively derived. The qualitative and quantitative typological traditions appear to be worlds apart. The qualitative traditions originated largely in sociology. They tend to be verbal typologies that may or may not have clear empirical referents. They are generally deductively derived. Types tend to be monothetic. Full typologies can be reduced through pragmatic, functional, and arbitrary numerical reduction. Full typologies can be constructed from one or a few types through substruction.

Quantitative typologies are generally empirically derived through either agglomerative or divisive methods. They originated in fields such as biology and psychology and go by names such as numerical taxonomy and cluster analysis. The types formed empirically through qualitative analysis tend to be called clusters or taxa and are generally polythetic. The processes of substruction and reduction are generally not recognized in quantitative approaches to typology construction. However, the resulting set of polythetic types is similar to a typology reduced through arbitrary numerical reduction or pragmatic reduction (but not functional reduction, in which the types of the reduced typology remain monothetic).

The Three-Level Model

An adequate understanding of typology construction and use entails understanding the relationships between qualitative and quantitative typologies. In traditional measurement terminology, the heuristic verbal type can be labeled a "mental construct" or "latent variable." The measurement process entails demonstrating a relationship between this conceptual level (qualitative type) and the empirical level (quantitative type). The correlation between the theoretical and empirical levels has been called an epistemological correlation. For example, a verbal typologist might construct the type concept of "career criminal." The quantitative typologist might group a sample of criminals via cluster analysis and judge one cluster to represent career criminals. Thus, the traditional approach envisions only two levels, the conceptual or theoretical level and the concrete or empirical level, and the epistemic correlation which measures how well the empirical cluster represents the underlying theoretical construct (heuristic type).

In reality, there are three levels, not two. These are the conceptual or theoretical level, the empirical level, and the documentary or index level. One can envision the 10-dimensional typology of 1024 monothetic cells, with each of the 10 dimensions coded in binary fashion. Thus, full typology is mutually exclusive and exhaustive. It is also a relatively easy task to search for empirical examples of each monothetic type. One might find 5000 empirical specimens and determine that examples of all 1024 cells can be identified from these. This process of first constructing multidimensional monothetic conceptual types and then identifying empirical examples of each is clearly a form of measurement. The type concept (e.g., student athlete) is constructed, an empirical specimen is measured on all relevant dimensions, and the specimen identified as fitting that type.

The problem comes when one seeks to represent the typology and its empirical examples in a documentary dimension that renders the typology amenable to dissemination and interpretation. An example of this documentary or index level would be any medium, such as a printed page (the most common), a computer screen, or a computer disk. As noted earlier, the 10-dimensional type cannot be properly represented on the two-dimensional page. This causes major problems. A typologist can envision the 1024 cell multidimensional full typology, and envision the process of identifying empirical examples. This can all be envisioned without any representation on paper, film, computer, etc. But portraying this on a printed page so that the information can be stored, interpreted, analyzed, and transmitted to others is currently impossible.

However, a small full typology such as the fourfold typology of Fig. 1 can be represented on paper (as long as it remains in one or two dimensions), and so it can be used to illustrate the three levels. The classical method of typology construction and use pioneered by Weber involved three successive stages. The first stage was for the researcher to conceive a mental image of the ideal type (e.g., "All American Boy" in his or her mind). This is Level A, the conceptual or mental level. The second stage was to write the designation of the type on paper. This is Level B, the documentary or index level. The third stage was to look for an example of a living person who fit the type concept. This is Level C, the empirical level. Qualitative typologists start with Level A and next proceed to Level B, but they often do not get to Level C and do not find empirical examples of the type. Quantitative typologists generally proceed in reverse. They begin with Level C (the empirical level) and construct polythetic clusters of objects that are printed on paper (Level B). They often do not proceed to Level A (conceptual).

Without using the full three-level model, it is difficult to clearly understand the typological process. Unfortunately, the full three-level model is rarely recognized in the measurement literature. The tendency is to present only two "measurement" levels. These dichotomies have many names, such as the latent variable and the concrete variable, concept and index, concept and empirical level, and theoretical and concrete levels. All of these labels fail to recognize the three-level model. More tragically, they all represent some particular conflation of Levels A, B, and C into only two levels. This is generally done unwittingly, without recognition (or even knowledge) of the three levels.

Thus, one researcher may present a mental concept (Level A) and an empirical example (Level C) as a "two-level measurement model," while another researcher presents Levels B and C as purportedly the same model, or another researcher presents A and B erroneously as the same model. Until these are recognized as three distinct levels (instead of simply alternative presentations of the same two levels) in the measurement literature, understanding of the complex typological process will remain flawed.

Advantages and Disadvantages of Typologies

Advantages

Typologies have a number of distinct advantages for research and measurement, and in fact are a central feature of those endeavors.

1. Description. The typology is the premier descriptive tool. It is the cornerstone of any discipline, as it provides the core set of descriptive, multidimensional types or taxa.
2. Exhaustiveness. No other research technique provides the comprehensiveness of a full typology. The typology represents the definitive reference source for a discipline.
3. Multidimensional complexity. No other concept or presentation can match the complexity and conceptual range of a mutidimensional type. Unidimensional descriptions are simply no alternative for the mutidimensional type.
4. Clarity. A rigorous explication of a multidimensional type exhibits a degree of clarity and absence of ambiguity that is badly needed in research.
5. Comparison. From the single ideal type to the full typology, the typology is the premier tool for the rigorous multdimensional comparison and analysis of both conceptual and empirical types. The comparative procedure is very parsimonious, as it allows one to only identify the types for which empirical cases exist. Other potential types can remain latent and unused as long as they are not needed, but still are available if needed.
6. Differences. Typologies, especially full typologies and polar types, are useful for illustrating differences among two or more empirical cases.
7. Identification of empirical cases. Typologies are the ultimate tool for identifying empirical examples of particular type concepts.
8. Illustration of Possibilities. A full typology allows one to illustrate possible types, even if they cannot be found empirically.
9. Reduction of complexity. Type concepts such as the ideal and polar types, along with the reduction processes of arbitrary numerical reduction, pragmatic reduction, and functional reduction, are excellent means of reducing complexity to manageable levels.
10. Theoretical explanation. Devices such as heuristic types, including ideal, constructed, and polar types, as well as the process of substruction, are excellent tools for facilitating theoretical illustration and explication.

Disadvantages

1. Unmanageability. Typologies can on occasion be so unwieldy and large that they are difficult to utilize efficiently.
2. Difficulties in interpretation. Even typologies that are not overly complex, such as the ideal type, can sometimes be difficult to interpret. The ideal type became immersed in controversy regarding its proper usage and interpretation because some critics found it difficult to understand or to use effectively.
3. Little explanatory or predictive power. Typologies have often been faulted as being overly description, with limited explanatory or predictive value. Some critics are wont to eschew typologies in favor of techniques such as multiple regression that are considered to have more explanatory power.
4. Noncausal. A related criticism is that typologies say little if anything about cause, mainly presenting a set of correlated objects or attributes.
5. Outmoded. Heuristic typology construction, most notably in the form of the ideal type, is associated with 19th and early 20th century social science. As such, it is considered to be obsolete by many, particularly in the age of computerization. Modern methods of cluster analysis and numerical taxonomy certainly cannot be regarded as obsolete, but many social scientists are not familiar with them and do not understand their relation to classical typological methods.
6. Primitive. Despite their underlying complexity, some classical methods (such as the ideal type), may be viewed by some critics as primitive and simplistic.
7. Lack of integration. Critics that are unfamiliar with the three-level model may lack a framework to integrate qualitative and quantitative approaches to typology construction. Such critics may view the field of typology construction as a whole as eclectic and not properly integrated.

Typology Construction as Measurement

The transparently descriptive nature of the typological endeavor masks its essential nature as a measurement tool. There are at least five chief factors that hinder recognition of the typology as a measurement tool. One is the claim by heuristic typologists that classical types such as the ideal type often do not have empirical

referents. A second is the descriptive nature of the typology. A third is the apparent limitation of clusters and taxa to the empirical level. A fourth is the obfuscation of the three-level model through its frequent conflation into a dichotomy. A fifth is use of Q-typology (objects) rather than R-analysis (variables).

A complete typological cycle involves three stages, and it can begin with either Level A or Level C (but not with Level B). The classical qualitative approach begins with the genesis of a conceptual type (Level A). The second stage is the mapping of the full typology onto the document level (Level B). This can be accomplished, for example, by writing the full typology on paper (even if this must be done two dimensions at a time). The third stage is the identification of empirical cases (Level C) for each respective type. Modern quantitative methods such as cluster analysis and numerical taxonomy repeat the process in the opposite direction. They begin with empirical analysis (Level C). The second stage is to represent the cluster on paper (Level B). The third stage is to envision a mental concept of the cluster (Level A), often by mentally generating a name or label for the cluster (such as "career criminal"). Whether one begins with Level A (qualitative approach) or Level C (quantitative approach), the process unfortunately remains incomplete in actual analyses. Generally, Level B (the second stage) is reached, either from Level A or from Level C. However, verbal typologists who begin with Level A generally reach Level B and write their types on paper. However, they often do not reach Level C (they do not identify empirical cases for the types). Similarly, quantitative researchers who begin with Level C also reach Level B, but may not reach Level A (may not form mental images of, or names for, the empirical clusters or taxa).

No matter whether the researcher begins with Level A or Level C, when the whole process is complete, empirical types are connected with their conceptual-type counterparts, in a quintessential measurement operation. Critics often fail to recognize that this is measurement simply because they are accustomed to measurement conducted in terms of R-analysis rather than Q-analysis. For example, contemporary measurement procedures generally operated solely in terms of R-analysis. The researcher might conceive of a multivariate concept such as "alienation" and then construct a multiple-item alienation scale to measure this characteristic empirically.

Typologists would have essentially the same goals, but would approach the problem in a different (but parallel) manner. The classical typologist might conceive of the multidimensional heuristic type of "alienated intellectual," and then would next seek to identical empirical examples of the real-life alienated intellectual person. The "alienated intellectual" must be recognized as a Q-type, as the basic unit is the object (person) rather than the variable. Further, the traditional typologist might not attempt the quantitative measurement of all the variables making up the alienation concept. However, in order to identify empirical cases of the type, all of the variables must be measured in some manner. Similarly, the quantitative cluster analyst or numerical taxonomist, while making more precise quantitative measurements than the classical typologist, and proceeding from the other direction (by beginning with the empirical level rather than the conceptual level), is also engaged in a measurement process. Once the polythetic empirical type is constructed, one can then seek a label for it (for example, the "alienated intellectual"), thus completing the measurement process in reverse.

Units of Analysis

Victor C. de Munck
State University of New York at New Paltz, New Paltz, New York, USA

Glossary

attributionist fallacy Confusing a behavior for a trait or attribute of a person or group.
ecological fallacy The error of interpreting variations in environmental settings as variations among individuals.
individual differences fallacy The error of interpreting individual characteristics as group characteristics.
large-scale collectivity Groups that have fuzzy boundaries and that cannot be observed as wholes but whose members share a common social identity. These collectivities are imagined communities.
small-scale collectivity Clearly bounded and observable social units consisting of a minimum of 2 and seldom more than 1000 members.
supracommunal level Two or more levels of institutionalized authority are considered a supracommunal collectivity.
unit A person, element, or some discrete indivisible property that can be treated as an entity and can therefore be measured.

Scant attention has been paid in the social sciences to the problem of defining units of analysis. Instead, the methodological lens has been aimed at describing, measuring, and analyzing variables. This article describes the problems that occur when the researcher neglects to clearly define the units of analysis and how to avoid them. Units of and for analysis are always entities, whereas variables refer to the attributes, events, or processes that are part of or impact on entities. For any research question it is necessary to clearly define the unit as well as the variables of the study. Ignoring this distinction leads to either the ecological or the individual fallacy. Both of these problems and their resolution are addressed. This is followed by an examination of defining units for cross-cultural research. Cross-cultural research requires that the units of comparison are independent of one another; otherwise, similarities found may be a result of diffusion rather than of independent origin. It is demonstrated that this problem can only be resolved on a case-by-case rather than a systematic basis. A checklist for determining the appropriate units of analysis for any social research project is provided.

Introduction

This article provides a detailed discussion of the meaning, uses, and limitations of the concept "unit" in the social sciences. There is some disagreement about how to define unit and what kinds of things can and cannot be classified as units. The first two sections of this article provide a definition and typology of social units. The following sections consider the three most obdurate and enduring problems associated with the unit concept: (i) the ecological fallacy—that is, conflating or confusing situational constraints with personality; (ii) the particulate-systemic or attributionist fallacy—that is, confusing a behavior for a trait or attribute of a person or group; and (iii) the problem of determining the independence of units. This latter problem has been dealt with most comprehensively in cross-cultural studies in which it is known as "Galton's problem." The final section offers a checklist for researchers in helping them decide what cultural units to choose for their research and the limitations and advantages for analysis of these different kinds of units.

Defining Unit

A unit is a person, element, or some discrete indivisible property that can be treated as an entity and can therefore be measured. Variables are never units. A unit contains or

expresses the variable that is under study. A unit may be an individual or a collectivity. What distinguishes a unit from a variable is that a unit is a discrete thing in itself. Time and space, as in minutes or inches, are units of measurement and not of analysis.

A unit of analysis is always treated as if it were an entity. If one is interested in the height of sixth-grade boys and girls, then each individual boy and girl is a unit of analysis. In the statement "he is six-feet-five," "he" is the unit of analysis and "six-feet-five" is an attribute of that unit, whereas feet and inches are the units of measurement. The individual is a discrete and indivisible thing that has the property of being "six-feet-five." Discussing a property as if it is an entity is called the attributionist fallacy, which is discussed later. In short, a unit is always an entity from which measurements are taken.

In a typical social science two-mode data matrix, rows identify cases and columns identify variables. In two-mode matrices, cases are usually equivalent to units and the column labels identify the variables in the study. A cell is the intersect of a unit and a variable. The value in any cell is a measure of the amount of that variable associated with that unit (Fig. 1). Social scientists usually analyze the cell value as a variable rather than as a social or cultural unit value.

Researchers use a two-mode matrix to test hypotheses about the relations between variables. The unit itself is seldom considered in the analysis because "variable" and "unit" are typically perceived to be in a figure–ground relationship with the units as the ground and the variables as the figure(s). The analytic lens is aimed at the variables rather than the units (i.e., the individuals). The units are figuratively drawn and quartered with only their salient parts incorporated into the analysis. For example, one can compare suicide rates across time, space (e.g., a rural–urban dimension), cultures, or religions without ever considering the units (i.e., the people committing suicide) as individuals. The individuals who ultimately comprise the units of analysis are extricated from the study except as they provide anecdotal material.

An example of a research strategy that retains the individuals as units of analysis and measurement is the 1995 study, "Environmental Values in American Culture" by Kempton *et al*. The researchers compared the environmental values of a sample of sawmill workers, dry cleaning managers, the general public, Sierra Club members, and members of Earth First! The study focused on the response profiles of all the individuals and compared these profiles both within and between groups. The researchers found surprisingly high agreement among the members of these groups. In this study, the individual was the unit of analysis and the unit of measurement, and the statistics and charts depicted the relationship between individuals rather than between variables. This study relied on consensus analysis (a relatively new method introduced in 1986 by Romney *et al*.) to measure the aggregate level of agreement across all variables for each individual, thus figuring the unit of analysis and grounding the individual variables. However, such studies are rare and most foreground the variables rather than the units. The following discussion of the different kinds of units considers the former rather than the latter situation. A problem with using the individual *in toto*, as both analysis and the unit of measurement, is that the profile variables may range from nominal to ratio and vary considerably in how they are operationalized and whether they are independent of one another. For example, measures of social class often aggregate different types of variables, such as income, religion, prestige, and education, as if they can all be measured by the same scale. This crude amalgamation of different types of variables to construct and then profile social classes both mystifies class and "washes out the actual grid of causal processes that distribute people across several dimensions of the social landscape" (Collins, 1990, p. 48). On the other hand, such mixing can lead to greater generalizability if it takes into account the limitations and difficulties of making summarizing inferences from an array of disparate variables.

Kinds of Units

The canonical taxonomy for types of variables was first presented by Stevens in 1946. Stevens described nominal, ordinal, interval, and ratio variables. Although there is debate over the utility and appropriateness of this classification scheme, it is found in all introductory statistics texts and most texts on research methods. A typology for units of analysis, although heretofore lacking, is presented in Fig. 2. This typology is, of course, open, and more types of units can be added onto it. Its purpose is to provide an initial taxonomy that is subject to further development. A discussion of the typology follows.

The individual is the most common unit of analysis. Studies on personality traits, agent-based analysis, decision making, and life histories are examples of individuals as the units of analysis. When data on individuals are aggregated and the analysis is based on the aggregate

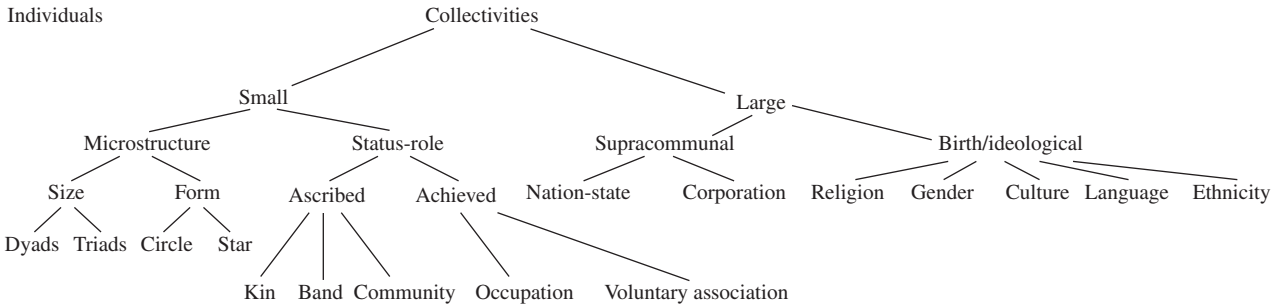

Figure 2 Units of analysis.

profiles, the collective is the unit of analysis. At a minimum, a collective consists of two or more individuals who recognize their common identity. The term *collectivity* is favored over *group* because the criterion "interaction" is often a defining feature of "groupness." Individuals can recognize their common identity on the basis of religion, gender, ethnicity, common language, culture, or nationality without interacting. Durkheim, Toenneis, Weber, and Benedict are among the many social theorists who have thought to distinguish the social structural and psychological differences between small and large collectivities. Relations in small collectivities are multiplex (i.e., many connections) and "face-to-face" with interactions characterized by intimacy or *gemeinschaft* (i.e., informality). Bonds in large collectivities are usually singleplex, relationships are imagined rather than actual, and interactions when they occur are characterized by formality or *gesellschaft*.

Small collectivities are often defined in terms of their structural components or their social function. Structural analyses of small groups use either the size of the group as the unit of analysis or the form of the group. Both Heider and Simmel were interested in the inherent sociological properties of dyads; both Simmel and Granovetter were interested in triadic relations. The study of dyads and triads is a vital cottage industry in the subdisciplines of social networks (in sociology) and personal relationships (in psychology). In these studies, it is the number of individuals that comprise a group that is the unit of analysis. For example, Simmel noted that one property of the dyad is that it is the only social group in which the individual has the option of terminating the group. Granovetter points out that a property of triadic relationships is that their stability rests on the mutual affinity of each member for the other. Group size, not its shape or its members, comprises the unit for analysis. Collectivities such as dyads and triads are studied as if they were single entities with the relationship of properties to collectivity analogous to that of traits and the physiological properties that pertain to an individual.

In 1950, Alex Bavelas initiated a series of experimental studies on the shape of small groups. He and his colleagues wanted to investigate the communicative efficiency of different social forms. By efficiency, he meant a combination of accuracy and speed in solving problems. Bavelas and associates discovered that "star-shaped" structures were the most efficient at solving problems in a laboratory setting, whereas "circle-shaped" structures were the least efficient. In a posttest survey, he discovered that those subjects who were placed in the circle structures were much happier participating in the experiment than those who were placed in the star structures (with the exception of the individual at the center of the star). The reason for these responses is based on emergent behavioral and emotional properties of the respective groups. The center person in a star-shaped structure received all the information from the people at the end of each "ray" or spoke. The subjects at the end of each ray were not in communication with each other and were completely dependent on the central person to make a decision for the group. Each would pass their bit of information to the central person, who then had complete information to solve the problem that was posed to the group. In circle-shaped structures, the information is distributed equally and the group seeks to make its decision via consensus, which is time-consuming, may be faulty, but necessitates the input of each participant in the decision-making process. The Bavelas research project was very successful in isolating group-level characteristics and analyzing their effects on communication. One can imagine many other types of social forms, as indeed Bavelas and many others have done, but most other forms of small groups lie somewhere between star and circle structures. In the growing field of network analysis (largely spurred by Bavelas's findings), much research has been conducted on cliques (where each member of a group is connected to everyone else), the directionality and the strength or valence of ties, and informal as well as formal networks. In these studies, the unit of analysis is not the individual or group but the pattern of relations.

Another division under "small collectivities" refers to those groups that are organized by status–role relations. Statuses are distributed through a bounded group creating a rich network of reciprocal privileges and obligations.

Roles are understood to be the rules for the appropriate engagement of a status. Thus, a status set is a system of reciprocal rights and duties. Ascribed statuses are acquired by birth or are assigned by convention. Two examples of an ascribed status acquired by convention are age–grades and kin statuses. Achieved statuses are those that are acquired by choice and through a social decree. In contrast to a social convention, a social decree refers to a claim for a status that is then legitimated by a referent group. A few statuses, such as adopted kin status, may be considered both achieved and ascribed, but the majority clearly belong to one or the other category. Research that relies on status–role as the unit of analysis typically examines (i) the qualifications of the position, (ii) the distribution of rights and duties of the position, (iii) the activities spawned by those rights and duties, and (iv) the settings associated with the status–roles.

Large collectivities are divided into supracommunal and birth/ideological types. Any collectivity that contains two or more levels of institutionalized authority is considered a supracommunal collectivity. For example, in a chiefdom there are local chiefs who have authority over the commoners in their locale and paramount chiefs who have authority over the local chiefs. A nation-state has, at a minimum, three supracommunal levels: national, regional, and local seats of authority. The nation-state is the unit of analysis in world systems theory, in which the transnational flow and exchange of natural resources, as well as humans, between core and peripheral nation-states is the subject of study. Supracommunal levels were used as the units of analysis by Elmond Service in 1962, who placed cultures into a cultural evolutionary scheme based on sociopolitical levels of integration. Bands and tribes were the simplest societies, with no or one supracommunal level; chiefdoms had two supracommunal levels; and states consisted of a minimum of three such levels. Corporations also have hierarchically nested seats of authority. Corporations are units of analysis in studies on corporate organization, the production and flow of goods and capital, and in analyses of the stock market.

Collective identities predicated on birth and/or ideology include culture, sex, language, and ethnicity. Sex is a unit of analysis in evolutionary psychology, in which it is assumed that sexual differences promote different mating strategies and work activities. Expendability theory, for example, suggests that in foraging societies the reproductive value of women was far greater than that of men and thus women were protected and kept near camps while men took on the high-risk activities such as big-game hunting. Sex is a unit of analysis when social differences are seen to be a result of inherent psychobiological differences between males and females. When these differences are evaluated in terms of gender, culture becomes the unit of analysis. Cross-cultural studies have shown that patriarchy is greater in Islamic countries and communities than in Hindu or Christian countries or communities. In this kind of study, religion is the unit of analysis, culture is held constant, and the properties of the religion are the variables. Religion and gender are cultural constructs and cannot be units of analysis in ethnographic studies. That is, culture is always the unit of analysis when the subject of study is a subsystem of a culture. Religion, gender, ethnicity, and other macrocollectivities are units of analysis only when they are being studied cross-culturally. In these instances, these units are treated as megacultures.

Ruth Benedict's *Patterns of Culture*, first published in 1934, laid the groundwork for the study of national cultures and the theoretical predilection of researchers to reify culture. She explicitly argued that cultures were not merely a collection of traits but were "like individuals," forming a more or less integrated pattern of emotions, thoughts, and actions. In reifying culture, Benedict promoted the use of culture and other social constructs as units rather than objects of analysis. Bellah *et al*. repopularized the notion of culture as an entity in their 1986 book, *Habits of the Heart*, and its 1992 successor, *The Good Society*.

The typology of social units of analysis presented previously will undoubtedly be modified over time. However its two primary nodes—the individual and the collectivity—must be the core divisions of the typology. Although it is true that collectivities are composed of individuals, it is not true that the properties of collectivities are identical with those of individuals. The following sections take particular issue with problems that result from confounding collectivities with individuals and individuals with collectivities.

The Ecological Fallacy

In 1950, Robinson coined the term ecological fallacy to refer to the error of interpreting variations in environmental settings as variations among individuals. One tactic for solving Robinson's ecological fallacy is to construct surveys in which questions clearly state whether they are asking personal opinions of the subject or general assessments of an environment setting. A Likert scale example of an ecological (i.e., environmental) question is to ask respondents to agree or disagree with the comment, "Sometimes class is very disorganized." A comparable example in which the individual is the unit of analysis is to ask respondents to agree or disagree with the comment, "Sometimes I am not prepared when I come to class." The ecological question provides a generalized assessment of the environment without targeting the source of disorganization. In the ecological example, it is unclear as to what unit of analysis the

subjects are responding to—the setting, the teacher, the other students, themselves, or all of these.

Richards and colleagues compared the use of individualist and ecological units to analyze classroom environments. They used the Classroom Environment Scales developed by Moos and Trickett, which consist of true–false questions about the classroom environment. Richards *et al*. (1991) noted that the questions were "modeled on and resemble the type of questions used in objective personality tests" (p. 425). Consequently, measures of dispersion (such as standard deviation) were much higher among individuals in settings than across settings and reliability measures (alpha) were also higher across than within settings. Richards *et al*. also suggested that assessments of setting measures were mediated by personality differences between the individuals and that this confounded the results within any one setting. Thus, survey questions should be crafted so that they distinguish and elicit assessments of the environmental setting rather than serve as "disguised measures of individual differences."

Richards and colleagues use the terms ecology and settings interchangeably. However, it should be remembered that, strictly speaking, the setting is not the unit of analysis but the group that inhabits the setting. The actual classroom does not fill out a questionnaire, students do. The Richards *et al*. study is important because it unequivocally confirms that by themselves, and without a theoretical justification, individuals as the unit of analysis are invalid and unreliable units by which to measure setting-level characteristics. It should be noted that by "setting," Richards *et al*. are referring to the small-scale groups that inhabit the setting and thus setting is a group-level unit. If the goal of the study is to understand the characteristics and dynamics of settings (in this case, the classroom), then the proper sample for the study is settings and not individuals, and the goal of the researcher is to examine variation between settings and not between individuals.

In 1997, Gary King proposed a statistical solution to the ecological inference problem. Leo Goodman had previously proposed an ecological regression model to estimate individual differences from census data. King added to Goodman's model by using random coefficients to further minimize the aggregation bias. His solution has met with partial success in finding estimators of subpopulations within a larger population. However, although statistical sampling is a powerful tool, statistics is not good at low-level inferences—that is, reducing the whole to its components, a kind of reverse statistics.

The ecological fallacy is the error of attributing the characteristics of a population to an individual. Statistical inference is intended to generalize from a sample population to the whole population. The goal of statistics is to generalize from the particular to the whole and not from the whole to the particular. As such, statistics cannot offer a solution to the ecological fallacy. Data on individuals or on subpopulations within a larger population can best be obtained by ensuring that the unit of analysis is the individual or the subpopulation and not the larger population. As Richards and colleagues note, this problem can be avoided by designing survey instruments that elicit individual characteristics and attitudes. It is only from individualistic data that the researcher can track individual and subpopulation characteristics when necessary.

In a study in which local and individual hospitalization rates were derived from community-level estimates of various indicators of socioeconomic status (SES), Hofer noted that SES community profiles may not be representative of those individuals in the community who are actually going to the hospital. For example, it is known that the proportion of elderly who have medical coverage is far greater than it is for young adults, and that some of these elderly patients will use the hospital many times. To obtain accurate estimates of the subpopulations using and not using the hospital, it is necessary to obtain data on samples of individuals, not social aggregates. The best aggregate estimator of subpopulation or individual differences is to either ensure that the individual characteristics to be analyzed are representative of the aggregate or to use complete analytical models that target only that set of SES data pertinent to a target population. In their study on hospitalization rates, Billings *et al*. found it necessary to include age and income interactions in assessing SES variables in small area studies.

Although ecological (groups) units comprise individuals, their characteristics are not equivalent to those of the individuals in the group; therefore, one has to apply a different theory to studies that use collectivities as units of analysis than to studies that use the individual as the unit of analysis. When collectivities are the units of analysis, the proper subject of inquiry should be the overall characteristics and emergent properties of populations. Group-level characteristics may be very different from those of the individual members of the group. Ethnographic and psychological studies are frequently guilty of the opposite of the ecological fallacy: the fallacy of mapping individual characteristics onto a group. This problem, called the "individual differences fallacy" by Richards in 1990, is discussed next.

The Individual Differences Fallacy

The individual differences fallacy occurs when the individual is used as the unit of analysis in order to investigate and describe the characteristics and behaviors of a collectivity. This error will be examined by discussing

the individual differences fallacy in studies of small- and large-scale collectivities. The appropriate stratagems for resolving this fallacy are substantively different for small- and large-scale collectivities. Small-scale collectivities are usually discrete molecular units; large-scale collectivities have indeterminate or "fuzzy" boundaries and are always "imagined" rather than actual. For small-scale collectivities, it is often possible to observe, survey, and collect qualitative and quantitative data from all the members of the collectivity; this is never possible for large-scale collectivities. Hence, the individual differences fallacy is of greater magnitude when dealing with large-scale collectivities, such as gender or culture, than with small-scale collectivities, such as classrooms and juries.

One example of this problem can be illustrated by a study of jury behavior by Kerwin and Shaffer. Verdicts are group-level decisions, so studies of juries should be based on a theory of group-level characteristics and dynamics and use the group as the unit of analysis. Kerwin and Shaffer committed the individual differences fallacy by assuming that central tendency measures of jury member characteristics as elicited through survey instruments mirrored the characteristics of the jury as a whole. They committed what Galtung (1967) called the "fallacy of the wrong level" (p. 45), taking for granted that there is a direct correspondence between aggregated individual and group characteristics.

In their study of a mock trial, juries were categorized as "dogmatic" or "nondogmatic" on the basis of their mean dogmatism score obtained through a survey. Statistically, a jury could fall into the nondogmatic column if five people graded average on the dogma index and one graded unusually low on this index. Kerwin and Shaffer assume that individual levels of dogmatism cause the jury, as an entity, to be dogmatic or nondogmatic.

The authors of the study also used analysis of variance inappropriately because it can only be used to analyze nominal-level data under specific conditions that were not met. In studies of small groups, researchers should rely on groups as the unit of analysis unless they are interested in the effect of the group on individual behaviors. When using groups as the unit of analysis, the researcher should consider whether group characteristics are independent of, derived from, or adequately represented by aggregate statistics of the individual members of the group. There are three stratagems a researcher can employ to develop a theory of group-level behaviors: (i) The group's behaviors and characteristics are completely independent of the individuals who comprise the group, (ii) group characteristics and behaviors reflect the overall statistical properties of those individuals, and (iii) the behaviors and characteristics of the individuals are by-products of the behaviors and characteristics of the group. It is probable that each of these approaches is valid for different types of groups. It is recommended that for small-scale studies concerned with group characteristics, the researcher should pretest each of these three stratagems to determine which best suits his or her needs.

The individual differences fallacy is magnified when the unit of analysis is a large collectivity such as culture. Culture is the central organizing concept for the major subfields of anthropology: sociocultural, linguistic, physical, and archeology. The core defining attributes of culture are that it is shared, learned, and holistic. No other social/behavioral science discipline has made holism such a central tenet of study as has anthropology. Psychologists may study memory, personality, perception, and so forth, but few are likely to claim that they are studying or describing the entire human psyche in the same way that an ethnographer presumes he or she is giving a description of a whole culture, more or less, even if this claim is unstated.

Unlike the individual or a jury, culture is, at best, a slippery unit of analysis because it lacks what Campbell in 1958 referred to as "entitativety"—a collection of material and/or mental things that "interact strongly, have a common fate, and resist dispersion." Although anthropologists customarily treat culture as a holistic unit, culture seems to be composed of a more or less random collection of things, some of which are only loosely connected. For example, things such as mousetraps, computers, and fast-food restaurants seem to have little in common with each other, much less with the various values, beliefs, and behavioral repertoires that also constitute culture.

Culture is not a unit of analysis like a jury is a unit of analysis. It is also a more ambiguous unit of analysis than religion, ethnicity, or gender—units that are possible to identify and define. Culture is a heterogeneous, not homogeneous, unit, and not only is it composed of different kinds of things but also it is understood at different levels of abstraction. At the macrolevel, it may be understood as a seamless weaving together of values, beliefs, and behaviors, much as Ruth Benedict in her typology of cultural patterns as personality writ large. At the mesolevel, culture may be construed as a set of interdependent but distinct functional systems. This is the most common understanding of culture and is reflected in ethnographies in which the material is divided into religious, kinship, political, economic, and other areas. At the microlevel, cultures are often depicted as token events, social interactions, and actors.

These different levels of abstraction are seldom, if ever, underpinned by, or justified in terms of, a theory of units. Anthropologists move with intellectual innocence from one unit of analysis and level of explanation to another. Given that culture is shared, the anthropologist is partially justified in presenting ritual, customary events, and profiles of individuals as token types, representative of the culture as a whole. Partial assurance of the validity

and reliability of ethnographic representations of a culture, in the absence of any attempt to address the cultural units dilemmas that inevitably arise, comes from the length of the ethnographer's stay in the field and a comparison with other ethnographies written about the same cultural area. Nonetheless, Barrett is correct in using the label "no name anthropology" to describe most of the work done in anthropology.

Cultural theorists have dealt with the problem of cultural units by considering symbols or cognitive structures to be the basic units of people. Clifford Geertz has been most influential in developing the notion of symbols as the units of culture. Humans are symbol-generating animals and culture consists of symbolic interactions and interpretations. Cultural symbols are public in that members of a culture know them and know that all other members of the culture also know and use these symbols in semantically appropriate ways. Geertz is the founding father of the interpretivist school of cultural theory, and he has influenced constructionist, poststructural, subaltern and hermeneutic theorists. What these schools have in common is the notion that culture is a text consisting of symbols that are publicly accessible and knowable, but these symbols are open to multiple interpretations depending on the position of the "reader."

The Geertzian position solves the individual fallacy problem since it does not view culture in terms of animate entities but in terms of symbolic entities, or "vehicles" as Geertz called them. However, this problem has been replaced by Whitehead's "fallacy of misplaced concreteness," whereby mental phenomena such as symbols are treated as if they were entities. This may work if we assume that these entities are in the minds of individuals and exist as a neural network, but interpretivists as constructionists are emphatic that symbols are not to be studied in the mind but in public arenas. It is also not true that the symbol can be the unit of analysis because symbols differ in meaning and levels of abstraction, all symbols are different, and we cannot study the categorical label "symbol" because, like all labels, it designates a category of things and does not, in itself, possess the property of "thingness." The Geertzian position ultimately exacerbates the fallacy problem because it is impossible to identify a unit of analysis from this theoretical perspective.

Metaphorically perceiving culture as text leads logically to the idea of culture being constituted of loosely or independent modules or systems of knowledge. This idea, that there are no grand cultures but only cultural modules, pares down the possibility of creating a cultural unit that is of manageable size. In 1956, Goodenough defined culture as knowing how to behave in a normative or appropriate manner in any given situation. This proposal is central to the ethnoscience and ethnomethodological schools of cultural theory. From this perspective, the researcher took a particular task, behavior, concept, or setting in a culture and found out what one needed to know in order to understand the concept or act in a setting in the same way as a native. Culture here is viewed as a series of recipe-like books that describe the lawlike regularities that govern behavior and knowledge in a particular setting. The position is similar to that of the interpretivists except that the symbol systems are located in the mind of the individuals, and the set of symbols to study are specific to a particular cultural target. The unit of analysis is not the mind or cognitive processes, as some ethnoscientists insist, but the individual from whom information about cultural models or schemas is elicited.

This theoretical position resolves the ecological–individual differences fallacy by using individuals as the unit of analysis and by investigating regularities in their thoughts, emotions, and behavioral repertoires. The study of culture is invested in the study of individuals to discover normative knowledge and behavioral clusters that are specific to a particular sociocultural domain, such as illness, attending funerals, and ideas of success. The limitation of this approach is that there is no theory of collective behaviors and characteristics except as these are normatively construed by individuals. Such a theory cannot provide an understanding of the characteristics of social units as social units because collective units are not the units of analysis.

The Independence of Units

In order to conduct statistical analysis, the units of analysis must be independent of one another. Random sampling and care that survey questions are not mere replicas of one another are the primary means to ensure independence between units and variables. However, culture is shared, and the members of a culture share common cultural experiences. Statistical analysis can be employed only when we distinguish between individuals or groups within a culture. Thus, we can compare across gender, ethnicity, age groups, regions, and the like, assuming that these differences are significant enough to ensure the independence of units. In cross-cultural studies, we can assume that cultures are independent units. However, what if they are not? What if many of the cultures in a sample have had extensive historical contact with one another and some have not? The cultures that have had extensive contact may unduly bias our results so that we are guilty of a type I error; that is, any statistical test will show that our results are significant when in fact they are not. In cross-cultural research this is known as "Galton's problem."

In 1889, Francis Galton attended Sir Edward Tylor's presentation of what appears to be the very first cross-cultural study relying on statistical methods. Galton questioned the results by suggesting that many of Tylor's

cases were replicas of one another because many of the cultures included in the sample had had extended historical contact with one another. Galton suggested that Tylor's conclusions were suspect because his sample was biased.

Since then, there have been many attempts, none completely successful, to solve Galton's problem. The failure to solve this problem is due to two separate issues. First, theoretically, anthropologists have assumed that cultures are holistic linguistic communities in which members share common traits, values, technologies, and complementary (if not similar) behavioral repertoires. Second, methodologically, anthropologists have assumed that Galton's problem is a statistical, not theoretical, problem; hence, solutions have focused on devising a proper sampling technique. However, it has been shown that there are no ultimate primitive units of culture and that the units researchers use depend on the questions asked. A common cross-cultural sampling criterion is to select only those cultures for study in which the natives speak different languages. It is argued here that if cultures diverge on language, then they are independent cultural units subject to statistical analyses. Unfortunately, the language criterion for independence does not always hold. For example, if the researcher hypothesizes that male circumcision is related to cultural prohibitions against drinking alcohol and has a sample containing predominantly Islamic cultures whose members speak different languages, the results will still be biased by these cultures sharing a common Islamic heritage. Since Christianity and Islam are global religions, it does not matter if a sample consists of cultures that are from disparate regions and where the indigenous people speak different languages: their common religious background is enough to bias the sample.

In an actual cross-cultural study, Andrey Korotayev and I hypothesized that the number of supracommunal levels (i.e., levels of political integration) is directly correlated with the presence of a class structure. The correlations for this hypothesis were found to be significant with a sample of only Islamic societies ($\text{Rho} = 0.55$, $p = 0.01$) and with a worldwide sample ($\text{Rho} = 0.62$, $p < 0.001$). In this case, it simply does not matter whether a large and diverse worldwide sample or a sample of just Islamic societies is used; any number of cultures from the Islamic world can be included in the worldwide sample without distorting the final results.

We decided to perform the same test using only ethnicity (rather than language or religion) as the criteria for delineating cultural units. In addition, we chose a sample of only equatorial Bantu cultural groups, selecting a sample of cultures that were, according to all sampling criteria, dependent units. The correlation between the two variables selected in this closely knit cultural region is even higher and more statistically significant than the one for the worldwide sample ($\text{Rho} = 0.72$, $p < 0.00000000000000001$). This cannot be explained by a Galton effect. The hypothesized correlation between political integration and class structure—the greater the political integration, the more stratification we find in that society—holds for all our three samples, with the range of variation more pronounced in the ethnically similar sample than in the worldwide sample. In this case, the Galton effect was utterly irrelevant to the analysis. The concern voiced first by Galton and later by George Murdock and Douglas White with regard to selecting independent cultures for comparative research appears not to be relevant for some cross-cultural comparisons.

These results demonstrate that it is impossible to know a priori what criteria to use for selecting units for cross-cultural analysis. The criteria will vary on a case-by-case (or rather hypothesis-by-hypothesis) basis. If culture is seen as modular, rather than holistic, and if those modules consist of a knowledge–emotional–behavioral repertoire cluster, then one has to determine what criteria are responsible for organizing the cluster. In certain circumstances, cultural clusters are not necessarily geographically contiguous or even proximate but can be organized on the basis of global transcultural and transcontinental systems such as Christianity or Islam. In other circumstances, linguistic and cultural area boundaries serve as useful criteria for identifying cultural units. At still other times, it is unnecessary to be concerned about linguistic or cultural areas because differences are predominantly affected by environmental or other extracultural factors.

Checklist for Determining Units of Analysis

Units of analysis are always entities. The least problematic entity is the individual. The individual is the primary unit of analysis for studies in which the focus is on individual agency or the characteristics and behaviors of individuals. The limitations of using the individual as the unit of analysis are that group characteristics and behaviors can only be measured indirectly and studies are prone to the individual differences fallacy in which groups are attributed to possess the characteristics of either token-type individuals or those characteristics derived from central tendency measures of a sample population. In order to describe and analyze group-level characteristics from the individual as the unit of analysis, the researcher must posit an *a priori* theoretical justification for making such a leap. Collectivities can be the units of analysis. For small-scale groups the use of such units is relatively unproblematic and has great advantages if one is going to analyze group or ecological characteristics and dynamics. However, one cannot reduce group-level units to

particular individuals. Statistical methods were devised to work from the part to the whole rather than from the whole to the part. Thus, inferences from the individual to the group can be plausible and inferentially appropriate if theoretically specified, but inferences from the group to the individual are seldom, if ever, plausible or appropriate. Symbols and concepts should be avoided as units of analysis because they lack entativity. Large-scale collectivities, such as gender, religion, and culture, lack generalized entativety but may have specific entativety; this is to be discovered on a case by case or, as mentioned previously, hypothesis-by-hypothesis basis. A unit of analysis must be clearly defined. It cannot be used as a variable; rather, variables are extracted from the unit of analysis. Most important, there should always be a theory of analysis that justifies the choice of the units for analysis.

Unobtrusive Methods

Raymond M. Lee
Royal Holloway University of London, Egham, Surrey, United Kingdom

Glossary

accretion measure A type of unobtrusive measure based on the deposit of material in some setting.
artifact A feature of a research design that affects the validity the results produced.
episodic records Archival records, the discontinuous form of which does not allow trends to be identified.
erosion measure A type of unobtrusive measure produced by wear on some material.
reactivity The potential for research participants to change their behavior due to the presence of an investigator.
running records Type of unobtrusive measure involving ongoing, continuous documentary sources.
simple observation A method of observation in which the observer acts in a largely passive and nonintrusive way.
traces A type of unobtrusive measure in which physical remnants are used to provide information about social behavior.
unobtrusive measure A measurement collected without directly eliciting information from a respondent or informant.

Unobtrusive measures are measurements of social phenomenon that derive from methods of data collection *not* involving the direct elicitation of information from research participants.

Introduction

In 1966, Eugene J. Webb, Donald T. Campbell, Richard D. Schwarz, and Lee Sechrest published a witty and somewhat irreverent book entitled *Unobtrusive Measures*, which made a case for using sources of data that did not rely on direct interactional involvement between researcher and research participant at the point of data collection. The strength of unobtrusive measures was argued by Webb *et al*. to lie in their nonreactivity; that is, they avoided sources of invalidity produced when researchers directly elicit information from respondents or informants. (Unobtrusive measures are sometimes also referred to as nonreactive measures, a term which served as the title of the revised version of Webb *et al*.'s book published in 1981.)

Webb *et al*. argued that data collection instruments of many kinds suffer from methodological weaknesses associated with reactivity. Thus, respondents in interview- and questionnaire-based studies often try to manage impressions of themselves in order to create a positive image in the eyes of an interviewer. There are well-documented tendencies, for example, for respondents to overreport socially desirable behaviors and underreport socially undesirable behaviors, to claim to have opinions about fictitious topics, or to choose responses to questionnaire items based on their perceptions of the social characteristics of an interviewer.

Respondents, moreover, must be accessible and cooperative if survey-based methods are to be effective. Yet, there appears to be evidence from a number of countries suggesting a decline in levels of survey response. Concern about the artifactual character of data might also extend to experimental methods if research subjects act in ways they presume will ensure a successful outcome, or if those willing to participate in experiments differ markedly in their social and attitudinal characteristics from those who do not.

Taking concepts, metaphors, and examples from disciplines as diverse as geology, archaeology, and historiography, Webb *et al*.'s writing on unobtrusive measures is strongly informed by "multiple operationism." The assumption here is that research findings are potentially subject to the hypothesis that they are artifacts of the method used to collect the data. Sources of

invalidity, however, are not the same across methods. In particular, the problems of reactivity that afflict direct elicitation methods are absent when data are collected unobtrusively. One implication of this is that unobtrusive methods are not simply alternatives to direct elicitation methods, but complementary to them. For any given theory, testing is only possible at those points, "outcroppings" as Webb *et al*. describe them, where theoretical predictions and available instrumentation meet. The outcome of any one test is necessarily equivocal. The more remote or independent such checks, however, the more confirmatory their agreement. There is clearly here a justification for the use of multiple sources of data; configuring different methods, each of which is fallible in a different way, gives greater purchase on the problem to hand than a reliance on a single method.

Sources of Unobtrusive Measures

Webb *et al*. propose three types of data as sources of unobtrusive measures: physical traces (the evidence that people in traversing their physical environment leave behind them), nonparticipant observation, and documentary sources. It seems that this classification was developed primarily for expository purposes rather than being intended to convey conceptual clarity. Some alternative typologies have been proposed. Emmison and Smith emphasizing the visual character of unobtrusive data distinguish between: (a) two-dimensional visual sources such as images, signs, and representations, (b) three-dimensional sources, like settings, objects, and traces, and (c) lived and living forms of visual data, i.e., the built environment, human bodies, and interactional forms. Lee has proposed that Webb *et al*.'s passive typology of data sources be recast into a more active typology of data acquisition methods to allow a greater understanding of how particular measures come to be generated. In this schema, traces become "found data," observation methods yield "captured data," and documents can be thought of as forms of "retrieved data." Whatever their provenance, Webb *et al*. place a heavy premium on measures which are novel, playful, creative, or serendipitous.

Traces

Traces are physical remnants produced by erosion of the environment or accretion to it. A classic example of an erosion measure is the wear on floor tiles as an index of the traffic passing over them. Webb *et al*. give the instance of an exhibit showing live, hatching chicks at the Chicago Museum of Science and Industry. So popular was the exhibit that the vinyl floor tiles around it needed to be replaced approximately every six weeks. Floor tiles in other areas of the museum lasted for years without needing to be replaced. Another such example is the use of smudges, finger marks, turned-down pages and the like in library books as an index of their popularity. Graffiti provide an example of an accretion measure. The materials and techniques used to make graffiti, the various forms graffiti take, and the content of messages are all suitable topics of study. Garbage collected either at the curbside or excavated from landfills is also a fruitful source of unobtrusive data. For example, the number of condom wrappers found in garbage might be taken as a measure of the effectiveness of public health messages about protection against HIV infection. Comparing garbage counts with self-report provides one way of validating survey findings. Alcohol consumption, it seems, is often underreported on surveys when compared with the numbers of discarded drinks containers found in garbage.

Traces are ubiquitous, available at low cost and easily quantifiable. There are few ethical problems associated with their use. Gathering trace data causes little or no inconvenience to research participants who are anonymous (indeed in many cases their identity is completely unknown). Traces are often cumulative, permitting the collection of longitudinal data. In contrast, traces usually produce conservative estimates of behavior; some activities leave no traces or obliterate those that already exist. Trace data can take time to accumulate. It is often difficult to obtain the necessary population data that would allow a rate for some measure to be calculated. In addition, detecting the presence of response sets and patterns of selectivity in data based on trace measures can be rather difficult. For example, what finds its way into garbage is affected by recycling practices. A measure like differential floor wear, for example, depends on the physical properties of the floor covering itself; carpet wears out more quickly than tile, while materials are eroded or deposited in ways that are not necessarily independent of other erosions or deposits.

Observation

What people do and say during the daily passage of their lives, how they move through time and space, and the social patterns associated with posture, position, demeanor, and display, are all amenable to simple observation. Emblematic objects such as tattoos, body piercings, and clothing styles lend themselves to observation, as do interactional gestures and the social organization and use of physical space. Simple observation, put rather baldly, is field observation. It differs from observation in experimental contexts in that the observer has relatively little control over the setting, and differs from the postcoding of film or video records because observation and recording occur contemporaneously with the behavior being studied. In its systematicity it can also be

distinguished from participant observation methods used in sociology and anthropology. Social processes involving very large or very small spans of time or space might need to be manipulated through, for example, the use of high speed filming or time-lapse photography if our sensory apparatus is to be fully able to apprehend them. Recognizable "observational genres" have grown up with researchers designing observation studies around activities such as driving behavior, help-seeking, the return of lost objects, and the provision of goods and services.

Observational methods are often used where interview methods are inappropriate, such as in studies where research subjects, young children for example, have limited verbal ability, where potential informants lack a social vocabulary for answering questions about some kinds of behavior, or where participants are deeply engrossed in activities that would be disrupted by the intrusion of an interviewer. Observation is appropriate in some cases because analytic interest is focused, not on individuals, but on the relationships or interactions between them. Settings such as bars or factories where ambient noise levels are high do not always lend themselves to interviewing but might be suitable for observational study. Observation might be the only way to capture activities that are fleeting, or where respondents are likely to react to questioning in a strongly defensive way. Weick suggests that many everyday activities can be modified in ways that yield opportunities for observation, and that naturally occurring "provocations" such as accidental disruptions to a setting often yield valuable information.

Observational studies minimize problems of reactivity because people who do not know they are being studied do not change their behavior. Studying people without their permission, however, potentially negates the principle of informed consent. In fact, since the social expectations that govern behavior in public places assume that it will be observable and subject to scrutiny by others, unobtrusive observation carried out in public settings is frequently regarded as being less problematic than, for example, covert participant observation, or the deception of subjects in social science experiments.

Observational Sampling

Observation inevitably involves sampling. Decisions need to be made about what is to be studied, where and when an observation is to take place, and what the observer should notice and record during the observation. It can, however, be difficult to identify suitable sampling frames for observational studies or to decide how many periods of observation are needed and how long each should be. Although their work draws mainly on field studies of animal behavior, Martin and Bateson have identified the major sampling procedures for observational studies: (a) *ad libitum* sampling, (b) focal sampling, (c) scan sampling, and (d) behavior sampling. In *Ad libitum* sampling, systematic procedures are not followed. The observer notes what is visible and potentially relevant. There is a tendency, therefore, to focus on behaviors that are visible and discernible, and the potential exists for missing transitory or subtle behaviors. Focal sampling involves observing for a specified time one sample unit, such as an individual or relational pairing, and recording during that time all instances of a number of different categories of behavior. Because the focal unit can leave the setting or be out of sight of the observer, focal sampling can be difficult under field conditions. Since behavior out of sight might differ from behavior in sight, focal sampling potentially produces a bias toward recording public behavior. Scan sampling involves scanning a group of subjects at regular intervals. At a particular moment the behavior of each individual in the setting is recorded. Conspicuous individuals or behaviors are more likely to be noticed and therefore overrepresented; it is also often only possible to record relatively few categories of behavior. With behavior sampling some group or setting is observed in its entirety. Each time a particular behavior occurs, its occurrence is recorded along with a note of which sample element was involved.

Recording Methods

Martin and Bateson identify two methods for recording behavioral data: continuous (or "all occurrences") recording, and time sampling. An intensive and thorough procedure, continuous recording aims to produce a precise and faithful record of how often and for how long particular behaviors occur, with accurate recording of start and stop times. The method allows the frequency and duration of behaviors to be measured precisely, and it does not involve the loss of information inevitably associated with sampling. Continuous recording, however, is a burdensome activity, usually making it possible for an observer to attend only to a relatively few categories of behavior.

Time sampling requires that observations be recorded periodically, rather than continuously, with a random selection of time points for observation. The intermittent character of the observation means that the burden of work on the observer is reduced. In consequence, time sampling is arguably more reliable than continuous sampling because it allows more categories to be measured and more of the subjects present in the setting to be studied. In sampling behavior there is a need to balance the accuracy of measurement against its reliability and the ease with which measures can be obtained. The former implies short sample intervals, the latter long ones. There is no automatic way of determining how long or how short a sample interval should be. Choosing an interval will often be a matter of trial and error and/or judgement, or dependant on a pilot study.

There are two types of time sampling: instantaneous sampling and one-zero sampling. In instantaneous (or point) sampling the period of observation is divided up into short sample intervals. At the instant each sample point is reached, the observer records whether the behavior of interest is occurring or not. Rare events, those of relatively short duration or inconspicuous activities are not well captured by instantaneous sampling. In one–zero sampling, the observer records at each sample point whether the behavior of interest occurred or did not occur during the preceding sample interval. The method can produce biased results since behavior is recorded no matter how often it appears or for how long it occurs, and because events clustered at particular times tend to be undercounted relative to those spaced evenly across the whole period of observation. One–zero sampling might be appropriate in studies of intermittent behavior which are difficult to capture with either continuous recording or instantaneous sampling.

Reliability

Observation often provides "content-limited data," as Webb *et al*. describe it, since the information available to the researcher is contained within what is visible, the import of which might not be obvious without access to other more potentially reactive forms of data. Levels of reactivity are affected by the extent to which people are caught up in what they are doing, and the extent to which they have become accustomed to the presence of the observer. To increase the reliability of an observation it might be appropriate to use multiple observers and multiple methods of data recording. Observers can also be asked to assess the degree to which they thought subjects were acting in a reactive manner during the observation. Reliability can be assessed by looking at levels of intraobserver reliability, i.e., the extent to which individual observers are consistent in their practice, and at levels of interobserver agreement, the extent to which different observers produce similar results when they observe the same behavior on the same occasions. In some contexts it might also be appropriate to assess the combined effects of observer, setting, situation and observational categories by estimating the ratio of within-individual or setting variation to between-individual or setting variation.

Documentary Sources

Webb *et al*. make a rather arbitrary distinction between "running records," that is, records or documents produced (and often published) on a regular basis, and "episodic and private records," which are archival materials having a discontinuous form.

Running Records

Actuarial records registering the volume of births, marriages, and deaths are perhaps the most obvious example of running records, while the mass media provide a vast wealth of measures in the form of news stories, obituaries, wedding announcements, personal advertisements, advice columns, cartoons, editorials, advertisements, and the like. Running records, which are increasingly available in digital form, are valued for their ubiquity, their low cost, and their convenience. They can serve as a source of validation data for self-report data. Although they produce data restricted in content, running records typically cover lengthy time periods and generate considerable volumes of material. Because they extend over long periods, running records allow trends to be established, permit the exploration of temporal patterns, and provide opportunities for quasi-experimentation. In addition, associations, continuities, and discontinuities between different sets of records can sometimes yield information of a kind difficult to obtain by other means, for example, producing estimates of deviant behavior routinely hidden from view.

Running records are socially situated products. The quality of records varies depending on the nature of the processes involved in recording them. Apparent trends found can reflect external factors such as changes in record-keeping practices, or result from selective recording. Moreover, researchers in using running records might need to make careful judgements about issues such as transformation, aggregation, and time-series analysis, in other words, about how measures are to be expressed, how they might be combined, and how changes over time are to be handled.

There are few ethical problems involved in the use of running records, except where record linkage makes it possible to deduce the identity of individuals in the data. Even here the likelihood of deductive disclosure can be minimized by using strategies such as releasing results only on random subsamples of the data, including small amounts of random error, or more technical strategies such as broadbanding (the avoidance of finely detailed report categories) or microaggregation (where average responses for small clustered aggregates of research subjects are reported rather than individual scores). Because these strategies cloak the identity of individuals by introducing indeterminacy into data, their use involves some inevitable degradation of data quality.

Episodic Records

The use of documentary sources by researchers outside disciplines like history has grown appreciably in recent years. The interest in personal documents—letters, diaries, journals, memorabilia, family photographs, and the like—reflects a growing interest in discursive and textual

practice, a desire to incorporate elements of personal experience into the research process, and a commitment to give voice to those, such as women and members of minority groups, that social science has traditionally excluded, silenced, or marginalized. The mass media are full of visual images. Changes in the composition of such images provide an indication of shifts in the social valuation of particular groups. How images are assembled often gives an insight into how activities, events, and roles are socially constructed. Visual materials provide a cheap, effective, and readily accessible vehicle for making cross-national comparisons, and in less recognized forms, such as product packaging, attention to the visual can produce insights into the social use of objects. The judicial and legislative processes are a frequently unanticipated source of rich material on white collar crime, political malfeasance, and interrogatory discourse. Court transcripts, testimony before legislative committees and commissions, and the results of requests made under freedom of information laws can all yield data useful to the social researcher.

The relationship between documents available to a researcher and the wider universe of potentially relevant documents that exist or have existed is a problematic one. How far a particular set of documents can be taken to be representative of a wider universe of documents is affected by patterns of differential survival and variations in the accessability of documents. Documents are also fragile. They can be deliberately or accidentally destroyed, or be lost. Neither the recovery of a document's intended meaning, nor of the meaning received by its recipient(s) or audience(s) is unproblematic. Documentary analysis requires an appreciation of genre and stylistics, and an understanding of the context in which a given document was produced. The potential for reactivity present when data are elicited face-to-face is absent in documents. Pressures toward positive self-presentation may, however, still be present, for example, in material produced with an eye to eventual publication.

A range of strategies have been developed for the analysis of textual and graphical data, including quantitative content analysis, grounded theory procedures, and semiotic analysis. A wide variety of software tools is now available to help in the analysis of textual, and to a lesser extent, graphical data.

Unobtrusive Measures and the Internet

The Internet lends itself rather readily to data collection that does not involve the direct intervention of an investigator. While not yet universal, the Internet has recast the constraints of space, time, and cost typically juggled by researchers, providing opportunities not previously available to researchers in remote, small-scale or resource-poor environments.

The possibilities for the retrieval of secondary data and archival material have expanded massively with the advent of the Internet, enhancing the availability of running records and at least some kinds of documentary sources. Large volumes of machine-readable data on computer use, networking, communication processes, and message content are all available to the researcher at low cost, and with relatively little effort. The patterns revealed in these data are often not necessarily discernible by the participants involved. For qualitative researchers, the Internet allows for first-hand naturalistic investigation into the character of computer-mediated communication itself. The Internet opens up opportunities previously unavailable to study behavior prospectively. The transmission of rumours, arguments, the development of relationships, the unmasking of previously unsuspected selves, and the remedial strategies used to reinstate the good character of those who trangress against normative expectations, all of which previously could only be captured in retrospect if at all, can now be followed in their electronic manifestations from their inception to their conclusion.

Research in cyberspace falls within the scope of existing guidelines on ethical research practice in respect of informed consent, privacy and confidentiality and the need to protect research participants from harm. It is less clear, however, that existing guidelines are adequate. For example, obtaining informed consent in cyberspace where patterns of participation and involvement shift rapidly can be much more problematic than in face-to-face contexts.

Generating Unobtrusive Measures

A difficulty with unobtrusive measures is that there is little explicit guidance on how to generate unelicited data relevant to a particular research problem. Some writers have adopted an *orientational* approach, which stresses the importance of a creative and playful stance toward possible and actual sources of data. This approach can be contrasted with a *taxonomic* strategy, the basic aim of which is to identify particular properties of measures. From these properties, it might be possible to develop a generative taxonomy which would allow unobtrusive measures fitted to specific research purposes to be generated on demand. Neither approach is entirely satisfactory. An alternative view is that the generation of

unobtrusive measures involves the use of a variety of implicit heuristic strategies for finding data sources relevant to a particular research problem. Heuristics derived from a close reading of Webb *et al.*'s work include asking: "What features of some setting or situation can be made perceptually, normatively or culturally problematic and how?"; "How are the physical properties of objects inadvertently implicated in their social use?"; "What performative opportunities do objects offer?"; and "At what points and in what ways in society is information logged about social behaviour?" To date, the development and elaboration of such heuristics remains limited.

Unobtrusive Measures: An Assessment

The case against self-report methods can be exaggerated, but the presence of the researcher potentially shapes the responses of research participants in socially patterned ways. Research based on self-report is also vulnerable to the social factors affecting both the availability of research participants and their willingness to respond to researchers' questions. The problems of reactivity that potentially affect data collected by direct elicitation are absent when data are collected unobtrusively.

Unobtrusive measures are not used as widely as they might be. Some researchers reject an opportunistic attitude toward data feeling it better to produce, design, or create data for a specific purpose. The inferential weakness inherent in particular measures, at least when used on their own, is also taken to be a liability. A playful or creative attitude to data might not be easy to generate at will. Existing approaches to the generation of unobtrusive measures have generally not been satisfactory.

Unobtrusive measures commend themselves as ways of producing data complementary to direct elicitation methods, but with different weaknesses and strengths. Configuring different methods, each of which is fallible in a different way, might potentially give more reliable outcome than the measures produce by a single method. Unobtrusive measures can also be used where direct elicitation is difficult or dangerous. Simplicity and accessibility are advantages of unobtrusive measures. They rarely require great technical or technological sophistication, and they can provide a pathway for the verbally inaccessible. Unobtrusive methods are valuable in themselves because they encourage playful and creative approaches to data, undermining the tendency to use particular research methods because they are familiar or routine rather than appropriate to the problem in hand.

Urban Economics

Daniel P. McMillen
University of Illinois, Chicago, Illinois, USA

Glossary

agglomeration economies Cost advantages from locating near other firms.
CBD A city's central business district.
Gini coefficient, Herfindahl index Measures of industrial concentration.
gradient The rate of decline in a variable with respect to distance.
hedonic price function A function relating prices to housing characteristics.
internal economies of scale Cost advantages owing to large firm size.
localization economies Cost advantages from being near other firms in the same industry.
location quotient A descriptive statistic measuring industrial concentration.
monocentric city model A theoretical model of urban spatial structure in which the central business district is the primary employment site.
polycentric city An urban area with large suburban employment centers.
subcenter A large employment center outside of the central city.
urbanization economies Cost advantages from being in an urban area with diverse industries.

Urban Economics is the application of economic modeling to problems affecting urban areas. A distinguishing feature of the field is the analysis of spatial relationships: urban economists traditionally seek to explain where economic activity takes place and why the spatial distribution of activity changes over time. Another major role of urban economists is the analysis of urban social problems using standard economic tools.

Agglomeration Economies

Why Do Cities Exist?

The starting point for any discussion of urban economics is the seemingly obvious question, why do cities exist? In the past, cities often were a means of defense—walled cities were easier to defend than scattered farms. Cities also served as religious centers. But throughout history, cities have served as trading centers. The question addressed in urban economics is what is it about a city that attracts economic activity?

The first answer to this question is that cities arise at critical points in the transportation system to facilitate trade between regions. Due to economies of scale in transportation, shipping is typically cheaper in large batches. Still today, most cities are located around harbors, rivers, and railroad and highway crossings. These sites offer advantages to large firms that ship their products to many different locations. Large firms exist because of internal economies of scale—cost advantages enjoyed by firms producing large quantities of a product. Large firms employ many workers, and these workers tend to live near the firm. The concentration of homes in turn attracts stores, restaurants, and other services that cater to the residents. The original transport advantage becomes the catalyst for diverse economic activity that begets more activity. Steel in Pittsburgh, meat packing in Chicago, and beer brewing in St. Louis are examples of industries with internal

economies of scale that were attracted to cities offering significant transportation cost advantages.

Cities also attract economic activity because of agglomeration economies, a term used to denote cost advantages enjoyed by a firm simply because other firms are located in the vicinity. Agglomeration economies are traditionally classified as localization or urbanization economies. A localization economy is a cost advantage that accrues to all firms operating in an industry as that industry expands within an urban area. For example, Silicon Valley in California's Santa Clara County has many small firms that together comprise a very large industry. Among other reasons, these firms find it worthwhile to locate in Silicon Valley because it is easy to hire the right workers in an area with a very large concentration of high-tech firms. In contrast, urbanization economies are cost advantages that are enjoyed by firms even when there are few other firms in the urban area in the same industry. A large urban area provides enough demand that even highly specialized companies can find local firms to provide a service, rather than having to provide the service internally with their own employees at a higher cost.

Measuring Agglomeration Using Location Quotients

Urban economists have used two primary measures of agglomeration economies. The first, the location quotient, is a simple descriptive statistic measuring the extent to which firms in a given industry are concentrated within individual cities. It is useful for identifying industries in which localization economies may be present. The second approach involves direct estimates of production functions to identify firms in an industry that are subject to internal economies of scale, localization economies, or urbanization economies. The production function approach is more direct and more insightful, but it is far more data intensive than the location quotient approach.

Location quotients are typically constructed using data on employment by industry. For a given urban area, the location quotient for industry i is simply:

$$LQ_i = \frac{\text{Percentage of the Urban Area's Employment in Industry } i}{\text{National Percentage of Employment in Industry } i} \quad (1)$$

For example, if 15% of a city's employment is in an industry, compared with 10% for the entire country, the location quotient is 1.5. High location quotients—those in excess of 1.2 or so—imply that a city specializes in an industry, which in turn implies that localization economies may be present.

Table I presents location quotients for selected cities for 2002. New York has significant specializations in information, financial activities, and educational and health services. The information sector also stands out in Los Angeles–Long Beach, Washington, DC, and San Jose. Although professional and business services are important in all five cities, this sector is particularly important in Washington, DC, and San Jose. Interestingly, the government sector is important but not overwhelming so in Washington, DC. Manufacturing—mostly in the computer industry—is a critical sector in San Jose. The preponderance of location quotients near 1.0 suggests that Chicago has a relatively diverse economy. Table I suggests that localization economies may be most likely in the information and professional services sectors.

Measuring Agglomeration Using Production Functions

The production function approach to measuring agglomeration economies provides direct estimates of the extent to which firms' production within urban areas is subject to

Table I Location Quotients for Selected Large PMSAs

	New York	*Los Angeles–Long Beach*	*Chicago*	*Washington, DC*	*San Jose*
Construction and mining	0.64	0.61	0.85	1.07	0.84
Manufacturing	0.36	1.13	1.02	0.23	1.91
Wholesale trade	0.97	1.25	1.33	0.56	0.92
Retail trade	0.70	0.86	0.90	0.81	0.79
Transportation and utilities	0.89	1.14	1.23	0.65	0.46
Information	1.81	1.97	0.99	1.59	1.43
Financial activities	1.93	0.95	1.26	0.90	0.64
Professional and business services	1.21	1.17	1.29	1.68	1.54
Educational and health services	1.46	0.90	0.94	0.85	0.83
Leisure and hospitality	0.78	0.95	0.88	0.90	0.83
Other services	1.01	0.88	1.04	1.41	0.71
Government	0.97	0.91	0.76	1.34	0.65

internal scale economies, localization economies, and urbanization economies. The typical production function is

$$y_{ij} = g(S_j) f(K_{ij}, L_{ij}, Z_{ij}), \tag{2}$$

where y_{ij} represents output for the ith firm in the jth city, and K, L, and Z represent capital, labor, and other inputs. The term $g(S_j)$ is a shift factor representing internal economies of scale or agglomeration economies, with $g \geq 0$. Scale, S_j, is measured by either metropolitan employment or population to represent urbanization economies, or industry employment to represent localization economies. In general, empirical studies find evidence that both urbanization and localization economies are important determinants of output in a variety of industries, countries, and times. A salient example is Henderson (2003).

Measuring the Spatial Distribution of Economic Activity

Urban theory predicts that agglomeration economies give firms an incentive to locate in large metropolitan areas even though the cost of land and labor is higher in cities. How spatially concentrated is the actual distribution of employment? Do large cities attract new firms? Are firms attracted to cities that already have a concentration of jobs in the same industry? Several methods have been proposed to study the spatial distribution of employment in urban areas. Of these, the most common are the Herfindahl and Gini indexes, and a new method proposed by Ellison and Glaeser (1997). These measures require the researcher to first specify a unit of analysis, such as counties or zip codes. Let z_i denote region i's share of national employment in a given industry, and let n be the number of regions under consideration. Then the Herfindahl index is given by

$$H = \sum_{i=1}^{n} z_i^2. \tag{3}$$

The index ranges from $1/n$ to 1. Complete concentration—all employment in an industry in one region—implies that $H = 1$ because $z_i = 0$ for all but the one region in which $z_i = 1$. Completely diversified employment implies that $z_i = 1/n$ for each region, which implies that $H = \sum_{i=1}^{n} (1/n)^2 = (1/n)$. That the Herfindahl index is simple to compute is its advantage. Its disadvantage is that it compares the actual spatial distribution of employment to an unrealistic counterfactual of complete homogeneity. Whereas the lowest possible value of H, $1/n$, implies that each region has exactly the same employment share, it is unreasonable to expect a small region such as Cheyenne, WY, to have a similar share of an industry as New York or Denver.

Due to this disadvantage of the Herfindahl index, a more commonly used measure of employment concentration is the Gini coefficient. As a simple example, suppose that we want to measure geographic concentration across five regions in the manufacturing sector. The first region is the largest, accounting for 60% of all employment. The remaining four regions each have 10% of total employment. Sorted from lowest to highest, the cumulative shares are 10, 20, 30, 40, and 100%. Manufacturing employment is more dispersed than the total: each region accounts for 20% of manufacturing employment. Figure 1 is a graph of the cumulative manufacturing employment shares against the cumulative shares of total employment. If manufacturing employment were just as dispersed as total employment, then the plot of manufacturing shares would follow the 45° line—the dotted line in Fig. 1. The area between the two lines is the Gini coefficient. The area is zero if manufacturing and total employment are equally dispersed. The Gini coefficient equals 0.5 if all employment is in one region since the plot of the cumulative share of manufacturing then follows the x axis, while the area under the 45° line is simply 0.5 by construction.

Ellison and Glaeser propose an index that formally incorporates random firm locations—a "dartboard approach"—as the alternative. They begin by defining a gross geographic index for a given industry within the manufacturing sector, $G = \sum_i (s_i - x_i)^2$, where s_i is the share of the industry's employment in region i, and x_i is manufacturing's share of total employment in the region. Thus, G measures the extent to which the industry's employment shares differ from the overall distribution of manufacturing employment. Ellison and Glaeser show that the expected value of G is $(1 - \sum_i x_i^2)H$ when the distribution of firms is completely random, where H is the Herfindahl index for the industry. Using this result, they define the following index:

$$\gamma = \frac{\left(G - \left(1 - \sum_i x_i^2\right)H\right)}{\left(1 - \sum_i x_i^2\right)H} \tag{4}$$

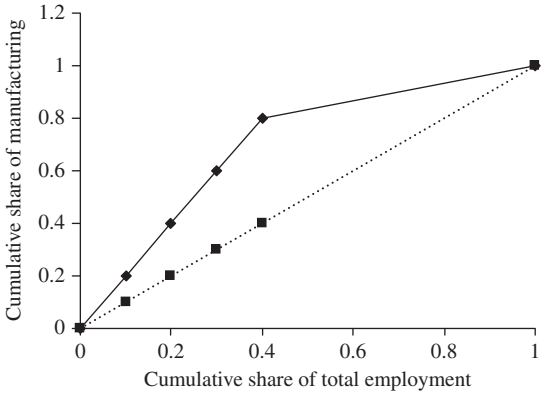

Figure 1 Constructing Gini coefficients for the manufacturing sector.

High values of G indicate that an industry is more spatially concentrated than expected given the overall spatial distribution of manufacturing employment.

If firms' location decisions are driven by internal scale economies alone, then there is no reason to expect that the distribution of the industry's employment should be different from the overall distribution of manufacturing jobs, and γ is close to zero. Localization economies imply clustering, and $\gamma > 0$. Ellison and Glaeser find that the U.S. automobile, carpet, and computer industries are highly concentrated spatially, whereas soft drink bottling, manufactured ice, and concrete products are not.

The Monocentric City Model

The monocentric city model, which is most closely associated with the work of Muth and Mills, is the core theoretical model of urban land use. In the Muth–Mills model, consumers receive utility from housing and other goods. Each household has a worker who commutes each day to the central business district (CBD). Each round trip to the CBD costs $\$t$ per mile. Since consumers have no direct preferences for one location over another, they would all try to live in the CBD in order to minimize their commuting costs unless house prices adjust to keep them indifferent between locations. In equilibrium, the price of housing must fall with distance from the CBD

$$\frac{\partial P_h(d)}{\partial d} = \frac{-t}{H(d)} \tag{5}$$

where $P_h(d)$ is the price and $H(d)$ is the quantity of housing at a site d miles from the CBD. This equation describes a simple relationship between house prices and distance from the CBD, as illustrated in Fig. 2.

The Mills–Muth model also includes producers who combine land and capital to produce housing. Since producers will pay more for land that is at sites with high house prices, land values will be high near the CBD. Where land prices are high, lot sizes are low, buildings are tall, and population density is high. Thus, Fig. 2 can be used to represent the price of housing, land values, building heights, and population density. The mirror image of Fig. 2—a smooth upward sloping function—represents lot sizes. All of these predictions are easily tested using simple regression procedures.

Measuring Urban Spatial Structure

The monocentric city model provides the basis for the method urban economists most often use to measure urban spatial structure. Figure 1 implies that variables such as the unit price of housing should decline smoothly and uniformly with distance from the CBD. The most commonly used functional form is the simple exponential function $y_i = e^{\alpha - \beta x_i}$ or $\ln y_i = \alpha - \beta x_i$, where x_i is the distance from the CBD for observation i, and y_i is any of the variables list in the previous section—population density, building heights, land values, etc. For example, suppose that y is population density. Then α represents the natural logarithm of population density in the CBD, and β measures the rate of decline in land values with respect to distance: land values fall by $100\beta\%$ with each additional mile from the CBD.

The coefficient β is referred to as the "gradient." Higher values of β imply a greater rate of decline in y. The gradient is the most frequently used measure of centralization. For example, Fig. 3 shows McMillen's estimates of the land value gradient for Chicago from 1836 to 1990. The gradient falls from 0.61 in 1836 to 0.14 in 1990. These numbers imply that land values fell by 61% with each additional mile from the CBD in 1836, compared with 14% in 1990. Clearly, Chicago was much more centralized near the time of its incorporation as a city than in 1990. Interestingly, the gradient has risen somewhat since 1960 as the city center has revitalized.

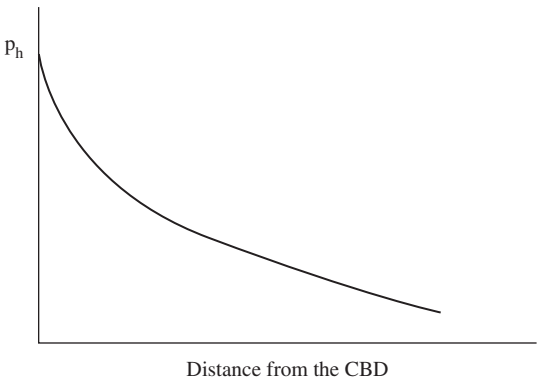

Figure 2 Predicted functional form for the price of housing.

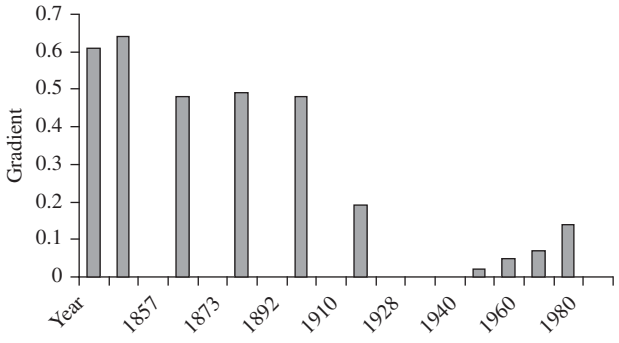

Figure 3 Land value gradients in Chicago.

Distance gradients have been used most commonly to study population density. Clark is the classic study. Both Muth and Mills made them an integral component of their research on urban spatial form. Coulson examines house prices using the approach. Gradients also have proved useful as a means of measuring rates of suburbanization and "sprawl."

Polycentric Cities

Recent extensions of the monocentric city model take account of the ongoing trend toward decentralized urban structure. As employment has moved to the suburbs, cities are more accurately portrayed as "polycentric"—a term coined to characterize urban areas with several employment centers outside of the traditional CBD. Suburban employment centers, or "subcenters," sometimes rival the CBD in total employment and in the scope of industrial activity.

Measuring the effects of subcenters on the urban economy is currently a popular research topic. The first step is to identify the subcenters. To qualify as a subcenter, an area must have a large concentration of employment, and it must have a significant effect on the overall spatial distribution of activity. The second requirement makes subcenter identification an empirical question.

McDonald proposed the first rigorous procedure for identifying subcenters. He estimates a simple exponential employment density function and identifies subcenters by looking for clusters of significantly positive residuals. Giuliano and Small define a subcenter as a cluster of contiguous employment zones where each zone has at least 10 employees per acre while the entire cluster has at least 10,000 employees. These cutoff points for minimum density and total employment can be altered to suit conditions unique to a metropolitan area. More procedures have been proposed since, and a variety of urban areas has been analyzed. The studies share the finding that subcenters are common in large metropolitan areas, but the traditional CBD still tends to dominate the spatial distribution of urban employment.

Urban Economics and Social Problems

Aside from studying the spatial distribution of economic activity, the other major role of urban economists is to use economic tools to analyze urban social problems. Examples include pollution, crime, poverty, racism and discrimination, education, and local public finance. These issues are important everywhere, not just in urban areas. But their effects are often more pronounced in cities because one problem can affect hundreds of thousands people.

The Hedonic Model

The first tool that urban economists use to measure the effects of urban social problems is the hedonic price function. The idea is to infer the value of a good, such as clean air, from house prices. Housing is the single most important asset for most households, and people gather lots of information before they are willing to spend thousands of dollars on a house. Home prices clearly are higher for larger, higher quality homes. Importantly, prices also reflect the characteristics of a neighborhood. An identical-looking house will trade for less if it is located in a polluted area with high crime and poor schools, and the size of the price discount will depend on the severity of these problems. Thus, we can infer how much people value clean air, low crime, and good schools from the value of housing in a neighborhood, once we have controlled for the house size and other characteristics of the homes.

Let P_i be the sales price of house i. Let X_i represent the vector of characteristics describing the house—living area, lot size, number of rooms, and so on. Also, let A_i represent the vector of characteristics describing the neighborhood, such as the crime rate, school quality, and air quality. The hedonic price function is simply $P_i = h(X_i, A_i) + \varepsilon_i$, where ε_i is an error term that is always present when estimating empirical relationships. The implicit market price of neighborhood characteristic j is simply $\delta h(X_i, A_i)/\delta A_{ij}$. In the absence of full arbitrage there is no reason to expect these hedonic prices to be constant; nonlinearity is a fundamental part of the hedonic equilibrium.

The hedonic approach can be extended to include both housing and labor markets. Metropolitan-wide amenities such as weather may be discounted into wages as well as house prices. However, most applied work analyzes either the housing market or the labor market alone, rather than both markets simultaneously.

Urban Crime

Lynch and Rasmussen use the hedonic approach to measure the economic impact of crime in Jacksonville, FL. They match data on over 2800 house sales to measures of crime across police beats. Explanatory variables for the home prices include structural and lot characteristics, neighborhood characteristics, and alternative measures of crime. They find that the cost of property and violent crime has only a small effect on sales prices. However, most places have little significant crime. In high-crime areas, homes trade at nearly a 40% discount relative to comparable houses in other areas.

Pollution

Kiel and Zabel analyze the effect of proximity to two Superfund sites on home values in Woburn, MA. The

Superfund is a federal program that was established in 1980 to clean up hazardous waste sites. Controlling for variables such as living area, age, and housing style, Kiel and Zabel find that proximity to the superfund sites lowered home values by as much as 12% in the time before the cleanup. They estimate the benefits from cleaning up the sites are between $72 million and $122 million in 1992 dollars.

School Quality

A final example of the use of hedonic price functions is found in the work of Gibbons and Machin, who analyze the benefits of school quality in England. The measure of school quality is the average performance on tests that are administered to all English students at age 11. Although the house price regressions have few controls for structural characteristics, Gibbons and Machin control carefully for locational effects. They estimate that the social valuation of a 1% improvement in primary school performance is £90 if the improvement is sustained over time.

Urban Studies

Paul A. Longley
University College London, London, UK

Glossary

geodemographic indicators Small area measures of social, economic, and demographic conditions.
lifestyles data Quantitative measures of the varied consumption choices, shopping habits, and practices of identifiable individuals.
urban Pertaining to towns and cities.
urban ecology The study of the social and spatial organization of urban society.

The adjective "urban" pertains to towns and cities, which are objects that, in measurement terms, are usually taken to be crisp, well defined, and clearly delineated in space. The umbrella term "urban studies" is commonly used to describe academic activities involving urban geography, economics, anthropology, politics, and sociology, predominantly but not exclusively focusing on developed Western cities. Since 1938, when sociologist Louis Wirth published his classic paper on urbanism, the focus of urban studies has been on spatial differentiation in the occurrences of particular lifestyles. However, the conceptual framework within which to set this differentiation, the attribute mixes that have been used to measure and describe lifestyles, and the scales at which they have been analyzed have changed during the evolution of the field. There is a strong and explicit spatial component to urban studies; this is manifest in the concerns of urban researchers with residential differentiation and residential segregation, often using informal and formal techniques of spatial pattern analysis. From a historical perspective, there has been an established focus on the ways in which the nature of differentiation has been conceived, the ways in which it has been measured, and some of the ways in which it has been analyzed. This will be used to account for current state-of-the-art practice, and the breadth of current applications in urban studies.

Definitions, Scales, and Terms of Reference

Urban studies are an interdisciplinary meeting place of enduring importance, not least because the 21st century is becoming increasingly urban. Following a half-century of astonishing demographic growth and change, about half the world's population is currently classified as urban. It has been helpful to differentiate between inter- and intra-urban studies in the sense of the analysis of the city as a system within a system of cities. In global terms, fast-growing cities (such as those of Latin America) contrast with the patterns of deconcentration and decentralization in more mature settlement hierarchies (such as those of Western Europe). This big picture of urban studies is very much driven by the dynamics of national and international economic development, technological change, and growth, whereas the focus in the developed areas of the world is more on processes of differentiation and change within much more established urban environments. What is clear, however, is that at most all geographical scales of measurement, the umbrella term "urban" accommodates ever-increasing diversity in lifestyles, and that effective measurement of urban lifestyles provides daunting challenges. There is inevitably an overlap between urban studies and what is described as "development studies," with the balance of activity in urban studies at the intra-urban scale, and this scale is the focus here.

The ways in which urban phenomena are conceived very much determine the ways in which they are measured and then subsequently analyzed. Studies concerned principally with urban extent (such as inventory analyses focusing on the rate at which open countryside is annexed by urban growth) tend to adopt definitions that focus on the geographic extent of irreversibly urban artificial structures on the surface of Earth. These different structures support a range of residential, commercial, industrial, public open space, and transport land uses. They can

provide simple, robust, and directly comparable measures that focus on the dichotomy of natural/artificial land cover, and may be measured using digital framework data or statistical classification of the reflectance characteristics of the land surface. The resultant urban development patterns may not be entirely contiguous, and techniques of geographic information systems (GIS) can be used to devise appropriate contiguity and spatial association rules. Such indicators provide useful and direct indicators of the physical form and morphology of urban land cover, and are very useful in delineating the extent of individual urban settlements and in generating magnitude-of-size estimates for settlement systems. In recent years, developments in urban remote sensing have led to the deployment of instruments that are capable of identifying the reflectance characteristics of urban land cover to submeter precision. In addition to direct uses, such measures are also of use in developing countries where socioeconomic framework data, such as censuses, may not be available. They also provide some useful indications of settlement size distributions within the global settlement system. For reasons that are explored later, improvements in the resolution of satellite images have not been matched by commensurate improvements in the details of socioeconomic data on urban distributions, and thus today's high-resolution urban remote-sensing data may also be used to constrain GIS-based representations of socioeconomic distributions. Although increasingly detailed and precise in spatial terms, such representations nevertheless tell us rather little about urban lifestyles, unless supplemented by socioeconomic data. If augmented with consistent population size data, such measures provide indirect estimates of lifestyle (e.g., sprawling low-density settlements suggest suburban lifestyles), but realistically they are only likely to satisfy the requirements of most intraurban studies, wherein lifestyles are, in any case, likely to be rather homogeneous over quite extensive areas (as, for example, in developing-country settings). Today there is no single urban way of life (if ever there was), and there is a need for sharper differentiation between lifestyles.

All of this does not amount to social measurement in a strict sense—precise measures of the extent and physical morphology of the carcasses of urban settlements provide rather few direct indicators of the lifestyles of those who work and live in the city. Urban studies in the broader sense require information on urban function, and thus research focuses on the creation of zones that may be uniform in socioeconomic characteristics (as in the delineation of areas that experience urban deprivation or hardship, as a precursor to neighborhood policy implementation), that may delimit a clearly defined urban function (as in empirical delineation of levels of a central place hierarchy, or identification of a travel-to-work zone), or that fulfill an administrative role. Analysis of urban function and lifestyle is fundamentally dependent on the collection and availability of data pertaining to socioeconomic characteristics, policy functions, and lifestyle activities. Where available, and notwithstanding some success at developing pan-European data sets, this often restricts the scope of urban studies to national units of analysis or to subsets of them. There are exceptions to this in the attribution of particular functions or interaction patterns to urban areas (for example, in recent analyses of international telecommunication data). Today, most developed and many developing countries have socioeconomic data infrastructures that are quite rich compared with the even quite recent past, although there is variability between countries in terms of content and in terms of the degree of reliance on national censuses, address registers, and public sector sample surveys. From the standpoint of the urban analyst, however, all data share the unfortunate characteristic that they are available only for aggregations of individuals, for reasons of ethics and confidentiality. The foundations to analysis are thus always artificial aggregations, such as census tracts. Data availability and measurement issues have driven much of the agenda of urban studies, but there has also been an element of choice in the variables selected, in turn driven by the social constructs that they are deemed to represent.

Historical Perspective on Social Measurement in Urban Studies

Studies by Charles Booth of the intraurban geography of poverty in Victorian London provided perhaps the earliest systematic intraurban social measurements of population characteristics. Yet the conceptual roots to urban studies are conventionally traced to the work of Robert Park, Ernest Burgess, and the other Chicago-based ecologists from 1916 onward. The root metaphor in this early work was that of vegetation competition and succession, and this was broadly deemed transferable to human communities by differentiating between the biotic and cultural levels of urban society. In this work, biotic forces were manifest at the level of the community, whereas social forces were deemed to be asserted only at the cultural level of society as a whole. In conceptual terms, urban society thus provided a superstructure above the more basic competitive level of the community, and neighborhood communities were fashioned by subsocial forces. Park and his colleagues saw the role of what would now be called urban studies as investigating the community level and the subsocial forces that acted within it. In 1923, Burgess envisioned the community-level forces in his famous concentric-zone model, in which ecological forces of competition for space were deemed to fuel a process of radial expansion. The resulting pattern of

urban land uses can thus be thought of as a snapshot of the ripple effects of urban growth.

Park was avowedly empiricist in his approach to measurement and analysis (one report notes that Parks once famously described his methodology as "walking the streets"), yet a central contradiction of the work of the Chicago school was that the biotic and social components of residential differentiation could never be observed and measured in isolation from one another. Nevertheless, an enduring appeal of the work lay in its reference to explicitly spatial terms such as "neighborhood" and "district," and these came to conjure up the image of the city as a mosaic (or perhaps, more dynamically, as a kaleidoscope) of subareas, defined not just in terms of built form but also in terms of the patterning of socioeconomic and demographic groups. In short, these became the major sociological and geographical structures that were seen by academics and policymakers as shaping urban form, although in subsequent work, the Chicago school's theoretical concerns with dominance, functional interdependence, and differentiation were to become decoupled from empirical classification of mosaics of social worlds.

Subsequent empirical work thus focused on the patterning of the tiles of the urban mosaic as the principal objective of analysis, and secondary data sources, specifically censuses of population, were used to attribute values to the tiles. What became known as "social area" analysis thus developed as *à la carte* selections from menus of available census variables, using the mosaic of zones used in census dissemination. The approach, epitomized by the work of Eshref Shevky, Marilyn Williams, and Wendell Bell in Los Angeles and San Francisco in the mid-1950s, essentially provided a descriptive empirical technique for reducing multivariate census tract returns to the tripartite constructs of social rank, urbanization, and segregation. These constructs were provided in Shevky and Bell's limited, *post facto*, rationalization of their initial work, and sought to embed social measurements in changes in the range and intensity of social relations (social rank), differentiation of industrial function (urbanization), and increasing complexity of the organization of society (segregation). However, by the 1960s and 1970s, the approach had become driven overwhelmingly by inductive generalization from secondary data, using the then fashionable analytical techniques of factor analysis in the developing field of computer analysis. Social measurement and data analysis thus became divorced from any substantial or coherent conceptual framework, and urban studies became submerged by the tide of inductivism that continues to run through science and social science to this day. Data were allowed, by and large, to speak for themselves—with increasingly occasional lip service paid to concepts and theories.

The tide of inductivism ran fast, but in urban studies it dissipated quickly, and by the mid-1970s, disenchantment with data-led empiricism had led to the demise of factorial ecology as a sustainable epistemology. In very general terms, the approach has been supplanted by successive waves of urban managerialism and Marxist sociology. The field of urban studies has, in important respects, become rather stronger in conceptual terms, yet work in these recent genres has by and large proved to be no more empirically verifiable than are the ecological metaphors and social constructs that preceded them. Urban geography appears to have been an obvious casualty, for most current research appears to lack an explicit spatial dimension. In an era in which there has been a resurgence of interest in the neighborhood as a unit of social action, economic planning, and policy implementation, the field of urban studies has very largely withdrawn from the quest to generalize about intraurban socioeconomic distributions. However, this is not to say that the significance of inductive generalization about urban social patterning has been entirely wasted. At the same time as factorial ecologies and multivariate classifications were becoming unfashionable in academia, Richard Webber (working at the London Center for Environmental Studies) developed the approach into the branch of urban studies that has become known as geodemographics. The earliest UK national classifications were developed from the 1971 Census of Population, at four scales, ranging from the enumeration district (census block) to the parliamentary (electoral) constituency. The classifications were initially intended to guide local government in neighborhood policy implementation, but, following Webber's move into the private sector in 1979, the basic approach was successfully developed into commercial applications through proprietary systems such as the MOSAIC and ACORN classifications. Today, these kinds of systems are a proved social measurement technology and enjoy repeat purchases by a wide variety of businesses and service organizations. Numerous different systems exist for general and niche markets in North America and Europe, and systems are under development in much of Latin America and China. More rudimentary approaches to multivariate socioeconomic classification remain an important area of activity in the public sector, as in the calculation of standardized composite indices of levels of hardship and deprivation.

Whither Social Measurement in Urban Studies?

Beyond the academy, there continues to be very strong interest in social measurement of urban socioeconomic distributions, and many interesting developments of

technique and application are underway. One important development has been the recognition that richer depictions of urban lifestyles can be assembled from diverse and under-used digital sources that are available at a range of spatial scales. These include the limited range of attributes that can be gathered for individuals from address registers, to georeferenced vehicle registrations, social surveys, shopping surveys, and guarantee card returns. Increasing numbers of commercial databases concerning lifestyles are now routinely used in commerce: many enumerate salient characteristics of tens of millions of individuals. Although they are rarely collected to the same exacting standards to which conventional public sector data sets are collected, they are updated continuously and provide very detailed snapshots of the diverse lifestyles that are often to be found in quite small urban areas. Some enlightened private sector data providers have been prepared to deposit these disaggregate data in research archives (subject to confidentiality constraints). Although these vastly enrich the potential content of social classifications, their use raises a number of profound and possibly frustrating issues of coverage and representativeness, not least because commercial organizations are unlikely to be motivated toward assembling detailed data inventories on the "have nots" of society. Companies that use lifestyle lists to identify potential mail-drop targets are unlikely to select households with low incomes. For this reason, most lifestyle operators have decided that it is more cost effective to target the blanket door drops of questionnaires to postcode sectors with higher rather than lower levels of affluence. However, coarse administrative zones (such as UK postcode sectors) are the lowest areal units that can be leafleted by distributors, and this is likely to improve the representativeness of response. There is a clear need to cross-validate small area lifestyle measures with respect to external data sources.

These issues illustrates a number of the tensions in current social research: digital data capture is now routine, but scientific surveys conducted to rigorous standards account for a diminished real share of available data; the scale and pace of change to urban systems now makes the decennial snapshots of censuses increasingly irrelevant to policy needs; and the fission of lifestyles among urban populations that are increasingly heterogeneous at fine scales of granularity makes the limited content (attribute base) of censuses increasingly limiting in analysis of urban systems. Taken together, this argues for the need to generate scientific findings in real time, and with frequent update cycles; the need for interdisciplinary approaches to urban studies that blend together salient indicator variables into comprehensive indicators; and the need for public–private partnerships in order to unlock the potential of the richest, most relevant, and most recent data.

In relating the success of social measurement through geodemographic applications in business, it is important to note some differences in the measurement goals of different academics and private sector practitioners. In general terms, it is worth distinguishing between two rather different applications. Direct marketers, who communicate with individuals rather than serve areas, desire measures that are optimally predictive at the person or household level, but are not materially concerned whether there is any geographically systematic error in this estimate. There are no inferential errors generated in one-to-one marketing applications. By contrast, retailers and other organizations that serve areas, rather than individuals, are not particularly concerned whether their social measures are accurate at the household level. They, like the academic or policy analyst, are more concerned that whatever inferential errors there may be are not systematic at the area level. Thus, the best social measurements for direct marketers are not necessarily the best measures for analysts concerned with geographic catchments.

Today's diminished academic interest in social measurement of urban systems is a pity for a number of reasons. In conceptual terms, the experience of factorial ecology did bring general recognition of the ways in which choice of classification method, choice of variables, and to some extent choice of data source would determine the outcome of the classification. Today, similar sensitivity to context is recognized in the measurement of local or regional effects. Second, in measurement terms, more data are collected about more aspects of our individual lifestyles than at any point in the past, through routine interactions between humans and machines. Enlightened approaches to public data access (especially through online portals) make wide dissemination of socioeconomic data a reality and the creation of general-purpose and bespoke data systems straightforward. Geodemographic systems based on socioeconomic framework data can be successfully fused to census sources to provide richer depictions of lifestyles. And third, in analysis terms, the toolkit of spatial analysis and GIS now make it easier than ever before to match diverse data sources and accommodate the uncertainties created by scale and aggregation effects.

Developments in computation, technique, and data analysis continue to offer incremental improvements in the ways that geodemographic representations are specified, estimated, and tested, but it is correct to suggest that it is repeat purchases of a core tried and tested technology that ensure retention of the approach as a mainstay of contemporary urban studies. Hitherto, the overwhelming majority of geodemographic applications has concerned tactical and strategic decision making in private sector applications (specifically retailing), and it is probably true to say that the clearest indicator of "success" is the way in which improvements in targeting of goods and service offerings improve measured profitability. One

of the interesting challenges of the coming years will entail use of these techniques in public service applications, given the pressures to demonstrate value for money in targeting public funds according to local needs. It is not possible in an article of this length to examine the various caveats to the geodemographic approach, but issues of the content and coverage of the data sources that are used to create and update geodemographic profiles are certainly likely to become important in developing and extending the realm of geodemographic applications. The approach has very important contributions to make to the developing rationalities, performance metrics, and change measures in the developing public policy debate. It is of strategic importance that academics and policymakers engage in these important measurement issues, and do not simply become passive consumers of geodemographic systems. In this context, it is important to return to the themes of conception, measurement, and analysis. In the early days of urban studies, the issue of empirical verification of ecological analogy was seen as a crucial issue. Much of the recent history of urban studies has also posited concepts and processes that can only rarely and unsystematically be observed. The geodemographic approach, by contrast, entails a return to the mosaic metaphor of urban structure, and provides robust, transparent, and disaggregate observations of what is going on in urban systems. In conceptual terms, it is founded on the basic theoretical premise that "birds of a feather flock together." This is by no means a trivial concept, whether viewed in the context of genetic selection and mapping of the human genome, or in the simulation of city evolution as the outcome of cellular interactions across a range of geographic scales. It has been suggested that the patterning of urban social areas may express more than the outcome of (unmeasurable) economic and social processes and, at a conceptual level, that there may be much that can be developed from the success in measuring urban phenomena through geodemographics. It is not just the urban ecology of the Chicago school that might be revitalized: neighborhood classification could also develop the ideas of Shevky and Bell in terms of classifying urban areas according to the range and intensity of social relations, differentiation of industrial function, and increasing complexity of the segregation of society.

Consolidation

The scale and pace of urban development in the 21st century is without historical precedent, and the patterns of functional interdependence within and between national settlement systems make it no longer sensible to envisage any direct correspondence between urbanism and a small range of lifestyles. We are all now urban in some senses, but so too we are increasingly differentiated from one another in terms of our lifestyles. The mosaic of urban areas provides the most obvious laboratory in which to study diversity in lifestyles. The fission of urban lifestyles, in terms of both conventional and other social indicators, presents profound challenges to urban studies, and engagement with the social measurement task is pivotal to progress. The success of geodemographics in commercial and (increasingly) policy settings provides testimony to the relevance of urban studies, and the rationale for the approach is by no means ill conceived or atheoretical. It also provides evidence that improved measurement guides the development of better theory in this important area of social science.

Finally, a broader aspect of this quest to reinstate social measurement at the core of urban studies entails redefinition of urban studies in more than conventional territorial terms. The emergent computer-linked "e-society" is defined in large part by the changing connectivity and interactions between individuals, and between individuals and the state (which is also changing profoundly as new information and communications technologies become ever more pervasive). As lifestyles and the institutions that shape them adapt to the technologies of the digital age, it remains clear that the urban nexus will remain pivotal. Social measurement is absolutely central to understanding changes in the modes of social and economic interaction, and hence the organization of society.

Utility

Michael Quinn Patton
Union Institute and University, Minneapolis, Minnesota, USA

Glossary

conceptual use Use of research or evaluation to influence thinking about issues, policies, or programs in a general way.
findings use Identifiable influence of research or evaluation conclusions on decisions, policies, programs, or thinking of people.
instrumental use Direct action or decision that follows, at least in part, from research or evaluation findings.
misuse Inappropriate, dishonest, and improper interpretations and applications of findings, both intentional and unintentional, that distort, confuse, or obfuscate.
non-use Ignoring research and evaluation conclusions.
process use Identifiable effects of participating in research or evaluation on the participants and/or their organizations or communities, for example, enhancing evaluation capacity or increasing research skills.
symbolic use Evaluation is undertaken simply to conform with funding mandates or to legitimate pre-existing conclusions or biases.
use In the context of research or evaluation, to employ inquiry processes and apply findings.
utility Actual or potential use of research or evaluation.
utilization-focused evaluation An approach to evaluation that focuses on facilitating and achieving intended use by primary intended evaluation users.

Utility concerns the extent to which research and evaluation are useful—and actually used—to inform action, decisions, policies, program improvements, and understanding. The primary proof of utility is actual use. Different research and evaluation purposes lead to varying kinds and degrees of utility and use. Some studies are designed to inform decisions and support taking action; such uses are instrumental. Other studies aim at enhancing understanding, but no specific actions or concrete decisions are expected. Moreover, utility concerns not only use of findings, but also the effects of participating in research or evaluation on the participants and/or their organizations or communities, for example, enhancing evaluation capacity or increasing research skills. The shadow side of use is misuse, that is, inappropriate, dishonest, and improper interpretations and applications of findings, both intentional and unintentional, that distort, confuse, or obfuscate. Some evaluation approaches, like utilization-focused evaluation, make monitoring and attaining utility the centerpiece of the design. The relative balance in social science between attention to utility versus attention to truth is controversial, as are definitions of and attempts to measure utility.

Utility as a Concern in Applied Social Science

Applied social science, as opposed to basic research, strives for utility. Concern about utility has emerged at the interface between science and action, between knowing and doing. Funders of applied social science expect that findings from research will be able to be applied in solving social problems. Funders of program evaluation expect results to be used to improve programs. Utility of research and evaluation is increased when the findings are viewed by potential users as understandable, relevant, and credible. Efforts to increase utility have raised fundamental questions about human rationality, decision-making, and knowledge applied to creation of a better world.

Conclusion-Oriented versus Decision-Oriented Inquiry

Not all social science strives for utility. A classic distinction contrasts decision-oriented inquiry with conclusion-oriented inquiry. Conclusion-oriented social

measurement aims at the creation of knowledge as a good in and of itself, for example, understanding how the brain functions when learning to read. In contrast, decision-oriented inquiry aims to inform and influence decision makers, for example, evaluating reading programs to determine which are most effective. In decision-oriented inquiry, concern about utility comes to the fore.

The Challenge of Knowledge Use

Getting people to use what is known has become a critical concern across the different knowledge sectors of society. A major specialty in medicine (compliance research) is dedicated to understanding why so many people do not follow their doctor's orders. Common problems of information use underlie trying to get people to use seat belts, quit smoking, begin exercising, eat properly, and pay attention to evaluation findings. In the fields of nutrition, energy conservation, education, criminal justice, financial investment, human services, corporate management, international development—the list could go on and on—a central problem, often the central problem, is getting people to apply what is already known. In agriculture, a major activity of extension services is trying to get farmers to adopt new scientific methods.

These examples of the challenges of putting knowledge to use set a general context for the specific concern of research utility: narrowing the gap between generating research findings and actually getting those findings used.

Problems of Underuse and Nonuse

Historically, a great many studies have documented and examined the problems of underuse and nonuse. Both the scholarly literature on the subject and various commission reports on the use of social scientific knowledge reached a decidedly gloomy conclusion that instances where social science research had a clear and direct effect on policy were rare.

Government Underutilization of Knowledge

Research and evaluation have become part of political debates and government decision-making around the world. A study in 1995 by the U.S. General Accounting Office (GAO) raised questions about how well governments use research and evaluation. Entitled "Improving the Flow of Information to Congress," analysts concluded that research and evaluation findings sent to Congress seldom reached the right committees and people, that reports were poorly organized and communicated ineffectively, and that much data was too highly aggregated to be useful or was too difficult to digest. It seems unlikely that this American example is unique.

Many factors affect research and evaluation use in government, but politics is the overriding factor. Ideological conflicts overwhelm empirical evidence. This is true at state and local levels of government as well.

Problems of Misuse

The other side of the coin when looking at utility is misuse. Results from poorly conceived studies have frequently been given wide publicity while findings from good studies have been improperly used, selectively applied, and distorted in political debates. One form of misuse is called symbolic use referring to the selective and distorted use of empirical findings to legitimate pre-existing positions or biases, for example, attempting to enhance the credibility of a political stance by selectively citing evaluation findings that support that stance. Undertaking evaluation simply to conform with funding mandates with no intention to use the results is also a form of symbolic use. Social scientists face a dual challenge then: supporting and enhancing appropriate uses of knowledge while also working to eliminate improper uses.

Evaluation Standards and Utility

In the past, many researchers took the position that their responsibility was merely to design studies, collect data, and publish findings; what decision makers did with those findings was not their problem. This stance removed from the social scientist any responsibility for fostering use and placed all the blame for nonuse or underutilization on decision makers. While the role of social scientists in policy-making has long been debated, the emergence of program evaluation as a distinct field of professional practice led to an explicit focus on utility as a criterion of excellence.

Before the field of evaluation identified and adopted its own standards, criteria for judging evaluations could scarcely be differentiated from criteria for judging research in the traditional social and behavioral sciences, namely, technical quality and methodological rigor. Use was ignored. Methods decisions dominated the evaluation design process. By the late 1970s, however, it was becoming clear that greater methodological rigor was not solving the utility problem. Program staff and funders were becoming openly skeptical about spending scarce funds on evaluations they could not understand or found irrelevant. Evaluators were being asked to be "accountable" just as program staff were supposed to be accountable. How would evaluation be evaluated? It was in this context that professional evaluators began discussing standards.

Standards were hammered out over five years by a 17-member committee appointed by 12 professional organizations, with input from hundreds of practicing evaluation professionals. The standards published by the Joint Committee on Standards in 1981, and revised in 1994, dramatically make utility a primary criterion of

excellence. The other three general criteria in the standards framework are feasibility, propriety, and accuracy. (For the detailed standards see www.eval.org.)

Utility Standards

The Utility Standards are intended to ensure that an evaluation will serve the information needs of intended users. The standards call for clear identification of primary stakeholders, assuring evaluator credibility, collecting information responsive to the needs and interests of stakeholders, making value judgments clear, writing clear reports submitted on time, and planning, conducting, and reporting studies in ways that encourage follow-through by stakeholders to increase the likelihood of use.

Types of Utility

Alternative research and evaluation purposes intend and support varying uses. Applied research and evaluation are characterized by enormous diversity. From large-scale, long-term, international comparative designs costing millions of dollars to small, short evaluations of a single component in a local agency, the variety is vast. Thus, reducing the complexity of utility types to a few major categories will inevitably oversimplify. Yet, three major purpose categories capture the primary alternatives with regard to using empirical findings: (1) generating useable, generalizable knowledge, (2) making overall evaluative judgments about the merit, worth, value, and effectiveness of specific policies or programs, and (3) facilitating improvements in policies and programs.

These are not mutually exclusive purposes and some studies strive to incorporate all three approaches, but one is likely to become the dominant motif and prevail as the primary purpose informing design decisions and priority uses; or else, different aspects of a study are designed, compartmentalized, and sequenced to address these contrasting purposes. Confusion among these quite different purposes, or failure to prioritize them, is often the source of problems and misunderstandings when it turns out that different intended users had different expectations and priorities about utility.

Generating Useable, Generalizable Knowledge

Generalizations and ideas that come from research and evaluation help shape the development of policy and program theory. Generalizations from evaluation can become part of the knowledge that influences future decision-making about programs generally. Understandings gleaned from evaluations can contribute to applied social science theories about how to produce social change as well as inform and test implementation theory to better understand variations in program delivery and outcomes. Such knowledge-generating efforts focus beyond the effectiveness of a particular program to future program designs and policy formulation in general.

Building General Program Theory about Effectiveness

As the field of evaluation has matured and a vast number of evaluations has accumulated, evaluation researchers look across findings about specific programs to formulate generalizations about effectiveness. This involves synthesizing findings from different studies. These kinds of "lessons" constitute accumulated wisdom—principles of effectiveness or "best practices"—that can be adapted, indeed, must be adapted, to specific programs or organizations when disseminated.

Making Overall Evaluative Judgments about Merit and Worth

Evaluation research aimed at determining the overall merit, worth, or value of a program or policy derives its utility from being explicitly judgment-oriented. Merit refers to the intrinsic value of a program, for example, how effective it is in meeting the needs those it is intended help. Worth refers to extrinsic value to those outside the program, for example, to the larger community or society. A welfare program that gets jobs for recipients has *merit* for those who move out of poverty and *worth* to society by reducing welfare costs. Judgment-oriented evaluation approaches include performance measurement for public accountability; program audits; summative evaluations aimed at deciding if a program is sufficiently effective to be continued or replicated; and quality control and compliance reports.

Facilitating Improvements in Policies and Programs

Using evaluation results to improve a program turns out, in practice, to be fundamentally different from rendering judgment about overall effectiveness. Improvement-oriented forms of evaluation include formative evaluation aimed at identifying a program's strengths and weaknesses, quality enhancement efforts, and learning organization approaches. What these approaches share is a focus on making things better rather than rendering overall judgment. Judgment-oriented evaluation requires preordinate, explicit criteria, and values that form the basis for judgment. Improvement-oriented approaches tend to be more open-ended, gathering varieties of

data about strengths and weaknesses with the expectation that both will be found and each can be used to inform an ongoing cycle of reflection and innovation.

Instrumental Utility

Both judgment-oriented and improvement-oriented studies involve the instrumental use of results. Instrumental use occurs when a decision or action follows, at least in part, from the study. Specifically, instrumental utility is knowledge used for action in contrast to conceptual utility, which is knowledge for understanding.

Conceptual Utility

With conceptual use, no decision or action is expected; rather, a study is used to influence thinking about or understanding of issues. Evaluation findings can contribute knowledge by clarifying a program's model, testing theory, distinguishing types of interventions, or elaborating policy options. In other cases, conceptual use is more vague, with users seeking to better understand the program; the findings, then, may reduce uncertainty, offer illumination, inform funders and staff about what participants really experience, enhance communications, and facilitate sharing of perceptions. In early studies of utilization, such uses were overlooked or denigrated. In recent years, they have come to be more appreciated and valued. Studies can be designed with conceptual use in mind or conceptual use may be a by-product or unintended secondary effect of efforts at instrumental use.

Enlightenment as a Form of Utility

Conceptual use is sometimes described as "enlightenment use." Evaluation theorist Carol Weiss first used this term to describe the effects of evaluation findings being disseminated to the larger policy community where they may affect the terms of debate, the language in which debate is conducted, and the ideas that are considered relevant in to resolve.

Process Utility

Process use refers to and is indicated by individual changes in thinking and behavior, and program or organizational changes in procedures and culture, that occur among those involved in evaluation or participatory forms of research as a result of the learning that occurs during the inquiry process. An example of process utility is the following kind of statement after an evaluation: "The impact on our program came not so much from the findings but from going through the thinking process that the evaluation required." Attention to process use is evident in approaches to organizational development that emphasize action research, capacity-building, and organizational learning.

Issues and Controversies Regarding Utility

Defining and Studying Utility

It has proved difficult to identify, measure, and substantiate how particular findings from research or evaluation directly affect decisions. Decisions result from multiple influences and flow from some combination of values, politics, social interactions, personal relationships, perceived risks, perceived benefits, perceived incentives, and knowledge. How much to attribute a decision to knowledge (empirical findings) in any complex decision-making process has proved speculative at best. Moreover, since both knowledge and changes accumulate incrementally over time, disentangling cause and effect relationships within the vagaries of varying organizational memories makes measurement of either instrumental or conceptual use imprecise and subjective.

Definitional Disagreements

Alkin and Hofstetter, in a comprehensive review, concluded that despite 30 years of research on knowledge and evaluation utilization, the definition of "utilization" has never been agreed on. Those who study utility disagree about what should be considered instances of use.

An Interactive Perspective on Utility

Most research on utility has been based on a linear model in which knowledge is generated, is then disseminated, and then influences action, decisions, and thinking. An alternative is an interactive perspective in which researchers and policy makers, or evaluators and information users, interact together and mutually inform one another.

Connecting New Knowledge with Prior Knowledge

Most research on utility focuses on research and evaluation findings as new knowledge. Theories of human cognitive processing add a layer of complexity to studies of how empirical findings are used by positing that individuals use their prior knowledge to assess how to interpret new information. The more persuasive the new information is, in relation to existing conceptions and information, the greater the level of agreement between the two. The more contrary the pieces of information are, the lower the level of agreement. The cognitive reactions, separate from the actual information itself, influence if

and how new information is used. Further, the user's motivation and ability to understand the information are also influential. Motivated, able users who are open to different ideas are more likely to cognitively incorporate new information than are those who are passive, closed-minded, and resistant. Thus, what is convincing and useful social evidence to one person may not be to another.

Factors that Explain and Predict Utility

Factors identified in the research literature on utility generally fall into three main categories. Though conceptually distinguishable, these factors generally interrelate across categories and at different times in affecting utility and actual use.

Human Factors

Human factors affecting utility include user and researcher characteristics, such as people's attitudes toward and interest in the inquiry, their backgrounds and organizational positions, and their professional experience levels.

Context Factors

Context factors include the social, organizational, and political climate for the inquiry, fiscal constraints, and how much empirical findings are valued.

Inquiry Factors

Inquiry factors include how the study is undertaken, its timeline and budget, the procedures and methods used (including their rigor), the information collected including its perceived relevance and credibility), and how findings are reported.

Utility Tests and Truth Tests

In a classic study of prevailing influence, Weiss and Bucuvalas found that decision makers apply both "truth tests" (whether data are believable and accurate) and "utility tests" (whether data are relevant) in deciding how seriously to pay attention to findings. Decision makers want highly accurate and trustworthy data, and they want those data to be relevant to their interests and concerns. The ideal, then, is both truth and utility. In the real world, however, there are often choices to be made between the extent to which one maximizes truth and the degree to which data are relevant.

The simplest example of such a choice is time. The timelines for evaluation can be ridiculously short. A decision maker may need whatever information can be obtained in three months, even though the researcher insists that a year is necessary to get high quality data. This involves a trade-off between truth and utility. Highly accurate data available in a year are less useful to this decision maker than data of less precision and validity obtained in three months.

Decision makers regularly face the need to take action with limited and imperfect information. They prefer more accurate information to less accurate information, but they also prefer some information to no information. This is why research quality and rigor are often only modestly important in determining utility.

Methodological Quality and Utility

The effects of methodological quality on utility must be understood in the full context of a study, its political environment, the degree of uncertainty with which decision makers are faced, and thus their relative need for any and all clarifying information. If information is scarce, then new information, even of dubious quality, may be somewhat helpful. Less rigorous conclusions provided on time can be more useful than highly rigorous findings supplied after a decision has had to be taken. Those are real world trade-offs. In contrast, debates about technical quality are more likely to be center stage in national policy evaluations than in local efforts to improve programs where the stakes are lower.

Efforts to Increase Utility

Much attention has been paid to strategies for increasing utility. Preskill and Caracelli surveyed evaluation practitioners and found several strategies that may enhance evaluation utility: planning for use at the beginning of an evaluation; identifying and prioritizing intended users and intended uses of evaluation; designing the evaluation within resource limitations; involving stakeholders in the evaluation process; communicating findings to stakeholders as the evaluation progresses; and developing a communication and reporting plan.

The Personal Factor

The "personal factor," that is, the extent to which specific decision makers or other primary intended users care about findings, appears from research on utility to be the most important determinant of what impact as well as the type of impact a given study will have. The importance of the personal factor has led evaluators to attempt to enhance use by engaging and involving intended users early in the evaluation, ensuring strong communication between the producers and users of evaluations, reporting evaluation findings effectively so users can understand and use them for their purposes, and maintaining credibility with the potential users. Utilization-focused evaluation is an example of a comprehensive strategy that incorporates the knowledge that has emerged from studying utility.

Utilization-Focused Evaluation

Utilization-focused evaluation is an approach that begins with the premise that evaluations should be judged by their utility and actual use; therefore, evaluators should facilitate the evaluation process and design any evaluation with careful consideration of how everything that is done, from beginning to end, will affect use.

Intended Use by Intended Users

The focus in utilization-focused evaluation is on intended use by intended users. Since no evaluation can be value-free, utilization-focused evaluation answers the question of whose values will frame the evaluation by working with clearly identified, primary intended users who have responsibility to apply evaluation findings and implement recommendations. Utilization-focused evaluation is highly personal and situational. The evaluation facilitator develops a working relationship with intended users to help them determine what kind of evaluation they need. This requires negotiation in which the evaluator offers a menu of possibilities within the framework of established evaluation standards and principles.

Utilization-focused evaluation does not advocate any particular evaluation content, model, method, theory or even use. Rather, it is a process for helping primary intended users select the most appropriate content, model, methods, theory and uses for their particular situation. Utilization-focused evaluation is a process for making decisions about these issues in collaboration with an identified group of primary users focusing on their intended uses of evaluation.

Psychology of Utility

A psychology of use undergirds and informs utilization-focused evaluation: intended users are more likely to use evaluations if they understand and feel ownership of the evaluation process and findings; they are more likely to understand and feel ownership if they have been actively involved; and by actively involving primary intended users, the evaluator is training users in use, preparing the groundwork for utility, and reinforcing the intended utility of the evaluation every step along the way.

Validity Assessment

Edward G. Carmines
Indiana University, Bloomington, Indiana, USA

James A. Woods
West Virginia University, Morgantown, West Virginia, USA

Glossary

construct validity A type of validity that is concerned with the relationship between the measure under consideration and theoretical expectations on other measures.
content validity A type of validity that focuses on the extent to which a particular empirical measure reflects a specific domain of content.
criterion-related validity A type of validity that concerns the correlation between a measure and some criterion variable of interest.
measurement The process of linking abstract concepts to empirical indicators of those concepts.
random measurement error All of the chance factors that confound the measurement of any phenomenon.
reliability The extent to which an experiment, test, or any measuring procedure yields the same results on repeated trials.
systematic (nonrandom) measurement error An error that has a systematic biasing effect on a measuring instrument.
validity The extent to which an indicator of some abstract concept measures what it purports to measure.

Validity is concerned with whether a measure actually measures the concept that it is being used to represent. In science, this relationship between the theoretical and the observable is crucial. The unobservable concept is the quantity of interest; how it is measured, or represented, is fundamental to any understanding of the inferences concerning the relationships among the various theoretical concepts.

Measurement

Measurement focuses on the representation of abstract concepts by empirical indicators. Thus, measurement concerns the relationship between abstract, theoretical, and unobservable concepts proposed in a theory and empirical indicators of those concepts for which there are direct observations. As such, measurement involves both theoretical as well as empirical considerations. Empirically, the focus is on the observable response—answers on a questionnaire, observed behavior, answers given to an interviewer, etc. Theoretically, the interest is in the underlying unobservable (and directly unmeasurable) concept that is represented by the response.

Measurement allows the scientist to move from the purely abstract to the empirical and testable. It is centered on the relationship between the empirically grounded indicator, or the observable response, and the underlying unobservable concept. When this relationship is strong, analysis of empirical indicators can lead to useful inferences about the relationships among the underlying concepts. Social scientists can evaluate the empirical applicability of theoretical propositions. If there are no empirical indicators of the theoretical concepts, then the empirical tenability of the theory remains unknown. In situations when the relationship between concept and indicators is weak or faulty, analysis of the indicators can lead to incorrect inferences and misleading conclusions concerning the underlying concepts. Research based on such inadequate measurement models does not result in a greater understanding of the phenomenon under investigation. From this perspective, the auxiliary theory specifying the relationship between concepts and

indicator is as important to social research as is the substantive theory linking concepts to one another.

Basic Properties of Measurement

There are two basic properties of measurement: validity and reliability. Reliability is the extent to which an experiment, test, or any measuring procedure yields the same results on repeated trials. It is concerned with the consistency of a measure over repeated observations. Reliability is driven by random measurement error—all of the chance factors that confound the measurement of any phenomenon. If an indicator is a reliable indicator of the theoretical concept, that indicator will produce consistent results on repeated observations because the random error is not great enough to cause notable fluctuation from one observation to the next. Thus, the greater the random error, the less reliable is the measure. For example, if a bathroom scale shows a weight as 5 pounds greater than the true weight on the first reading, 8 pounds greater on the second reading, and 10 pounds less on the third reading, the readings are being affected by random error and the reliability of the scale is low.

Nonrandom, or systematic, error does not detract from a measure's reliability. All of the error in a measure could be nonrandom and it would not affect that measure's reliability. For example, if a bathroom scale always shows a weight as 5 pounds over the true weight, it is a reliable, or consistent, measure. The error in this case is not random; indeed, it is entirely nonrandom—it is 5 pounds too high every time. Thus, the measure is perfectly reliable, but it is not a valid measure. The scale does not measure what it is intended to measure.

Types of Validity

Validity is the extent to which any measuring instrument measures what it purports to measure, rather than reflecting some other phenomenon, i.e., nonrandom measurement error. In testing, the purpose of the test must always be considered when assessing validity. That is, a driver's test may be valid for determining if a person knows how to drive, but it may not be valid at all for determining intelligence. Validity is always an argument between competing theoretical claims. Because of this, what is validated is not the instrument, but rather the instrument in relation to the purpose for which it is being used.

Several types of validity are appropriate in social science research. Each has a slightly different approach in assessing the degree to which a measure is valid. In the body of measurement literature, there are references to internal validity, statistical validity, construct validity, convergent validity, discriminant validity, cross-validation, face validity, concurrent validity, external validity, content validity, sampling validity, criterion validity, predictive validity, and empirical validity. Some of these types of validity overlap. Face validity is sometimes discussed as a separate type of validity and sometimes as a subtype of content validity. Some types of validity are the same, only with different names, e.g., criterion-related and empirical validity are used to mean the same thing. Some are used to denote subtypes of a main type of validity. For example, both concurrent validity and predictive validity are subtypes of criterion-related validity. Convergent validity, discriminant validity, and cross-validation are used to denote types of construct validity. The following discussions cover the three most basic types of validity—content validity, criterion-related validity, and construct validity—and the relevance of each to social science.

Content Validity

Content validity focuses on the extent to which a particular empirical measure reflects a specific domain of content. That is, does the indicator adequately and comprehensively represent what it is supposed to measure? The indicator is said to be content-valid if it reflects the full domain of content. For example, a driver's test that consisted only of right turns and excluded left turns, parking, stopping, and an understanding of traffic signals would not be content-valid. Similarly, and more relevant for the social sciences, a measure of political ideology that included only a question about support for or opposition to government-sponsored medical care would not be valid because it excludes many other policy preferences relevant to ideology.

Obtaining content validity involves two interrelated steps. First, the researcher must be able to specify the entire domain of content that is relevant to a particular measurement situation. In the example of the driver's test, everything that is necessary to know to operate an automobile safely and legally is contained in the state's driver's manual. This is the domain. Specifying the full domain for social science concepts is much more difficult. Minimally, the researcher would need to include questions about a wide array of political issues, certainly issues that go well beyond health care. The second step involves selecting or constructing the specific indicators that are used in the measure. For example, a written driver's test contains a sample of indicators from the driver's manual. In this example, specification and selection procedures are relatively straightforward. However, in the social sciences, this may be quite complex. Specification of the domain of content for abstract concepts such as ideology or alienation is a formidable task. A beginning would be to consult the literature on the subject to gain an understanding of the concept. Once a general understanding of the abstract concept is obtained, indicators that reflect the meaning

of particular aspects of the phenomenon would then be selected or constructed. It is impossible to state a general rule concerning the number of indicators that are necessary to represent any particular domain of content. However, it is always preferable to begin with too many indicators rather than too few, because deficient items can be dropped, but it is much harder to add new or better items at a later stage in the research.

Establishing a content-valid measure of concepts used in the social sciences, such as ideology or alienation, is a very difficult task; indeed, it is much more complex than developing a content-valid measure of driving proficiency. When dealing with abstract concepts, it is difficult to establish concurrence about a domain of content relevant to the phenomenon, because most theoretical concepts in the social sciences have not been described with the required exactness. Further, when measuring most concepts in the social sciences, it is impossible to sample content. A researcher uses one or more indicators that are intended to reflect the content of a given theoretical concept. Without a random sampling of content, however, it is impossible to ensure the representativeness of the particular indicators.

Thus, there are two fundamental limitations of content validity as applied to the social sciences. First, the chosen indicators must reflect the full domain of content relevant to a particular theoretical concept. However, as easy as this may be to achieve with regard to some tests, such as proficiency tests, it is extremely difficult to accomplish for the more abstract phenomena that tend to characterize the social sciences. The second limitation of content validity is the lack of concurrence concerning the criterion for determining the extent to which a measure has attained content validity. This leaves the researcher with the task of having to provide a plausible rationale for accepting a version of what constitutes the appropriate domain of content and for establishing that the indicators included in the measure have been satisfactorily sampled from that domain. Because of these limitations, content validity is not a fully satisfactory means of assessing the validity of social science measures.

Criterion-Related Validity

A second type of validity, more closely related to what is usually meant in everyday usage of the term, is criterion-related validity. This type of validity concerns the relationship or correlation between a measure and some criterion variable of interest. Using criterion-related validity, a driver's test can be validated by demonstrating that the test is a good predictor of the ability of a well-defined group of individuals to drive a car. Criterion-related validity is fully determined by the degree of correspondence between the measure, or test, and its criterion. If the correlation is high, the measure is valid for that criterion. If the test does not correlate significantly with the criterion, it is not valid for that criterion and, thus, is useless for that particular purpose.

The higher the correlation, the more valid is a measure for a specific criterion. For criterion-related validity, this is all that matters. It is the only evidence that is relevant. It does not matter if the test makes no theoretical sense as a predictor of the criterion. If the accuracy of horseshoe pitching, for example, is found to be highly correlated with college success, then horseshoe pitching would be a valid measure for predicting success using criterion-related validity. There is also no single validity coefficient. There are as many coefficients as there are criteria for a particular measure. Technically, criterion-related validity can be differentiated into two types. If the criterion exists in the present, then concurrent validity can be assessed by correlating the measure and the criterion at the same point in time. For example, a verbal report of voting behavior could be correlated with participation in an election, as revealed by official voting records. Predictive validity, on the other hand, concerns a future criterion that is correlated with the relevant measure. Using the Scholastic Aptitude Test (SAT) as a predictor of success in college is an example. Scores on the SAT could be correlated with students' subsequent performance in college to demonstrate the predictive validity of the SAT. The logic of concurrent and predictive validity is the same. The only difference between them concerns the current or future existence of the criterion variable.

What is sometimes overlooked in assessing criterion-related validation procedures is that the scientific and practical utility of criterion validity depends as much on the measurement of the criterion as it does on the quality of the measuring instrument. For example, in many different types of training programs, much effort and expense goes into the development of a test for predicting who will benefit from the program in terms of subsequent job performance. However, the subsequent performance, the criterion, is often given very little attention. Job performance is very difficult to assess. Thus, those using criterion-related validation procedures should provide independent evidence of the extent to which the measurement of the criterion is valid. Although criterion validation is intuitively appealing, it has a major limitation in regard to the social sciences. For many if not most measures in the social sciences, there simply do not exist any relevant criterion variables. For example, to return to the earlier example, it is not clear what an appropriate criterion variable would be for political ideology. Thus, criterion-related validation has limited usefulness in the social sciences. Further, the more abstract the concept, the more difficult it is to find an appropriate criterion for assessing a measure of it.

Construct Validity

The third basic type of validity is construct validity. Construct validity is important when there is no universal agreement concerning the domain of content for the phenomenon, and no relevant criteria. This type of validity focuses on the theoretical expectations surrounding a particular empirical indicator. Thus, construct validity is theory driven. Using theory, the researcher formulates theoretical predictions about the existence, direction, and extent of relations among empirical indicators of different theoretical concepts. If the empirically observed outcomes are consistent with these theoretical predictions, then the measure is said to be construct valid. This type of validity is more pertinent in the social sciences than is either criterion-related validity or content validity.

Construct validation involves three distinct steps. First, the theoretical relationship between the concepts must be specified. Second, the empirical relationship between the measures of the concepts must be examined. Finally, the empirical evidence must be interpreted in terms of how it clarifies the construct validity of the particular measure. Again, to return to the earlier example, a researcher might specify that political ideology is related to social class, such that those respondents with lower social status would more likely be leftist in political orientation, whereas those with higher status would more likely be on the right. If income was employed as the measure of social status, and attitudes toward the government provision of health care were used as the measure of political ideology, then the researcher could calculate the relationship between these variables. If this relationship was significant and in the expected direction, this evidence would constitute one piece of evidence supporting the construct validity of the measure of political ideology.

The fundamental feature of construct validation is theory. There must be a theoretical framework about the concept or it will be impossible to validate the measure. Without this theoretical framework, it is impossible to generate theoretical predictions that, in turn, lead directly to empirical tests involving measures of the concept. What is required, then, is to be able to state several theoretically derived hypotheses involving the particular concept. Construct validity is not established by confirming a single prediction on different occasions or confirming many predictions in a single study. Instead, construct validation ideally requires a pattern of consistent findings involving different researchers across a significant portion of time and with regard to a variety of diverse but theoretically relevant variables. Only if and when these conditions are met can the construct validity of a particular measure be spoken of with confidence.

A problem exists if the theoretically derived predictions and the empirical relationships are inconsistent with each other; that is, there is a problem when the evidence relevant to construct validity is negative. The most typical conclusion to draw from negative evidence is that the measure lacks construct validity. That is, the indicator does not measure what it purports to measure—the construct of interest. The accumulation of negative evidence leads to the interpretation that the measure is not construct-valid and should not be used as an empirical manifestation of that concept in future research. Previous research using that particular measure of the concept is also called into doubt. There are other conclusions that are consistent with this sort of negative evidence, however. First, the interpretation could be made that the theoretical framework used to generate the empirical predictions is incorrect, i.e., the theory is wrong. Another interpretation is that the method or procedure used to test the theoretically derived hypotheses is faulty or inappropriate. That is, the statistical technique used in the test could be inappropriate and the researcher could be using it incorrectly. The final interpretation regarding negative evidence is that it is due to the lack of construct validity or due to the unreliability of some other variable in the analysis. It is a very subtle point, but when the construct validity of the measure of interest is assessed, the construct validity of measures of the other theoretical concepts is also being evaluated simultaneously. Thus, it could be the case that the construct validity of the measure is quite high, but the measure hypothesized to correlate with that measure is invalid. In the example of social status, if social status turned out to be unrelated to political ideology, perhaps the problem is that income is not a valid measure of social status.

There is no foolproof procedure for determining which one (or more) of the interpretations of negative evidence is correct in any given instance. The first interpretation, that the measure lacks construct validity, becomes increasingly compelling as grounds for accepting the other interpretations become less tenable. To the extent possible, the construct validity of a particular measure should be assessed in situations characterized by the use of strong theory, appropriate methodological procedures, and other well-measured variables. Only in these situations can it be confidently concluded that negative evidence is probably due to the absence of construct validity of a particular measure of a given theoretical concept. It is apparent that construct validity is the most appropriate and generally applicable type of validity used to assess measures in the social sciences. The researcher can assess the construct validity of an empirical measurement if the measure can be placed in theoretical context. That is, this type of validity, unlike other types, focuses on the extent to which a measure performs in accordance with theoretical expectations.

Glossary

concept An abstract object or thought.
contextual specificity Different meanings for the same measure in different contexts.
construct validity The degree of how well a measure fits within existing hypothesized relationships with other measures.
convergent validity The comparison of a measure against one or more measures that are also measures of the same concept, but none holds the distinction of being considered as a direct measure.
criterion validity The comparison of a measure against a single measure that is supposed to be a direct measure of the concept under study.
definition A concept placed into words.
external validity The generalizability of the relationship between two concepts beyond the research question under study.
internal validity The robustness of the relationship of a concept to another internal to the research question under study.
measure Data related to a concept.
operational definition Classification rules for a concept's definition.
reliability The degree by which repeated scoring of a measure provides consistent values.
scoring Gathering information for a measure based on the rules of classification.
validity The degree that an abstract concept is accurately measured.

Validity is the degree by which an abstract concept is accurately measured. Validity is best thought of as a degree, since no variable completely captures an abstract concept. Although this may be a discouraging limitation, much of social science research is driven by the quest for more valid measures. This chapter describes many of the threats to the validity of a measure, tests of validity, and the relationship of validity of a measure to research questions.

Introduction

Hypotheses are tested by projecting abstract concepts onto the real world through measurement and observing the strength of the hypothesized relationships. Validity concerns the component of projecting abstract concepts to the real world through measurement. This projection is best described as an approximation, as there is rarely a one-to-one correspondence of clean abstract concepts to the dirty world of reality. In this context, validity plays an important role in theory building. As subfields within the social sciences mature, competing hypotheses linking concepts arise. Often there are multiple ways of measuring different aspects of the same concept, and these measures may not commonly be used among studies within a subfield. The hypothesis that is ultimately accepted as the best explanation of observed causal relationships may depend upon the widely agreed degree of validity of the measures of the concepts researchers use in their studies.

Validity from the abstract to the real world may be thought of as having four stages, as presented in Fig. 1. In the abstract is the *concept*, the underlying theoretical construct that is to be studied. The *definition* gives the concept meaning though a concrete description. The *operational definition* provides rules of classification to distinguish cases. *Measures*, also called indicators or variables, are generated through the process of *scoring*, or gathering data by following the rules of classification.

The validity of the concept of democracy serves as an example that may help readers grasp the concept of validity itself. Many readers will have an internal

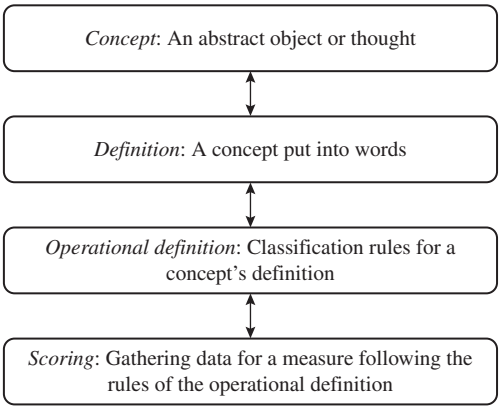

Figure 1 Four stages of validity of measurement, linking an abstract concept to scoring of data.

conception of democracy, even if they have not thought much about it. One widely agreed upon necessary component of the definition of democracy is participation of a people in choosing their government. A measure of democracy within the context of participation might be the percentage of people who choose to vote in elections. Scoring the measure of the voter turnout rate measure requires gathering election returns and the number of persons eligible to vote.

Threats to validity may arise at any of the links between the four stages of validity. First, the concept is defined. Although participation may be a common aspect of a minimal definition of democracy, it is not the only component. Indeed, there is a spirited debate among cross-national researchers as to the minimal definition of a democracy. In an example drawn from Adcock and Collier, political scientists who study Latin America noted that some Central and South American countries scored high on measures of the widely agreed minimal definition of democracy even though the scholars themselves did not believe these countries were fully democratic. Despite participation of citizens in relatively free elections, Latin American democratic governments were not effective because the military still controlled "reserved domains of power." This inconsistency led researchers to amend their definition of democracy to include the requirement that the civilian government must have an effective power to rule.

The measurement of the definition of participation may also be challenged. American scholars have oft-lamented the on-going decline in one measure of participation, voter turnout rates, over the last half of the 20th century. McDonald and Popkin show that the perceived decline in United States turnout rates in recent United States elections turns on the operationalization of the measure of eligible voters. Measures of turnout rates in these previous studies are defined as dividing the number of persons who voted by the voting-age population (VAP), a Bureau of the Census estimate of all persons age 18 and older residing in the United States. The VAP includes persons ineligible to vote, most importantly noncitizens and ineligible felons, who as a percentage of the VAP have increased considerably since 1972. When United States turnout rates are recalculated for those eligible to vote, the decline of turnout rates is relocated to the 1960s, with a relatively flat "trend" since 1972.

The protracted recount of the Florida presidential vote in 2000 exposed the entire country to the reliability of scoring election returns. The Florida presidential election of November 7 was so close, less than 0.5% of the vote, that it invoked an automatic recount of the presidential vote in that state. The overall outcome of the Electoral College, and who would be president, rested in the balance of the Florida recount. Presidential candidate Al Gore contested election returns in certain Florida counties, dragging out the counting and recounting of ballots until the United States Supreme Court decision to halt recounting on December 12, 2002. Most disturbing to the legitimacy of the outcome for either candidate was that each new recount produced a new vote total. "A confounding array of vague laws (and) arbitrary local decisions . . . resulted in turmoil across the state—from the way voters were treated to how ballots were designed and counted." Afterward, with time to carefully reexamine ballots, newspaper organizations hired accounting firms to classify and tally ballots and found that the election outcome still depended on which standard was used to score ballots.

Validity also works in the direction from the bottom of scoring up to the concept, and for this reason the arrows connecting the stages of validity in Fig. 1 point in both directions. Validity may be seen as a dynamic process, whereby definitions of a concept and the rules of measurement are fine-tuned as cases are observed. In the proceeding example, Latin Americanists found the scoring of the concept of democracy did not conform to the perceived degree of democracy in Latin American countries. Researchers reevaluated the minimal definition of democracy and a new definition emerged that included the effectiveness of the democratic government to govern policy areas. Here, the process of scoring led researchers to formulate a new definition.

Validity covers a broad scope linking concept to data, only some of which is touched upon in the proceeding example of democratic participation. With such a broad scope, it is not surprising that one study found 37 different adjectives to describe aspects of validity. Adcock and Collier argue that differentiating the different types of validity detracts from the overriding goal of validity, "... validity must be seen, not as establishing multiple independent *types of validity*, but rather as providing *types of evidence for validity*" (emphasis in original).

Since no abstract concept may be perfectly projected onto the real world, the quest for valid measurement of concepts in the social sciences is one of degree, not of absolutes, where different aspects of validity evidence serve to strengthen the overall validity of a measure, but can never guarantee with absolute certainty the perfect validity of any measure.

Explanation of the different aspects of validity will proceed with this admonition in mind. The discussion is organized around three aspects of validity. In the first section, threats to validity of a measure that may occur between the four stages of concept, definition, measure, and scoring are discussed. In the second section, validity of a measure in relation to other measures of the same concept, or proposed causal relationships between concepts is discussed. These are called *criterion validity*, *convergent* or *divergent validity*, *content validity*, and *construct validity*. It is important to note that with these tests of validity, observed relationships between measures of the same concept or the observed casual relationship between two measures depends on how well the measures are themselves valid measures of the concept they seek to measure. In the final section, validity of data in terms of hypothesis testing, *internal* to the research question and *external* to the application of a hypothesis outside of the research question under study is discussed.

Threats to Validity

Because social science measures do not correspond neatly to the latent concepts to be measured, social scientists are confronted continually with validity issues. Threats to the validity of a measure are posed at the three linkages of a measure to the latent concept with which it is associated. Below, the three points where threats to the validity of a measure may occur are described. A measure may not be valid if (1) an incomplete definition of the concept is proposed, (2) if an inadequate measure is used, or (3) if the scoring of a measure is unreliable.

Formulating the Definition of a Concept

Adcock and Collier distinguish the link between the concept and its definition from the links between rules of measurement and actual scoring of cases; the latter they refer to as measurement validity. They argue that the two have little in common with one another. Formulating a definition of a concept is a theoretical exercise while measurement is a process that lends itself to explicit tests of validity. Indeed, much of what is discussed in this article is within the sphere of what they term measurement validity. Still, a complete discussion of validity warrants a discussion of threats to the link between concept and definition.

In defining a concept, researchers make the first step in approximating the abstract to the real. Some concepts are simple enough that a single, universally accepted definition exists, such as the colors black and white. More often, social scientists operate in a gray area wherein multiple definitions are posited for "contested concepts," such as gender and race.

At first, one may be discouraged to contemplate that there are competing definitions of concepts. Ironically, " . . . it is fortunate that we cannot in reality achieve widely accepted definitions of most constructs." The different definitions provide researchers with the opportunity to tackle the same concept from different angles. The validity of measures, and the validity of causal relationships between measures, may thus be "triangulated" by comparing measures of the same concept derived from different definitions of that concept. These sorts of tests of validity are considered in the next section on validity tests.

Within a contested concept, a consensus definition may emerge among researchers. A proper balance must be struck, such that the scope of the definition is broad enough to quantify the meaning of a concept, but must not be so broad as to include irrelevancies. Well thought out parsimony is the key to the development of a good definition.

Operationalizing Measures

Formulating or operationalizing measures of concepts is the next stage in creating a valid measure of a concept. The relationships between concept and definition, and between definition and measure are very similar. Whereas a definition of a concept is a concept put into words, the measure of a definition is the definition projected onto data, following the rules devised to create the measure. From the introductory example, democracy might be simply defined as persons choosing the government, while a measure of democracy might be the proportion of people who participate in the electoral process.

A primary difficulty in developing measures is context. Consider a cup of coffee. A cup served in European restaurants is very different than what is served in the United States. Americans ordering their first European coffee will be tempted to eat the sludge they are served with a spoon, while Europeans will simply conclude that Americans do not know how to make a strong drink, be it coffee or beer. *Contextual specificity* refers to a measure possessing different meanings in different contexts. Two cases of a measure may possess the same score, but the score may have entirely different meanings in different contexts. Contextual specificity may arise in cross-national

studies, in comparisons across subgroups, in panel studies on polls, and in historical research.

Survey research is particularly sensitive to contextual specificity. Respondents may assign different meanings to the same question. Survey methodologies (beyond random sampling) such as sample design, weighting, interviewing techniques, question wording, and question ordering may vary between surveys. Even seemingly trivial issues such as the order in which questions are asked of respondents may affect their answers. Compilations of surveys, such as the American National Election Survey Cumulative Dataset or the Cumulative General Social Survey, provide illusions of consistency by assembling answers to similar questions asked over time into one variable within a data file, but careful reading of codebooks reveal many of the minutia that may pose a threat to the validity of comparing answers across time and between respondents.

Contextual specificity may arise whenever comparisons are made across cases, be it persons, groups, countries, or time. Since these categories cover virtually all social science research, it is important for researchers to be aware of the potential for contextual specificity and take corrective measures, if warranted and possible. For example, American politics researchers who make comparisons between U.S. states often distinguish the special nature of Southern politics by including a dummy variable for that region in their statistical analyses. (The concept of the "South" is itself a contested concept.) This definition is operationalized and then interacted with other variables. In doing so, these researchers attempt to "establish equivalence" of their measures across regions.

Equivalence may also be established when the measures themselves are operationalized and scored, by carefully considering what important components are necessary to measure the concept to be studied, making sure that the full scope of components are indeed measured. For example, a study of civic participation that neglects activities available through the internet would be deficient, especially one that compares participation across time.

Content validity refers to the scope of the measure accurately capturing the definition of a concept. Just as with developing a definition for concept, researchers must strike a compromise between completeness and parsimony when developing measures. While it is desirable to capture the full scope of the definitional concept, including the beating wing of a butterfly into the operationalization of a measure is too broad, and thereby the meaning of the concept one is trying to capture with the measure is blurred. The continual drive of social science research is toward completeness, as most concepts have at some point in time been already measured at least once. The challenge for future researchers is to refine the measurement of concepts without overly increasing their complexity.

The content validity of social sciences measures is a subjective matter. As a branch of study develops, widely agreed upon measurement of the definitional concept may arise. That does not mean that there is not room for improvement. By cataloging the operationalization of the concept of democracy used by leading researchers, Paxton noted that the scholars used male suffrage as the operationalization of universal suffrage. Paxton reformulated the operationalization of suffrage to include female suffrage and was rewarded with different results. This is a lesson that young researchers should heed, as finding these sorts of errors of omission often prove fertile ground for groundbreaking research.

Reliability of Scoring

Validity is often distinguished from *reliability*, the degree by which repeated scoring of a measure provides consistent values. Alwin provides a detailed treatment of reliability in the *Encyclopedia for Social Measurement* but a brief discussion is warranted here because reliability is a necessary condition for validity. If repeated attempts to score the cases of a measure yield dramatically different results, then validity may be impossible to ascertain.

Virtually all social science data have measurement error. The naïve researcher accepts all data at face value while the cynical researcher never fully trusts that any data source reports the exactly correct values for all cases. A classic example of measurement error is the statistical "margin of error" of polling percentages associated with random sampling of a population. Because of random selection of respondents, no two surveys will produce the same result, and no survey is guaranteed to represent the true value. Instead, margins of error are reported to indicate where we have confidence in where the true value may lie. Measurement error extends well beyond surveys to any setting where human error in coding and classifying cases may occur. Some cases of a measure may even be missing entirely.

The reliability of a measure is determined by the size and bias of the measurement error. If measurement error is large, then the noise in the scoring of the measure may make any meaningful interpretation of the measure in relationship to the concept, or other concepts, impossible to determine. In the context of polling, the margin of error of a poll is inversely related to the sample size of the survey. If the sample size is small, then the margin of error will be large, so large that the location of the true value will fall within such as large range as to be virtually unknown. In a similar vein, if the poll result is within the margin of error of the thing that one wishes to determine,

such as the winner of an election, then the outcome is said to be within the margin of error of the poll, and impossible to determine with confidence.

Measurement error may be small but still have bias, systematic measurement error that may also invalidate a measure's usefulness. For example, in 1932, *Literary Digest* magazine conducted a poll of over two million respondents selected from telephone directories and automobile registrations. The poll predicted a landslide victory for Alf Landon, but the landslide that year went to Franklin D. Roosevelt. Even with two million respondents, the poll was unrepresentative of the population, since only the most affluent owned phones and cars at that time. Thus, even though the margin of error of this poll would have been relatively smaller than usual surveys, because of the extremely large sample size, the survey was still unreliable because it was biased.

Biases may appear in many guises. In polling, it is well known that respondents may lie to the interviewer to provide the socially correct response. For example, more respondents consistently report voting than official government figures indicate. Sociologists term the dual nature of bias that enters when humans observe human behavior as the insider versus the outsider biases. Sociologists who seek an insider perspective attempt to gain the trust of those that one studies by becoming active participants in the subject they are studying. As an insider, the sociologist hopes that the subjects are more willing to provide their true feelings on a subject to the researchers. However, the gap between researcher and subject may never be fully gulfed, as subjects will always know that they are being studied. Furthermore, a researcher may never be able to achieve insider status, such as a person studying different races. In becoming an insider, the sociologist gains the trust of the study subjects, but at the same time loses the perspective of detachment. As an outsider, the sociologist is able to see the large picture and place the observations into a larger meaningful context. A careful balance of insider insight and outsider perspective is needed to produce meaningful sociological research.

Since polls rely on random sampling, a poll may, by just sheer bad luck of random chance, draw an aberrant sample. The margin of error refers to the 95% confidence interval of a poll, and provides a false sense of reliability of a poll since one out of twenty times the true value will lie outside the confidence interval. During the course of a presidential election, many polls, much more than 20, are conducted. Unfortunately, the surprise poll, the one with a surprising result that may be the result of a bad sample, is the one that receives the most attention. To turn statistics on its head, 1 out of every 20 statistical results may incorrectly reject the null hypothesis merely as a consequence of random chance.

Although polls provide classic examples of reliability issues, by no means is reliability an issue restricted to polling. For example, Ward chronicles how research into the retirement of U.S. Supreme Court justices was fatally flawed because the first study of retirement incorrectly reported the text of a 1937 law that set the age at which judges may retire with benefits. Subsequent researchers cited the original study, without checking the statute itself, and propagated the error. The lesson is that it is important to check the reliability of secondary sources.

In the course of data entry, inevitably cases will be incorrectly scored through human error. These sorts of data entry errors are may appear as *outliers*, atypical cases with values far from other cases. Outliers are not necessarily the product of an error, but they often are, and they can severely affect observed relationships between measures. Researchers should carefully check the extreme and highly implausible values of a measure, as these cases are typically the result of data entry errors. For example, in analyzing election data for a project, one election outcome had an exact 50–50 split of the vote between two candidates. Since an exact tie is unlikely, checking the observation revealed the vote total for one candidate had been incorrectly entered twice, for both candidates. Some of the same techniques to test the validity of a measure may also reveal outliers. For example, plotting two related measures against one another will reveal deviant cases. To improve the reliability of a measure, when a new data entry project has been completed a careful researcher will perform checks for outliers and check their validity. Just as importantly, data obtained from even the most respected outside sources should not be blindly accepted as error free, and should be similarly scrutinized.

Data may also be missing: randomly or with bias. Statisticians have developed methods to impute, or fill in, missing data and incorporate the statistical error of imputation into results. Imputation of missing data is a statistical guess for the true values, and thus it inherently contains measurement error in the resulting scores for missing cases. The loss of reliability associated with imputation will be proportional to the number of missing cases and the reliability of the imputation procedure, which itself may also contain bias.

Reliability is also an issue for statistical software. The world of pencil and paper does not directly translate into the binary arithmetic of computers. Silent, small measurement error is introduced when numbers, particularly fractions, are entered into statistical software programs. Even for perfectly valid measure, if such a thing existed, these errors may propagate through statistical algorithms to produce wildly inaccurate statistical results. An understanding of the limits of the computers can help researchers from avoiding these undesirable results.

Summary

As researchers move from the abstract concept to the actual scoring of measures they operationalize, threats to the validity of the measure arise. No social science measure is a perfect indicator of the latent concept it purports to measure. Validity should be considered as a degree, not a dichotomous "valid" or "invalid" label. Validity of measures is constrained by degree of abstractness of the concept. Validity of measures for extremely abstract concepts, such as "love," may be low, while concepts that are well defined and linked to empirical data will have a greater degree of validity.

The flow from the abstract to the real through the process of measurement is not a one-way street, either; it is a dynamic process. An observant researcher will, in the course of scoring cases, refine the operationalization of measures to account for cases that do not neatly fit the typology of the rules of the measure. This may even lead researchers to refine the working definition of the concept. Since many measures that have been formulated by researchers are available in electronic form, the careful process of scoring through data entry may be deemed inefficient by the impatient researcher. But, it is an art form that should not be undervalued, especially in the early stages of research.

Validity Tests

In a perfect world, perhaps, there would be one measure that would be universally accepted as the valid measure for each concept. Inevitably, social science concepts are open to the threats to validity discussed in the previous section. Fortunately, the limitation of imperfection is leveraged into an opportunity in the social sciences to improve research by developing tests for the validity by comparing measures of the same concept or related concepts.

In isolation, the validity of a single measure cannot be guaranteed. This poses problems for emerging research, such as polling of the attitudes of minority groups such as Hispanics and Asians, who until only recently, had a large enough population for which to formulate sampling schemes. The first studies of Hispanic attitudes found less support for immigration policies than their political leaders had expected, leading them as question the validity of the polling. Subsequent polls found the same results.

As a field of research evolves, researchers begin to formulate more indicators to measure the concept they are studying. When subsequent polls of Hispanic attitudes found similar results to the first poll, the overall validity of this finding was strengthened. Similarly, as new measures are developed in other fields, the validity of the new measures, and even remeasurement of existing indicators, may be ascertained by comparing measures against one another.

Three types of validity tests will be considered in this section. *Criterion validity* is the comparison of a measure against a single measure that is supposed to be a direct measure of the concept under study. *Convergent validity* is the comparison of a measure against one or more measures that are also measures of the same concept, but none holds the distinction of being considered as a direct measure. A measure is considered to be valid if, by these tests, the measure is positively correlated with the other measures. If a negative correlation is found, the test offers existence of discrimination. *Construct validity* is final evolution in the tests of validity; it is the degree of how well a measure fits within existing hypothesized relationships with other measures. Here, the normal context of hypothesis testing in turned on its head. The hypothesis is assumed to be correct, and the measure itself is validated by how well it fits within the existing hypothesized theoretical framework.

Criterion Validity

Criterion validity is the comparison of a measure against a single measure that is supposed to be a direct measure of the concept under study. Perhaps the simplest example of the use of the term validity is found in efforts of the American National Election Study (ANES) to validate the responses of respondents to the voting question on the post-election survey. Surveys, including the ANES, consistently estimate a measure of the turnout rate that is unreliable and biased upwards. A greater percentage of people respond that they voted than official government statistics of the number of ballots cast indicate.

To explore the reliability of the measure of turnout, ANES compared a respondent's answer to the voting question against actual voting records. A respondent's registration was also validated. While this may sound like the ideal case of validating a fallible human response to an infallible record of voting, the actual records are not without measurement error. Some people refuse to provide names or give incorrect names, either on registration files or to the ANES. Votes may be improperly recorded. Some people live outside the area where surveyed and records were left unchecked. In 1984, ANES even discovered voting records in a garbage dump. The ANES consistently could not find voting records for 12–14% of self-reported voters. In 1991, the ANES revalidated the 1988 survey and found 13.7% of the revalidated cases produced different results than the cases initially validated in 1989. These discrepancies reduced the confidence in the reliability of the ANES validation effort and, given the high costs of validation, the ANES decided to drop validation efforts on the 1992 survey.

The proceeding example is of *criterion validity*, where the measure to be validated is correlated with another measure that is a direct measure of the phenomenon of concern. Positive correlation between the measure and the measure it is compared against is all that is needed for evidence that a measure is valid. In some sense, criterion validity is without theory. "If it were found that accuracy in horseshoe pitching correlated highly with success in college, horseshoe pitching would be a valid measure of predicting success in college" (Nunnally, as quoted in the work of Carmines and Zeller). Conversely, no correlation, or worse negative correlation, would be evidence that a measure is not a valid measure of the same concept.

As the example of ANES vote validation demonstrates, criterion validity is only as good as the validity of the reference measure to which one is making a comparison. If the reference measure is biased, then valid measures tested against it may fail to find criterion validity. Ironically, two similarly biased measures will corroborate one another, so a finding of criterion validity is no guarantee that a measure is indeed valid.

Carmines and Zeller argue that criterion validation has limited use in the social sciences because often there exists no direct measure to validate against. That does not mean that criterion validation may be useful in certain contexts. For example, Schrodt and Gerner compared machine coding of event data against that of human coding to determine the validity of the coding by computer. The validity of the machine coding is important to these researchers, who identify conflict events by automatically culling through large volumes of newspaper articles. As similar large-scale data projects emerge in the information age, criterion validation may play an important role in refining the automated coding process.

Convergent Validity

Frequently, there are a number of competing measures that are posited as viable indicators of a given concept, but none is given the special status as a direct measure that may be used as a reference to make use of criterion validation. *Convergent validity* is the comparison of different measures for the same definitional concept or different definitional concepts, respectively. When a measure correlates with other measures that have been posited to measure the same definitional concept as the measure in question, this is taken as evidence for convergent validity. Conversely, lack of correlation between measures of different concepts is evidence of discrimination that the tested measure is not related to the other measures analyzed.

Tests of convergent (or divergent) validity will only be as good as the validity of the measures that are being tested. If the measures are weakly valid, then correlations among them may also be weak, unless by chance the biases or randomness in the measures align. Tests of convergent validity are particularly difficult for comparative researchers, who often have only a small number of cases to analyze, and thus the variability of measurement is not evened out by the law of large numbers.

Often, it is understood that a single measure is not a perfect indicator of a concept. Instead, a bundle of indicators is used to develop a measure of a latent concept. For example, the measurement of the concept of political knowledge would not rely on the answer by a survey respondent to a single question. A more accurate measure would incorporate answers to several questions, summed to form an index of political knowledge.

The problem with indexes is that all items in the index may not be equal. Should the answer to "Who is President?" be given the same weight as the question "Who is Postmaster General?" A related concern is that some of the proposed indicators used to construct an index may discriminate from one another. Respondents may or may not have general political knowledge as well as specialized knowledge in specific subjects that matter to them. Further, the list of measures used in such an index must have content validity, lest an important indicator is missing from the measurement. This problem applies beyond survey research, as researchers are often faced with the task of condensing several measures into a single measure fitting on a scale, such as how democratic a country is based on several measures of democracy.

A number of methods have been proposed to determine the convergent validity of measures, and to determine how measures that correlate should be weighted, for example, Chronbach's alpha. Beyond simply constructing indexes, researchers often rely upon factor analysis to estimate the convergent validity between different indicators and develop measures of latent concepts among those indicators that correlate. Factor analysis essentially attempts to identify similar measures and fit them onto a single quantifiable measure of a latent concept. Factor analysis may find more than one grouping and combine discriminated groups of indicators into multiple "dimensions" of different latent concepts. More sophisticated methods exist, such as Poole and Rosenthal's NOMINATE procedure to estimate measures of political ideology of legislators from legislative roll call votes. Similar Bayesian methods have been proposed to cover a wider scope by combining multiple measures into one measure of a latent concept.

Construct Validity

Tests of convergent validity assume that the measures under study are related to the same concept. It may be that two measures correlate not because the two capture the same concept, but that casual relationships exist that drive the correlation. For example, Poole and Rosenthal's

measure of the ideology of members of Congress based on their roll call votes is highly correlated with measures of party unity of the members on roll call votes. The most liberal and conservative members of the legislative parties tend to vote strongly with their party while those in the ideological center may occasionally cross over and vote with the other side. Do these measures capture the same concept of ideology, does one cause the other, or are both caused by some other factor?

Construct validity refers to how well a measure is associated with measures of other latent concepts that are theorized to have causal relationships, or constructs, with one another. The normal rules of inference are turned on their head. Instead of assuming the measure is correct and testing the causal hypothesis, the causal hypothesis is assumed to be correct and the validity of the measure is tested. If the relationships among the measures perform as expected according to the construct, then the measure is deemed to possess construct validity.

An example of construct validation is drawn from Adcock and Collier. Lijphart uses construct validation to justify his classification of India as a consociational democracy, a democracy where all ethnic groups are provided with institutional roles in the government. He first classifies India as a consociational democracy using the criteria he associates with his definition of the concept of consociationalism. He then identifies causal factors that are hypothesized to produce consociational democracies, and notes their presence in India, providing evidence of the construct validity of his classification of India.

The information age provides the fingertips of researchers with numerous measures developed by other researchers developed in the course of their inquiry. Care should be taken in importing precompiled measures into a new line of research, as a measure developed by one researcher may not have construct validity in another line of inquiry. For example, Epstein and Mershon show how Segal and Cover measures developed to represent the political preferences of Supreme Court justices in civil liberties cases may not be valid for judicial processes outside of civil liberties.

Summary

There are limits to the testing of measures against one another to ascertain their validity. First, the measures must be valid indicators of the concepts they purport to measure. Unfortunately, this is exactly the question one is trying to determine through validity tests. If the measures one is testing against are flawed, then the test itself will usually be similarly flawed. Second, if statistics are used, the proper statistical assumptions must be made commensurate with data and hypothesized relationships, and the statistical tools must be reliable enough to correctly estimate the relationships. Finally, for construct validity, the hypothesized theoretical constructs must also be "valid" in the sense that they hypothesize the correct relationships.

Internal and External Validity

The causal relationship of one concept to another is sometimes also discussed in terms of validity. *Internal validity* refers to the robustness of the relationship of a concept to another internal to the research question under study. Much of the discussion in the section under threats to validity and the tests for validity is pertinent to the internal validity of a measure, vis-a-vis another concept with which it is theoretically correlated. *External validity* refers to the greater generalizability of the relationship between two concepts under study. Is the uncovered relationship applicable outside of the research study?

The relationship between one measure and another may be a true relationship, or it may be a spurious relationship that is caused by invalid measurement of one of the measures. That is, the two measures may be related because of improper measurement, and not because the two measures are truly correlated with one another. Similarly, two measures that are truly related may remain undetected because invalid measurement prevents the discovery of the correlation. By now, the reader should be aware that all measures are not perfectly valid, the hope is that the error induced in projecting theory onto the real world is small and unbiased so that relationships, be they findings that two measures are or are not correlated, are correctly determined.

All of the threats to validity apply to the strength of the internal validity of the relationship between two measures, as the two measures must be valid in order for the true relationship between the two, if any exists, to be determined. Much of the discussion of tests of content and convergent validity also applies to internal validity. In addition, researchers should consider the rules of inference in determining if a relationship is real or spurious. Are there confounding factors that are uncontrolled for driving the relationship? A classic example in time-series analysis is cointegration, the moving of two series together over time, such as the size of the population and the size of the economy, or any other measure that grows or shrinks over time. In the earlier example of voter turnout, the confounding influence of a growing ineligible population led researchers to incorrectly correlate a largely invalid measure of decreasing voter turnout to negative advertising, a decline of social capital, the rise in cable television, campaign financing, the death of the World War II generation, globalization, and decline in voter mobilization efforts by the political parties.

External validity refers to the generalizability of a relationship outside the setting of the study. Perhaps

the most distinguishing characteristic of the social sciences from the hard sciences is that social scientists do not have the luxury of performing controlled experiments. One cannot go back in history and change events to determine hypothetical counterfactuals, while physicists may repeatedly bash particles together and observe how changing conditions alter outcomes. The closest the social sciences come to controlled experiments is in laboratory settings where human subjects are observed responding to stimuli in controlled situations. But are these laboratory experiments externally valid to real situations?

In a classic psychology experiment, a subject seated in a chair is told that the button in front of them is connected to an electric probe attached to a second subject. When the button is pushed an increasing amount of voltage is delivered. Unknown to the subject, the button is only hooked to a speaker, simulating screams of pain. Under the right circumstances, subjects are coerced into delivering what would be fatal doses of voltage.

Such laboratory experiments raise the question as to whether in real situations subjects would respond in the similar manner and deliver a fatal charge to another person, i.e., is the experiment externally valid? Psychologists, sociologists, political scientists, economists, cognitive theorists, and others who engage in social science laboratory experiments painstakingly make the laboratory as close to the real world as possible in order to control for the confounding influence that people may behave differently if they know they are being observed. For example, this may take the form of one-way windows to observe child behavior. Unfortunately, sometimes the laboratory atmosphere is impossible to remove, such as with subjects engaged in computer simulations, and subjects are usually aware prior to engaging in a laboratory experiment that they are being observed.

External validity is also an issue in forecasting, where relationships that are based on observed relationships may fail in predicting hypothetical or unobserved events. For example, economists often describe the stock market as a random walk. Despite analyst charts that graph levels of support and simple trend lines, no model exists to predict what will happen in the future. For this reason, mutual funds come with the disclaimer, "past performance is no guarantee of future returns." A successful mutual fund manager is likely to be no more successful than another in the next business quarter.

The stock market is perhaps the best example of a system that is highly reactionary to external shocks. Unanticipated shocks are the bane of forecasting. As long as conditions remain constant, modeling will be at least somewhat accurate, but if the world fundamentally changes then the model may fail. Similarly, forecasts of extreme values outside the scope of the research design may also fail, or when the world acts within the margin of error of the forecast then predictions, such as the winner of the 2000 presidential election, may be indeterminate.

Conclusion

It is worth emphasizing again that no indicator is a perfectly valid indicator of the concept one is attempting to measure. Abstract thought is not cleanly translated to the complexities of the real world. Awareness of the potential pitfalls of validity, outlined in the first section of this article, help researchers to avoid these problems. Still, no measure will be perfect. The tests in the second part of this article help researchers to have some confidence that their measures are indeed valid.

Ironically, the social science profession exists, partially, because no measure is a perfect measure. This limitation of completely valid measurement provides researchers with opportunities to attack theories from different angles, rather than settling on one absolute truth. A concluding word of advice: a healthy dose of skepticism regarding the validity of the measures that one may use in the course of research may unexpectedly open new pathways to viewing the world one studies and hopes to explain.

Web Hyperlink Analysis

Liwen Vaughan
University of Western Ontario, London, Ontario, Canada

Glossary

external link (also called external inlink) An inlink coming from a Web site outside the site being linked to. See the example of Total Link below for further explanation.
inlink (also called backlink) A link coming into a Web page. See the example of Outlink below for further explanation.
internal link (also called as selflink) An inlink coming from a Web page that is on the same site as the page being linked to. For example, the "back to home" link from one of the pages on a site to the home page of the site. See the example of Total Link below for further explanation.
outlink (also called outgoing link) A Link going out from a Web page. Suppose that Web page X has some kind of relationship with Web page Y so that page X has a link pointing to page Y. This link will be an inlink for page Y and an outlink for page X.
total link (also called all link) All inlinks to a Web page regardless of the origin of the links. It is the sum of internal link and external link (see above). For example, page X receives 50 inlinks from other Web sites (external links). Meanwhile, there are 20 internal links (links coming from other pages of this site to page X). Then there are 50 external links, 20 internal links, and 70 total links.

One of most important characteristics, in fact the defining feature, of the Web is the hyperlinks embedded in Web pages. It is these hyperlinks that join otherwise separated Web sites into an interconnected Web. Given their importance, Web hyperlinks have been studied by researchers from various disciplines including computer science and sociology, as well as information science. This article focuses on the social science aspects of Web hyperlinks. It traces the history of hyperlink analysis to citation analysis, a mature area of information science. It then introduces data collection methods for hyperlink analysis. Finally, it reports important findings from hyperlink studies, including both link count and link topology studies. Research in this area is developing rapidly as the Web is still evolving. Findings and theories reported in this article are not as "time tested" as those in other, more mature, areas of social sciences. However, this does not undermine the significance of what is reported, it only highlights the need for an open mind. The constantly changing nature of the Web provides both challenges and opportunities for future research in this area.

From Citation Analysis to Web Hyperlink Analysis

The astonishing development of the World Wide Web (the Web for short) that started in the 1990s and is still continuing in the 2000s propelled the research into this increasingly important area of the modern society. One of the key features that sets Web pages apart from traditional documents is the hyperlinks (links for short) embedded in the Web pages. Indeed, it is these hyperlinks that tie individual Web sites into an interconnected Web. Users of the Web follow hyperlinks to visit related sites while search engines use these hyperlinks to discover new Web sites. Web hyperlinks are significant in a number of ways. The more links to a Web site, (1) the more visible the site is on the Web; (2) the more potential traffic there will be to the site; (3) the more likely it is that the site will be covered by search engines; and (4) the higher the site will be ranked in search results. In addition, there is the "success breeds success" effect in that a site with more links will potentially attract even more links because of its visibility. In short, Web hyperlinks can have social, political, and even economic power.

Since hyperlinks play such an important role on the Web, researchers from a number of disciplines have studied them. For example, computer scientists have investigated ways to use link information for search engine development. Google pioneered the link-based ranking algorithm in which link counts are used in ranking search results. Other major search engines adopted the concept and used link counts in various ways. Meanwhile, social researchers such as sociologists and interdisciplinary researchers such as information scientists examined hyperlinks as a social phenomenon. This article naturally focuses on the social science aspects of Web hyperlinks. It should be noted that research efforts from various disciplines are not mutually exclusive but in fact are mutually beneficial and can inform one another.

While Web hyperlink analysis is a new research area given the relatively short history of the Web, it has roots in citation analysis, a fairly mature area of information science that has regular coverage by major academic journals such as *Nature*. Citation analysis studies the nature of citations that appear in scientific or scholarly literatures. These citations, in the form of references cited in papers, show the explicit linkages between current research and prior work. The main data sources for citation analysis are citation indexes that are produced by the Institute for Scientific Information founded by Eugene Garfield. The commercial success of citation indexes is evidence of the widespread utility of citation-based information. A compelling body of research findings supports the theory that citations can be used as valid indicators of quality, utility, or impact of cited papers although, like other social measurements, they are not a perfect measurement. Citation data have been used to successfully (1) identify influential scholars; (2) map relationships among academic fields; and (3) predict movements of fields and trends in research.

Even in the early years of the Web, researchers pointed out the similarity between citations and Web hyperlinks. The first use of the neologism "sitation" was probably made by Gerry McKiernan on his Cited Sites Web page http://www.public.iastate.edu/~CYBERSTACKS/Cited.htm. Rousseau defined the term (a combination of the words "citation" and Web "site") more explicitly in the context of Web hyperlink analysis. Cronin analyzed in detail the relationship between citation analysis and Web hyperlink analysis and discussed the validity and reliability issues surrounding the link analysis. Ingwersen proposed a new measure, the Web Impact Factor, modeled on the Journal Impact Factor in citation analysis. The Journal Impact Factor is a measure of the frequency with which the "average article" in a journal has been cited in a particular year or period. It is calculated to be the number of current year citations to the citable items published in that journal during the previous two years divided by the number of those items. The Web Impact Factor of Web site X is defined as the number of Web pages with at least one link pointing to Web site X divided by the number of pages in Web site X. The parallel between the Journal Impact Factor and the Web Impact Factor is clear: the former measures the impact of a journal while the latter does the same for a Web site.

Many studies of Web hyperlinks, including those in computer science, draw the analogy between citations and hyperlinks and acknowledge the intellectual inspiration from citation analysis. However, there are also differences between citations and Web hyperlinks. One major difference is that an academic citation represents a more formal connection between the citing and cited articles. Citations, especially those in refereed journals, have quality control. In contrast, Web links can be created by anyone for any reason without any control. It may seem that Web links are random and may not contain much useful information. However, studies have shown that the number and the pattern of Web links can reveal useful information when aggregated over large area of the Web, as described below.

Data Collection for Web Hyperlink Analysis

The two main tools used in data collection for quantitative analysis of Web hyperlinks are Web crawlers and commercial search engines. Qualitative studies of Web hyperlinks use data collection methods that are commonly used in social science research. For example, personal interviews have been used to investigate link creation motivations, while content analysis has been used to classify types of Web links. These methods are covered elsewhere in the Encyclopedia so they will be not repeated here. The two methods for collecting quantitative data are described below.

Using a Web Crawler

A Web crawler is a computer program that automatically traverses Web hyperlinks by retrieving a Web page, then recursively retrieving all Web pages to which that page is linked. A Web crawler can be used to find and record the hyperlinks on the set of Web sites that are being studied. These recorded links can then be analyzed in various ways to discover patterns of links on these sites, e.g., what kind of sites are being linked to (commercial sites vs government sites; domestic sites vs international sites). You can also find out how the sites in the study interconnect to each other. While generic Web crawlers are available for downloading free of charge, specialized Web crawlers have been developed for research projects.

Using Commercial Search Engines

Major commercial search engines, such as Google (www.google.com) and AllTheWeb (www.alltheweb.com), have the capability of searching for links pointing to a particular Web site. For example, the search query "link:www.abc.com" in Google will find links pointing to Web site www.abc.com (i.e., inlinks to site www.abc.com). The search result not only shows the total number of links (e.g., 100) pointing to the site in question but also lists all these 100 sites so that users can visit each site to see under what circumstances the links are being made. Different search engines use different query syntax for link searching. The syntax can be easily found on the search engine's FAQ sheet or "help" page. Some search engines such as AllTheWeb and AltaVista (www.altavista.com) can further distinguish between external links and total links (see Glossary), which is an extra function that is very useful for Web hyperlink analysis.

Comparison of the Two Data Collection Methods

The main advantage of using commercial search engines for data collection is that these engines typically cover a much larger area of the Web (i.e., index more Web sites) than a Web crawler for a particular research project can do. However, the crawling algorithms of commercial search engines are typically proprietary and are not revealed to the general public. The crawling algorithm affects what Web sites get covered and what portion of a site (what pages on a site) gets covered. In contrast, a Web crawler designed for research purposes can be programmed to crawl in the way that is most appropriate for the study. In addition, commercial search engines can only search for inlinks while a research Web crawler can record both inlinks and outlinks (see Glossary). However, if a study only needs inlink data, then it is appropriate to use only commercial search engines. Studies that used both a research crawler and commercial search engines found that data collected from these two sources are correlated.

Validity and Reliability of Data Collected from Commercial Search Engines

Web hyperlink data collected from different search engines will differ because different search engines employ different crawling algorithms and thus index different Web sites. One of the ways to overcome the possible bias of a particular search engine and to improve the quality of data is to use multiple search engines. Data collected from different search engines can be pooled or averaged to achieve a more reliable count of links. Studies that used multiple search engines for data collection have found that the number of links to Web sites reported by different search engines are highly correlated, providing some assurance the quality of data collected from even a single search engine. However, the use of multiple search engines will provide an extra safeguard to the quality of data.

Results from commercial search engines were found to be volatile in that the same search query retrieved different results on different days or even during different times of the same day. This calls into question the suitability of commercial search engines for data collection. Due to the improvement of search engines in general, recent (from late 2001 on) data collection experiences show that search engine performance is fairly stable. However, the stability of a search engine used in a research project still needs to be monitored in data collection.

Web Hyperlinks as an Indicator of the Calibre of Hosting Organization

Numerous studies have been carried out to determine if Web hyperlinks do contain useful information. The main method of this line of investigation is to compare the number of links to Web sites with existing measures of the organizations operating the Web sites. Significant correlations between the two types of data have been found, providing evidence that the hyperlink is a new source of information and Web data mining using this source could be fruitful. This type of research has so far been conducted on the following three types of Web sites, academic Web sites, commercial Web sites, and scholarly journal Web sites, as summarized below. There are also studies that analyze links between universities and other sectors of society, such as industry and government. More of this kind of cross-sector research is needed.

Academic Web Sites

Studies on academic Web sites attempted to establish a positive correlation between the number of links to university Web sites and the scholarly activity of the universities such as research and teaching. Thelwall collected data on the external link counts of university Web sites in the United Kingdom using both a specialized Web crawler and the commercial search engine AltaVista. He then compared the link data with the official U.K. government measure of university research called the Research Assessment Exercise (RAE) and found a positive correlation between the two measures. Studies that investigated university Web sites of other countries such as Australia, Canada, and China also

found significant relationships between inlinks and various university quality measures. Similar correlations were also found when the unit of analysis is individual university departments rather than the whole university.

Commercial Web Sites

There are fewer studies of Web hyperlinks on commercial Web sites than those on academic sites. Reid developed a method for analyzing the Web's hyperlink structure for gathering business intelligence information. The first step of the method is to conduct a link search to identify the implicit business community surrounding a particular company or product. The Web sites of this community can then be analyzed to obtain business information.

Vaughan and Wu investigated the Web sites of China's top 100 information technology companies and found significant correlation between counts of links (both external link and total link) to a company's Web site and the company's business performance measures such as revenue and profit. A follow up study that applied the same research process to top U.S. information technology companies found the same correlation. Even more remarkable is that the two sets of correlation coefficients for the two countries are very close although the two groups of Web sites are very different in terms of characteristics such as age. Further analysis that examined Web site age as a possible confounding variable confirms that the correlation found is genuine rather than spurious.

Journal Web Sites

Since Web hyperlink analysis is rooted in citation analysis and there is a direct analogy between Web hyperlinks and citations in journal articles, as described above, it is natural to analyze links to journal Web sites. While early studies did not establish a relationship between links to journal Web sites and the quality of the journal, probably due to limitations of the methodology employed and the lack of maturity of the Web sites, more recent studies did find a significant correlation between the two, where the quality of journal is measured by the Journal Impact Factor described in the first section of this article. Furthermore, the Vaughan and Thelwall study found that the ages of Web sites correlated with the numbers of inlinks in that older Web sites received more links to them. The study also found that sites containing more detailed content attracted more links.

Reasons for Web Linking

All the correlations reported above, although statistically significant, were not very high and outliers that did not fit the general pattern existed. It is very important to study the reasons or motivations for linking to gain a better understanding of Web hyperlink phenomenon. Such studies are qualitative in nature, which complement the quantitative link count studies reported above and shed light into the correlations found. However, link creation studies have lagged behind although most correlation-based quantitative studies did some basic qualitative analysis of anomalies. The most comprehensive link creation motivation study so far was conducted by Wilkinson, Harries, Thelwall, and Price. A random sample of 414 links among university Web sites in the United Kingdom was taken and classified into various types based on the reasons for linking. The study found that over 90% of links were related to academic activity in some way, including research and teaching. There are other studies on the reasons for Web linking. Combining results from these studies with the link count correlation studies, it can be said that Web hyperlinks could be an indicator of the caliber of the organization operating the Web site. Links to academic sites indicate the quality of the universities while links to commercial sites reflect the business performance of the companies. However, the word "indicator" here should be interpreted in the context of correlation rather than causation. Studies so far have demonstrated correlation but no causation has been established.

Analyzing the Topology of Web Hyperlinks

While the studies reported above focused on the number of links to Web sites, the topology (i.e., structure) or the pattern of Web hyperlinks has also been examined resulting in important findings.

Social Network Analysis Using Web Hyperlink Data

Social network analysis, a research method developed primarily in sociology and communication science, focuses on patterns of relations among people and among groups such as organizations and states. As the Web connects people and organizations, it can host social networks. Therefore, social network analysis has been used to study Web hyperlinks. Garrido and Halavais studied the networks of support for the Zapatista movement, a contemporary social movement in which the Internet played a central role. The study collected data on links to the Zapatista Web site and mapped these links into a Zapatista network on the Web. This network of Web sites provided a unique insight into the character of the Zapatista's phenomenal success. Park, Barnett, and Nam examined Korea's 152 most popular Web sites and defined the affiliation among the Web sites based on

interdomain hypertext links. They then applied cluster analysis to reveal a hyperlinked network in which financial Web sites were found to be in the most central position.

The "small-world" theory, which stems from research in social network analysis over 30 years ago, deals with the short distances between two arbitrary persons through intermediate chains of acquaintances. The theory has been applied to the Web environment where the number of intermediate acquaintances between two persons is replaced by the number of links along directional link paths between two Web sites or Web pages. In a "small-world" network, such as in a Web network, it is sufficient to have a very small percent of links to function as "shortcuts" connecting "distant" parts of the network. Many studies have been conducted on the subject including a Ph.D. thesis. There are a number of applications of the "small-world" theory on the Web including analyzing Web communities and examining cultural and social currents and formation. For example, Björneborn used the "small-world" theory to identify central connectors, gatekeepers, and cross-disciplinary contacts in academic Web spaces. Furthermore, the "small-world" phenomena affects the speed and exhaustivity with which Web crawlers can discover and retrieve Web pages when following links from Web pages to Web pages.

"Success Breeds Success" Phenomenon of Web Hyperlinks

Numerous studies have discovered and confirmed the "success breeds success" (also called "preferential attachment") phenomenon of Web hyperlinks. When the number of inlinks is plotted on the Y axis and the number of Web sites plotted on the X axis, the result is a hyperbolic curve with very long tails (see the work of Rousseau for an example). This means that a small number of Web sites receive many links while the majority of Web sites attract very few links. The underlying cause of this phenomenon has been explained by the fact that the more inlinks a Web site has, the more visible the site is, and thus the more likely it is that the site will receive further links. This "success breeds success" or "cumulative advantage" phenomenon is similar to the rich-get-richer phenomenon in the society in general.

Identifying Web Communities Based on the Hyperlink Structure

The interconnected Web pages can be viewed as a "graph" in mathematical graph theory where the Web pages can be seen as "nodes" and the hyperlinks among pages seen as "edges" in the graph theory terminology. It is beyond the scope of this article to discuss the details of the graph theory. Instead, a brief description of the work on community identification based on hyperlink structure is provided to illustrate the potential of Web hyperlink analysis. A Web community can be defined, in nontechnical terms, as a group of people whose Web pages share a common interest. The identification of Web community is useful not only for improving Web searching by displaying similar pages together but more importantly, from a social science point of view, to study social communities. Web link data have been used successfully to identify Web communities and a faster algorithm has been developed recently to make this method more viable.

Glossary

framing (or priming) Activating different mental constructs to see how they influence responses. In surveys, this usually involves altering question wording or the information accompanying questions.
Internet Term used to capture both e-mail and World Wide Web (WWW) applications.
random digit dialing (RDD) A method of number selection that includes all possible telephone numbers including unlisted numbers and new numbers. RDD often uses information about which interchanges will likely contain residential numbers as a basis for selecting a sample of telephone numbers.
sample The units from the population that are drawn from the sampling frame to be included in the survey.
sampling frame A list of sampling units from which the sample can be selected.
sampling units Groupings of the target population that cover the whole population but do not overlap—every element of the population belongs to one and only one sampling unit.
self-completion survey A survey completed by the respondent without assistance from an interviewer.
target population The entire set of units (whether individuals, households, organizations, institutions, geographic entities, or others) for which the researcher wants to make generalizations or inferences.
World Wide Web (WWW or Web) A system of extensively interlinked hypertext documents.

The World Wide Web (WWW) or Internet has recently been recognized as a valuable instrument for conducting surveys. Low costs, rapid turn around, access to a vast geographically diverse pool of potential respondents, and the ability to present complex graphical material make the Web appealing as a new survey mode. While this new survey mode may offer many opportunities, its strengths and weaknesses are still being studied. As the Internet develops—especially as Internet access widens to include a more representative cross-section of the adult population—the applications for Web-based surveying are likely to flourish. The future of Web-based surveys will undoubtedly be hotly debated, but an understanding of the fundamentals of Internet surveying is a prerequisite for such a debate.

Introduction

What Are Web-Based Surveys?

Web-based surveys are not a new creation. Rather, the World Wide Web simply provides a new medium through which survey data can be collected. Surveys published on the Web can be accessed by potential respondents who have a computer with an Internet connection and Web-browsing software. A variety of computer programs and languages, such as the Hypertext Markup Language (HTML), are used to present surveys and collect data. To participate in these surveys, respondents are usually required to visit a particular Web address or universal resource locator (URL). Once respondents complete the survey and submit their responses, data is transmitted electronically to the researcher for analysis. Early Internet surveys were generally distributed by e-mail; but, while e-mail facilitates the distribution of surveys, e-mail responses cannot be automatically submitted to a database. This article focuses primarily on Web-based surveys,

since this new survey mode appears to offer more opportunities that e-mail surveys.

The flexibility of HTML and related computer languages allows the deployment of diverse types of surveys. Exploiting the graphical capabilities of Web browsers, such as Internet Explorer or Netscape, Web-based surveys can incorporate images and multimedia material. Web-based surveys can also be programmed to provide respondents a tailored experience. Like other types of computer-assisted surveys, Web-based surveys can be designed to automatically skip questions that are irrelevant based on responses to previous questions, or they can randomize the order of questions or response options.

A key feature of Web-based surveys is that they do not require interviewers. Like mail surveys, Internet surveys are self-administered. Respondents complete the survey at their leisure and transmit their responses electronically. This process makes Internet surveying relatively low cost, reduces data entry requirements, eliminates the possibility of transcription or data entry errors, and greatly accelerates survey administration. As a result, Internet surveys are proliferating at an amazing rate. In 1999, Kaye and Johnson identified over 2000 Web-based surveys using an informal Yahoo! (www.yahoo.com) search.

How and Where Web Surveys Are Used

Web-based surveys have been used for a variety of different purposes; these surveys have been used to collect opinion data, demographic information, and purchasing behavior, to name a few. Web-based surveys are used by academics, market researchers, corporations, the media, and many others. Topics range from political polls to surveys of illicit drug dealing behavior. Web-based surveys are used for marketing purposes for public opinion polling and to study the behavior and beliefs of Internet users.

Internet searches reveal a large number of companies that offer Web-based survey services and software. Existing research companies expanded their services by offering Internet-based surveys while other new companies entered the field offering unique Web-based technology for surveys. Academic institutions are also using the Internet to contact respondents. Some prominent Internet survey groups include Harris Interactive, Knowledge Networks, the Internet Survey of American Opinion, the GVU WWW User survey, and Greenfield On-line. Although coverage error and nonresponse bias are a concern for Web-based surveys, several surveys have performed well on the objective measure of election forecasting; in the 2000 presidential election, the Harris Interactive poll did better at predicting state level presidential votes than similar telephone surveys.

Since Web-based surveys generate a large number of responses and can be easily programmed to provide respondents a tailored experience, they are optimal venues for testing how the wording of questions affects responses. By providing different respondents with different question wording or accompanying text, researchers can examine how framing or priming affects responses. Rapid turn around, low costs, and high response volumes make Web-based surveys an attractive medium for this type of survey experimentation.

Web-based surveys also promise to democratize the process of survey data collection: "Not only can researchers get access to undreamed numbers of respondents at dramatically lower costs than traditional methods, but members of the general population too can put survey questions on dedicated sites offering free services and collect data from potentially thousands of people" (from Couper). Given the popularity and accessibility of Web-surveying, it is important that we understand the fundamental issues related to Internet surveying. Not all Web surveys are equal. The validity and value of Web surveys will depend on how the survey is designed and implemented. Recognizing the strengths and weaknesses of Internet surveys will ensure that Web surveys are designed appropriately and that results are considered carefully.

Article Overview

This article examines some of the fundamental issues about using the Internet as a survey tool. In addition to considering the practical issues involved in implementing Web-based surveys, this paper presents an overview of the different types of Web-based surveys. Methodological issues such as coverage and sampling are examined. In an attempt to facilitate the task of evaluating and improving Web-surveys, a typology of Web-surveys is also offered. The last section contains some final details about implementing Web surveys.

Methodological Issues

While the Internet or WWW offers a new and exciting mechanism for the collection of survey data, this new survey mode faces many important methodological issues. The validity of survey results depends on how well the survey is designed and the techniques used to obtain the sample. Cochran lists the following principle steps that should be considered in any sample survey:

- Determine the objectives of the survey.
- Define the population about which information is wanted (*target population*).
- Determine the relevant data to be collected.
- Specify the degree of precision wanted from the sample.

- Determine format of the survey to be implemented.
- Define the sampling frame from which a sample is to be drawn.
- Divide the population into sampling units and select a sample from among these units.
- Organize the survey administration
- Summarize and analyze the data.

Careful implementation of these steps helps to ensure that survey results are valid and generalizable. In the context of Internet surveying, there are three components of survey sampling that may introduce problems. These issues are coverage error, sampling issues, and nonresponses bias. Recognizing the concerns surrounding these issues, adjustments in survey objectives, and administration may be necessary.

Coverage Error

Coverage error is the deviation between the sampling frame and the target population. The degree to which coverage error is an issue depends on the population about which we wish to make general statements. For example, if we are interested in sampling from a population for whom we have e-mail addresses there is no coverage error because we can use the list of e-mail addresses as the sampling frame. If, however, we are interested in surveying a large group, such as all eligible voters in the United States, the coverage error is a significant concern because not all voters have Internet access, nor is there a list of e-mail addresses for this population.

In order to develop an appropriate sampling frame for Web-based surveys, we must be able to identify the units to include. In some cases, the population and sampling frame are known with certainty: examples of these types of situations usually involve smaller populations, like groups with known e-mail addresses, visitors to particular Web-sites, or the like. In these circumstances, it is possible to easily identify all members of the target population and ensure that they have a positive probability of being sampled.

Unfortunately, there are many circumstances where the population is not known with certainty, especially if we are interested in studying large populations like the universe of Americans adults. For many large populations of interest a simple list—for the sampling frame—does not exist. For example, there is no general list of e-mail addresses for the adult American population. Web-based surveys of large groups, like all eligible voters, is further complicated by the fact that not all potential respondents have computers or Internet access. According to NUA Ltd. (www.nua.ie/surveys/how_many_online/index.html), in February 2002, approximately 544.2 million people (8.96% of the population) had Internet access throughout the world. Internet penetration is the highest in North America; in the United States, approximately 164.4 million people (58.5% of the population) had Internet access. While Internet penetration rates continue to grow, we are a long way from being able to access all potential respondents if the target population is the entire American population.

Sampling

Despite the difficulties in developing a complete sampling frame of Internet users, researchers have pursued a variety of ways to obtain Internet survey responses. Since no established methods exist for recruiting survey respondents, a variety of approaches have been considered to obtain Web-based survey samples. Couper identifies two basic approaches to Web-survey recruitment: probability and nonprobability surveys.

Probability approaches involve the researcher identifying the population, developing a sampling frame, and using the sampling frame to generate a random research sample. Using this approach, the probability that any unit of the population will be sampled is known and thus the sampling error can be calculated. Probability-based Web-surveys can be used to make generalizations about the population upon which they are based.

Two basic approaches have arisen to conduct probability-based surveying on the Web. One is to restrict the population to only Internet users and to devise methods of randomly selecting Internet users into a sampling frame. The second is to use other approaches to contact a broader spectrum of potential respondents (i.e., telephone) and then recruit them into a pool or panel of potential survey respondents.

The other types of Internet surveys, based on nonprobability approaches, are probably the most ubiquitous surveys on the Internet. These surveys make no attempt to identify the sampling frame or randomly select respondents. These types of Web-survey are frequently used when it is difficult to identify members of the target population or contact a probabilistic sample from the population. Any inferences made about population parameters from nonprobability surveys are potentially problematic.

For surveys of the general American population, probability-based sampling over the Internet is complicated. While the same problem arose in telephone surveying, the development of technologies like random digit dialing (RDD) enabled researchers to approximate random samples of the American population. Assuming that most households have a telephone and given that RDD techniques ensure that each residential phone number has an equal probability of being drawn, RDD generates a random sample of potential respondents. Unfortunately, this method does not generalize directly to the Internet.

First, over 95% of households have telephones but less than 50% of households have Internet access (from the U.S. Department of Commerce). In addition, since e-mail addresses (the Web equivalent of telephone numbers) involve more than simple seven-digit numerical combinations, it is extremely difficult to randomly generate valid e-mail addresses. Furthermore, even if random generation of e-mail addresses were possible, sending large quantities of unsolicited e-mail (spam) is frowned upon. As a result, contacting a random sample from a large population for which no contact list exists is difficult and may not generate representative samples even if we condition on having Internet access.

Until Internet access becomes universal and all-inclusive e-mail directories are developed, obtaining probability samples using only Web-based tools will be difficult. To overcome this, many researchers have implemented multimode surveys. Respondents are often contacted by telephone and asked to participate in a Web-based survey. Knowledge Networks claims to have solved the problem of sample representativeness by providing prerecruited pools of survey respondents Internet access in exchange for completing regular Web-based surveys. Alternatively, researchers have used telephone surveys to supplement Web-based surveys. For example, Harris Interactive undertakes a telephone survey in order to develop appropriate weights for their Web-based survey responses.

Nonresponse Bias

The methodological concerns do not end once a sample of potential respondents has been contacted. Error or nonresponse bias may also be introduced because some members of the selected sample are unable or unwilling to complete the survey. The extent of bias depends on both the incidence of nonresponse and on how nonrespondents differ from respondents on variables of interest. The effect of nonresponse is to confound the behavioral parameters of interest with parameters that determine response. Nonresponse bias is not unique to Internet surveys but the potential problem is quite severe for Web-based surveys that have low response rates and nonrandom recruitment procedures.

Web-survey nonresponse might be aggravated because potential respondents encounter technological difficulties. Internet respondents need to have basic literacy skills, know how to surf the Web, be able to use the mouse to select response options from menus, and know how to type answers in the fields provided. Furthermore, technological hurdles, such as browser incompatibility and slow Internet connections, will influence whether a potential respondent completes a survey. Since Internet access tends to be correlated with demographic characteristics such as income and age, Internet survey data will provide biased results if these demographics affect the variables of interest.

Several methods exist to account for selection bias in survey samples but these corrections are complicated by the fact that Web-based surveys provide very little information about nonrespondents. Techniques such as propensity weighting or other simple weighting schemes may be useful in improving the representativeness of Internet survey samples. Simple weighting schemes may be useful in minimizing these biases and errors if there is a strong relationship between the weighting variable and the data in the survey. Supplementing Web surveys with telephone surveys can be used to develop appropriate weighting schemes.

While nonresponse bias is a significant concern for Internet surveys, recent research makes apparent the fact that traditional methodologies, like RDD telephone surveys, may also be problematic. Alvarez *et al*. report data from a telephone survey in which they began with 13,095 residential telephone numbers to obtain 1500 complete interviews. Of these, 3792 phone numbers were bad in some way, 5479 produced no answer or complete interview, and 1469 produced a valid contact but the survey interview was refused. As few telephone survey studies report statistics like these, it is impossible to characterize the extent to which contemporary telephone survey techniques produce representative samples. The Alvarez *et al*. evidence suggests that RDD techniques do not necessarily provide truly random samples. Obtaining random samples from large populations may be difficult over the Internet but telephone surveys are not a panacea.

Web-Survey Typology

Probability vs Nonprobability Surveys

As discussed above, Web surveys can be classified based on how they generate respondent samples. The two basic ways of recruiting respondents involve probability or nonprobability approaches to Web surveying.

Couper identifies at least four different types of probability-based Web surveys:

1. Intercept-based surveys of visitors to particular Web-sites.
2. Known e-mail lists.
3. Prerecruited panels.
4. Mixed-mode survey designs.

The first, the intercept-based approach, is based on interview techniques used in exit poll surveys or many types of market research. With a sampling frame being all visitors or users of a particular Web site, the sample is some randomly selected set of visitors who are asked to participate in some form of survey. Known e-mail lists are

a second form of probability-based Web survey. When the population is one that has universal Internet access and for which a directory of e-mail addresses is available, Web-based surveys can be extremely useful; student, university faculty, or employee surveys are examples of known e-mail list surveys. These two types of surveys can minimize sampling and coverage errors.

The remaining approaches for probability-based Web surveys are based on already having a probability sample and then using this sample to obtain Web-survey subjects. In the prerecruited panel approach, researchers use other techniques of probability sampling, like RDD telephone surveys, to recruit Web-survey samples; such an approach works well for studies of the Internet-using population if respondents with Internet access are willing to provide their e-mail addresses and participate in subsequent Web surveys. Knowledge Networks (www.knowledgenetworks.com) extended this concept by offering a random sample of respondents' Internet access in exchange for a commitment to participate in on-going Web-based surveys. Finally, mixed-mode approaches simply offer Web surveys as one of a multitude of modes for their participants to use (in addition to telephone or other modes).

Nonprobability Web surveys are probably the most ubiquitous surveys on the Internet. There are three types of nonprobability Web surveys identified by Couper:

1. Entertainment surveys.
2. Self-selected surveys.
3. Volunteer survey panels.

The first, entertainment surveys, are found all over the Internet. Generally they are not intended for scientific surveying, but for the entertainment of visitors to Web sites. Self-selected surveys are those on the Internet that give visitors to a Web site the opportunity to participate in a survey; thus, only visitors to the site are possible subjects and only if they actively initiate the interview. The third type of nonprobability Web survey is volunteer survey panels, where respondents are recruited on the Internet through advertisements of various types. Harris Interactive (vr.harrispollonline.com/register/main.asp) and Greenfield Online (greenfieldonline.com) are perhaps the best known volunteer panels, but the technique is used by many other survey researchers. Volunteer panels require that prospective respondents go to a particular Web site and provide some information about themselves (including their e-mail address). This data is then maintained in a database from which respondents can be sampled for participation in subsequent Web surveys. Although volunteer panels are not based on probability sampling they are more likely than the other nonprobability surveys to attract a representative sample.

Nonprobability Internet surveys are not based on rigorous sampling procedures, raising concerns about the validity of inferences drawn from them. However, nonprobability Internet survey samples can and are being used in situations where researchers desire to exploit within-sample variance in a situation where statistical power can be maximized. For example, Internet survey samples can be used to examine priming or framing, especially studies that might involve graphical or multimedia materials. In such designs, thousands or tens of thousands of subjects might be included in a potential study and, as long as these subjects are assigned to control and experimental groups using some type of probability assignment protocol, this could produce powerful experimental results.

Web-Survey Formats

Examining the different Web-survey formats is also enlightening. While Web surveys involve many different topics, there are only two main formats for presenting a Web survey: interactively or passively. These two formats are aesthetically different and have distinct advantages and disadvantages.

Figure 1 contains an example of a typical interactive survey. As illustrated in this figure, interactive surveys are presented screen-by-screen. By clicking on a button, like the "to continue" button in Fig. 1, respondents can go to a new question on a new screen. This allows the data from the question to immediately be electronically transmitted to the surveyor ensuring that data from partially completed surveys is maintained. However, this format may make it difficult for respondents to review and correct their answers. Interactive surveys can also automatically skip questions which are determined to be irrelevant to the respondents based on how they answer previous questions. For example, if respondents indicate that they do not have children, all subsequent questions related to children can be automatically skipped. A drawback of this design is that respondents do not see the survey in its entirety and therefore cannot easily determine its length. To compensate, a progress indicator can be used to inform the respondent how much of the survey remains to be completed. Another difficulty with interactive surveys is that they may require special software, such as Java, potentially making it difficult for respondents with older, less powerful computers and Web browsers to respond.

Passive survey designs involve presenting the entire survey at once. Figure 2 displays the first part of a passive survey. The bar on the right-hand side of this figure indicates that respondents can scroll down on the page to view the rest of the survey. The data from passive surveys is transmitted once the respondent has completed all questions and clicked a submit button. An advantage of passive surveys is that respondents can easily browse through questions and review their responses before

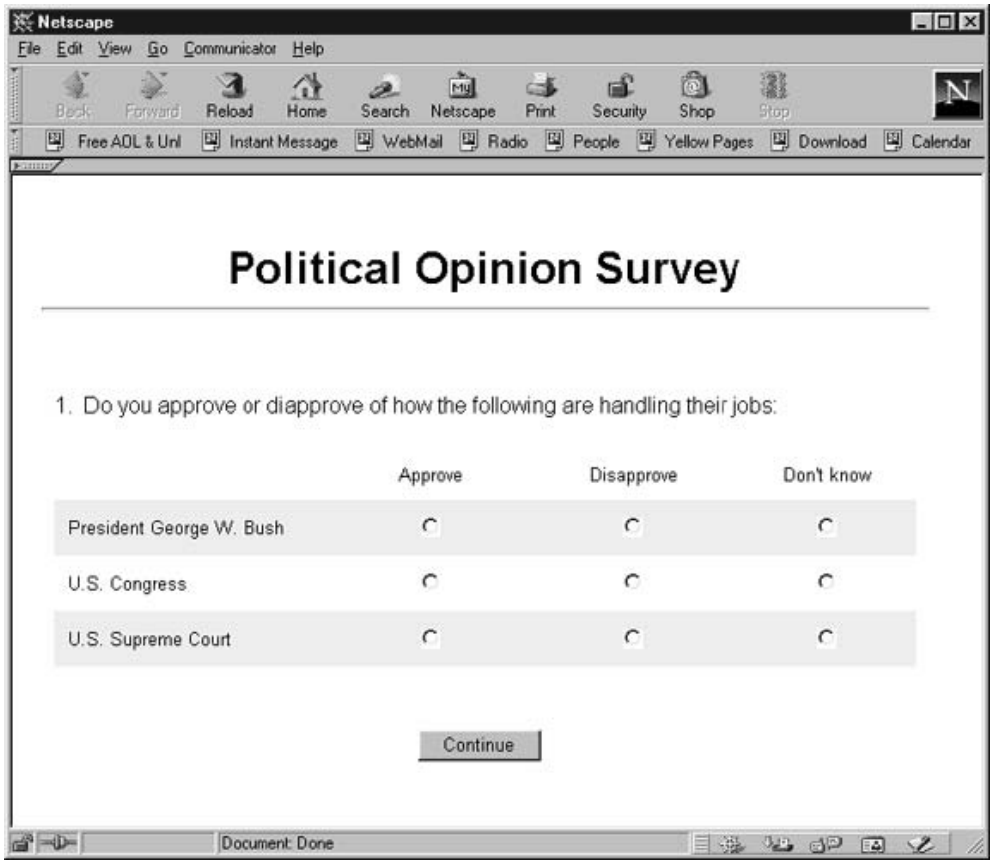

Figure 1 Example of an interactive style Web survey.

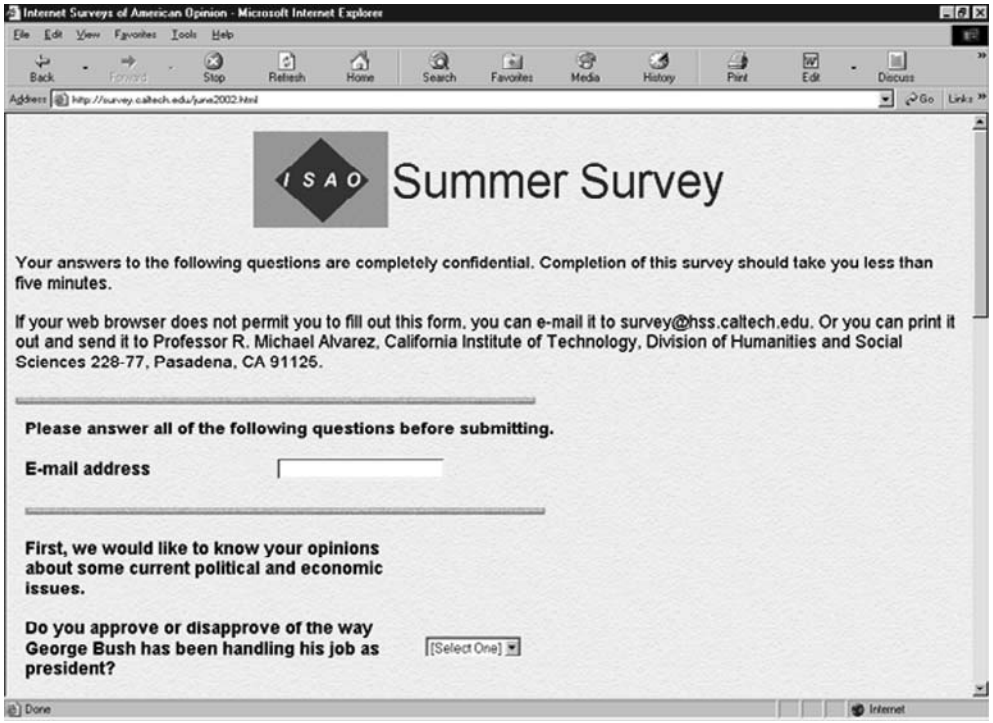

Figure 2 Example of a passive style Web survey.

submitting. These types of Web surveys are also easy to produce and easy to access so technical difficulties are less likely.

In addition to these two basic formats, the appearance of a Web-based survey also depends on how question response options are presented. There are four distinctly different ways to present response options: drop-down boxes, radio dials, check boxes, and open-ended boxes. Figure 1 contains an example of radio dials while Fig. 2 illustrates both open-ended boxes and drop-down boxes. Drop-down boxes appear in the questionnaire as a box with a downward pointing arrow—clicking on this arrow displays the list of response options and allows respondents to select from the list provided. Drop-down boxes are convenient for long lists of items since the response options are hidden. Radio dials, on the other hand, display all the responses options and require the respondent to click in the circle corresponding to their choice. Both drop-down boxes and radio dials are usually used when only one response must be selected from among the options provided. When respondents are allowed to select more than one option from a list, check boxes are the appropriate question format—respondents click on all the boxes that correspond to their answers. Finally, open-ended boxes allow respondents to type their responses in the space provided. As with other survey formats, open-ended question boxes can be useful when the associated question does not have responses that can be conveniently listed.

Developing Web Surveys

Respondents

Web-based surveys are only useful if they actually generate data, thus recruiting respondents is a priority. As discussed in the section on Web-survey typology, there are many different ways to recruit subjects. The choice of recruitment method will of course depend on the objectives of the survey. If the target population can be identified and easily contacted then producing probability-based Web surveys should be feasible. If, however, the intended target population is not well defined or readily contactable over the Internet, nonprobability respondent recruitment methods may be necessary. Inferences made about population parameters from nonprobability surveys are potentially problematic although several techniques have been proposed to improve the representativeness of Internet surveys.

Alvarez *et al.* discuss two prominent methods for recruiting respondents over the Internet. The first involves Web advertisements. Advertisements on various Web sites or newsgroups encouraging people to complete the Web survey is a fairly effective way of obtaining a large nonprobability sample of respondents. Another method to recruit respondents is through subscription or coregistration procedures. This involves asking individuals registering for another service whether they would like to provide their e-mail address and participate in Internet surveys. Once respondents provide their e-mail addresses, they can be contacted by e-mail to participate in Web-based surveys.

Web-Based Survey Panels

Because recruiting respondents over the Internet can be somewhat complicated, survey panels are popular. Rather than asking respondents to complete a single survey, Web-based survey panels recruit subjects to participate in a series of surveys. In order to obtain probability-based subjects, potential respondents are often initially contacted by telephone. Once respondents agree to participate in a survey panel, they are contacted by e-mail when they are required to complete a new survey. Using panels, researchers can draw samples from the registered respondents in order to undertake studies of specific subpopulations. Knowledge Networks claims that their Web-based survey panels is particularly effective for market research. Panels also offer the opportunity to examine temporal changes in respondent behavior and beliefs.

Researchers are currently studying the long-term effectiveness of Web-survey panels. Although the concept is relatively new, studies to date do not indicate that extended participation in Internet panels affects respondent behavior. However, preliminary data indicates that response rates do tend to decline with panel tenure. A significant problem for many Internet panels is that participants are frequently unreachable by e-mail because they have changed e-mail addresses or there are technical problems. These issues need to be continually examined especially for long-standing panels.

Creating the Survey

An advantage of Web-based surveys is that they are relatively easy to conduct. All that is needed is a Web site and some basic Web programming skills. Many surveys are created simply using Hypertext Markup Language (HTML); there are dozens of HTML editors available and they are becoming increasingly sophisticated and easy to use. Data from surveys can be captured either by programming the form to e-mail the data to a specified address or through a common gateway interface (CGI) script. Several HTML development packages automate the process of developing CGI scripts necessary to capture data from HTML forms. Internet survey companies have even developed computer programs that automatically create surveys.

Despite the fact that Web-based surveys are easy to implement, their effective use requires an understanding

of the methodological issues presented above. While Web surveys have many potential uses, making general statements about large populations based on Internet survey results is currently problematic. The Web opens up a whole new realm of survey possibilities, but it is important to evaluate surveys based on the fundamental criteria outlined in this article.

Glossary

empirical social research Obtaining and analyzing data on social topics using a variety of observational techniques and quasi-experimental study designs.
methodological individualism A theoretical principle that holds that groups, institutions, collective beliefs, and supra-individual entities can be explained only with reference to the actions, beliefs, attitudes, and motivations of individual human beings.
social survey Quantitative inquiry on a social topic using a standardized instrument or method applied to a sample of units, respondents, or informants.
verstehen (understanding) Weber's method of explanation in the human sciences.

In several episodes over his intellectual career, Max Weber engaged in empirical social research, experimented with a variety of techniques of inquiry, and reflected on the importance of individual and group research by scholars to supplement data from census bureaus and from historical studies. His most concentrated effort came in 1908 when he investigated industrial labor in a textile factory and explained the output of workers in terms of psychophysics (e.g., fatigue), cultural influences on work habits, social dynamics (e.g., peer solidarity), and instrumental goals (e.g., wages and earnings). His empirical work and methodological writings did not achieve the influence that his comparative historical and cultural studies and his theory of action did.

Overview of Weber's Work

Max Weber was born in 1864 and died in 1920. He was an influential comparative historian, legal scholar, economic historian, sociologist, historian of religion, and social scientist. Most of his professional life he was a private scholar in Heidelberg, although for short spells he lectured at various German universities. He was active in a number of German scholarly and policy associations, and he co-edited the *Archiv fur Sozialwissenschaft*, where he also published many of his essays.

Weber took on the big questions and themes in the social and historical sciences of the late 19th century. The biggest question was the origins of capitalism in early modern Europe and, more broadly, the distinctive causes and trajectory of Western rationalism that enabled the West to exit from tradition into modernity and to dominate non-Western civilizations. Though he remained indebted to Marx in many ways, he challenged the dominant Marxian historical materialism and argued for the unintended but powerful consequences of religion for other, including economic, institutions. Using the comparative historical method and relying on the specialized historical scholarship of his time, he also wrote specific essays and monographs on the evolution of the city as a distinct institution, the decline of the social and economic system of the Roman–Mediterranean world, the Puritan religion's impact on the saints' worldly activities (which he termed "inner worldly asceticism"), the economic ethic of world religions, political sociology, social stratification, nationalism, the Russian revolution of 1905, the stock market, socialism, the sociology of music, and other topics.

Second in importance was Weber's effort to create the foundations for a single social science, and to counteract the differentiation of the social and historical sciences into specialized and splintered disciplines. In *Wirtschaft und Gesellschaft* he anchored that venture on a theory of action whose primitive elements describing individual human actions are combined and elaborated into

aggregate level and relational concepts such as authority, legitimacy, state, and bureaucracy, using the principles of methodological individualism.

Third, he wrote several methodological essays on concept formation; explanation in the human sciences ("verstehen"); theoretical concepts and models ("ideal types"); the relation of unique events and individual actions to general explanations; the fundamental chasm between fact and value and between science and politics; the role of physical, biological, and hereditary factors in explanations of human behavior and institutions; the impact of great men ("charismatic leaders") on social change; the problem of intersubjectivity in understanding and interpreting human actions; causation in human affairs, and other topics in the philosophy of social science and the logic of social inquiry.

The fourth and the least known, indeed sometimes ignored, part of Weber's intellectual output was his empirical studies dealing with social policy issues such as the condition of farm workers in East Prussia, and the condition of life and productivity of industrial workers, together with methodological guidelines on how to design and conduct such empirical research. German social scientists in the Verein fur Sozialpolitik came to the conclusion that the facts and figures churned out by statistical agencies, which had stimulated the field of "moral statistics," based as they were on official documents such as birth and death registration, crime and suicide records, trade and production figures, public health records, and the like, were not always suited to answering questions scholars and policy analysts were interested in. They organized social surveys for obtaining additional data. Weber was an active participant in a major 1891–1892 Verein social survey on agricultural labor in East Prussia and a follow up survey in 1893 by the Evangelical Social Congress. He was the principal intellectual inspiration behind the Verein's 1909–1911 survey of industrial workers which failed in the end because of a trade union boycott. In preparation of the survey, in the summer of 1908, Weber undertook his most intense empirical study at the textile factory of a relative where he had complete access to personnel, production, and earnings records as well as to the workers themselves in the plant as a participant observer. At the founding of the German Sociological Society in 1910, which Weber conceived as an association for coordinating collective research projects, he outlined plans for a sociology of the press using content analysis and an empirical investigation of voluntary associations "from the bowling club ... to the political party and to the religious, artistic and literary sect." However, these plans were not implemented.

Weber's commitment to empirical social research ran deep. He labored to teach himself Russian just so he could read the Russian press on the revolution of 1905. He spent hours doing statistical calculations on factory workers' production records, and told university students in his well-known "Science as a Vocation" lecture that "No sociologist ... should think himself too good, even in his old age, to make tens of thousands of quite trivial computations ... perhaps months at a time. One cannot with impunity try to transfer this task entirely to mechanical assistants if one wishes to figure out something ..." He declined to join the Heidelberg Academy of Sciences in 1909 because he believed its resources would be better spent on a social science research institute for undertaking social surveys and postdoctoral field work.

Weber's Logic of Social Inquiry

In his methodological essays, "verstehen" (usually translated as "understanding" but sometimes better rendered as "interpretation") plays a central role. It is Weber's term for what the Enlightenment philosophers and Scottish moralists called sympathy or fellow feeling. Weber put it most succinctly when he wrote that "one does not have to be Cesar in order to understand Cesar, otherwise the writing of history would make no sense at all." "Verstehen" solves the problem of intersubjectivity between the historian–social scientists and their human subjects, and also allows them to make sense of the transactions among the human subjects themselves.

"Verstehen" is also the justification for methodological individualism in social science, because the cognitive, emotional, attitudinal, and motivational processes of human action are attributes of individual human persons and not of collective entities such as armies, states, social classes and the like, except in a metaphorical sense: "Interpretative [verstehende] sociology considers the individual and his action as the basic unit, its 'atom' ... the individual is the sole carrier of meaningful conduct ... for sociology, such concepts as 'state', 'association', 'feudalism', and the like, designate certain categories of human interaction. Hence it is the task of sociology to reduce these concepts to'understandable' action, that is, without exception, to the actions of participating individual men" (Weber, 1956 [1921]). For purposes of simplification, Weber recognized that collective entities acting in a coordinated and homogeneous manner could be attributed an interest, mentality, motive, or disposition. As well, if collective entities have meaning for the minds of individual persons, as something actually existing, these collective representations can have causal influence on their actions.

In keeping with his methodology, Weber explains the stability of custom, a group property, in terms of individual actions and interactions: "the stability of custom rests on the fact that those who non-conform are maladapted, i.e. they have to put up with inconveniences and disadvantages, so long as the actions of the majority in their

social milieu expect the persistence of the custom and act in conformity with it." This mode of analysis is a hallmark of contemporary game theory and Weber's example is an instance of the Prisoner's Dilemma paradigm. By unpacking group attributes with methodological individualism, Weber links agency to structure, and avoids causal explanations based on supra individual phenomena, e.g., traditional mentality and collective consciousness, that themselves need explanation.

"Verstehen" is also central in Weber's notion of causality in human affairs. Multiple outcomes from similar initial conditions are common. The intervening processes that account for the variance are the different cultural meanings that humans attach to the same events and actions. Therefore, the appearance of a comet can be viewed as a natural event obeying the Newtonian laws of motion, and it can also be viewed as a manifestation of divine wrath and a warning to humankind to change its sinful ways. Intervening cultural variables thus play a key role in human causation. As an illustration, Weber describes how a belief in predestination can give rise to fatalism in everyday behavior or, on the contrary, to active ethical action, such as the inner worldly asceticism of the Puritans. A causal chain by way of a cultural intervening variable is for Weber a typical means by which nonrational beliefs and motives (e.g., predestination) give rise to institutionalized instrumental actions (work as a calling).

Weber applied his causality model in his empirical sociology of industrial work as well as in the sociology of religion and historical writings. Some causal relations, such as between fatigue and work output among textile workers, can be explained as a physiological reaction, without intervening mental or cultural variables. He observed some workers' output over the course of the day, as they get more tired, and over the course of the week, and inferred two fatigue cycles. Yet, superimposed on the physiologically determined production cycles, for some workers he found other intervening cultural processes that modified physical output: some socialist workers purposely reduced output ("bremsen') toward week's end to avoid becoming norm busters out of solidarity with their peers, and some Pietist women who had been socialized for work as a value and not just a means for making a living exceeded output projected from the fatigue cycle of typical female workers.

As these examples from Weber's historical writings and empirical research show, the principle of "verstehen" which justifies intersubjectivity, methodological individualism, the unity of the social and historical sciences, and causal analysis with intervening cultural variables, enabled Weber to navigate confidently across history and cultures, past and present, qualitative and quantitative data, from contemporary textile workers to the 17th century Puritans, from the prophets of ancient Israel to the mandarins of the Ming dynasty, from the condottieri of medieval Italian cities to the members of revolutionary assemblies in 1905 Russia. His scholarly reputation grew on his unique talent for such explanations.

Study Design and Measurement: The Psychophysics of Industrial Work

Weber did not write explicitly about the techniques of social research, e.g., sampling, study design, measurement, and data analysis, as he did about the logic of social inquiry. We can however analyze how he handled these techniques by examining his most comprehensive empirical research on industrial labor in a relative's textile factory, and his research guide to the collaborators in the larger Verein fur Sozialpolitik survey of industrial workers. In preparation, Weber carefully studied the physiological and psychological experiments on work, especially those of his Heidelberg colleague Kraepelin and of the industrialist–innovator Abbe and reflected on how to transfer and modify laboratory techniques to a survey instrument and field work in the factory. The dependent variables, productivity and earnings of particular workers, could be measured from registers and pay records. The explanatory variables were of three types: physiological (fatigue, gender-linked skills) and physical (different machinery) variables could be measured quantitatively as in the laboratory; motivational and cognitive variables based on instrumental rational reasons (working for piece rate or fixed rate) could be "interpreted pragmatically" by talking to workers; and mentality and attitudes (work habits from upbringing and religious milieu) could be "reconstructed introspectively," i.e., using "verstehen." Among his findings were the fatigue cycles, the effects of Sunday alcohol consumption upon reduced productivity on Monday, the socialist workers' goal of limiting output for maintaining peer solidarity and equality, and the Pietist women's excellent attendance and superior work habits.

Although Weber believed cultural variables (e.g., workers' beliefs, attitudes, political orientation) were important, he was uncertain whether quantitative methods based on questionnaires could be used to measure them. He relied on participant observation and conversations with the workers on the factory floor. When Adolf Levenstein, a self taught worker, succeeded in carrying out a survey of steel, textile, and mine workers, with over 5000 respondents, about their hopes and aspirations, political views and "weltanschauung," he was at a loss of how to analyze and present his findings, and turned to Weber for advice. Weber recommended coding each question and running frequency counts, then cross tabulating with background variables, then creating a typology of worker

mentalities based on the quantitative analysis of responses, much as such data are currently analyzed.

If one classifies the measurement techniques used by Weber and his German contemporaries along two dimensions, unobtrusive to obtrusive techniques, and qualitative to quantitative, one will find that the bulk of it was based on published statistics of state agencies and census bureaus, e.g., the field of moral statistics, which was unobtrusive and quantitative. Another way to describe it is that it was armchair research. The Verein fur Sozialpolitik surveys did use intermediaries and informants (e.g., ministers, school teachers) and eventually also the subjects themselves, for studies of farm laborers and industrial workers. That was an attempt to overcome the limitations of armchair research by somewhat more obtrusive and more qualitative techniques. Weber himself was quite open to a variety of techniques: the factory records were unobtrusive and quantitative; but he also gathered qualitative information on disposition and mentality with participant observation. His plan for the sociology of the press combined quantitative and qualitative data analysis. Despite some promising beginnings, by and large the academic social scientists remained comfortable with armchair research.

The lack of influence of Weber's empirical and methodological writings on his contemporaries was due to the devastating impact of the First World War on Germany, the lack of students he mentored, dominance of the historical method in German academia (lone scholar working on archival, literary, and archeological data), and the absence of any social science research institute for collaborative, continuous, cumulative, and large-scale empirical undertaking, which Weber and some others wished to found but were not successful funding. It may be somewhat of a paradox that it is also the success and virtuosity of the other parts of the Weber oevre that contributed to the neglect of his episodic but only partially successful, yet determined efforts, in empirical social science.

Weighting

Peter J. Lynn
University of Essex, Colchester, United Kingdom

Glossary

adjusted sampling weight Synonymous with combined weight.
adjustment cell Synonymous with weighting class.
basic sampling weight Synonymous with design weight.
combined weight A weight that combines the design weight with weighting adjustments to reduce error due to under coverage, sampling and nonresponse. Techniques such as poststratification, response propensity modeling, and calibration may be used to derive the adjustments.
design weight A weight that is inversely proportional to the selection probability of a sample unit, as determined by the sample design (ignores the impact of nonresponse or coverage errors).
nonresponse weighting A class of methods that adjust the distribution of the responding sample, through weighting, to match that of the selected sample in terms of variables believed to be associated with propensity to respond.
population-based weighting A class of methods that involves comparing the responding sample to external population data.
post-strata Comprehensive and mutually exclusive subgroups for which population counts are known and to which survey respondents can be allocated. Post-strata are used in post-stratification and do not typically coincide with sampling strata (pre-strata).
post-stratification A technique that adjusts the sample distribution, through weighting, to match the population distribution over post-strata.
raking A method for deriving weights by iteratively weighting a sample to two or more sets of comprehensive and mutually exclusive classes for which population numbers or proportions are known. A form of population weighting.
raking ratio estimation Synonymous with raking.
rim weighting Synonymous with raking.
sample-based weighting A class of methods that involves defining weights based solely on information available for the selected sample units.
sampling weight Synonymous with design weight.
trimming The restriction of extreme weights, typically to some arbitrary maximum value, in an attempt to minimize the variance-inflation effect of weighting.
weight A numeric value associated with a responding sample unit, representing the relative importance of that unit in analysis that aims to makes inferences from sample to population.
weighting class A set of sample units meeting some criterion, each of which is assigned the same weight.

Weighting is a process by which the units in a survey sample are assigned different numeric values (weights), representing the contribution that they will make to estimates based upon the survey data. The weights are designed to make the sample representative of the population from which the sample has been drawn. The weight for any particular responding unit may be interpreted as the relative number of population units that it represents. The calculation and application of weights is part of the process of statistical inference, by which conclusions can be drawn about a population of interest based upon knowledge of a sample drawn from that population.

Basic Principles

The idea of weighting is conceptually quite simple. In order to make statistical inference from sample to population, the sample units must in some defined sense represent the population. As there are more units in the population than in the sample, each sample unit must represent at least one, and on average usually considerably more than one, population unit. The number of population units represented by a sample unit is the weight

of that sample unit. In the simplest case, if a simple random sample of n units is selected from a population of N units (and there is no nonresponse), each sample unit can be thought to represent N/n population units. Thus, the weight for sample unit i ($i, = 1, \ldots, n$) is: $w_i = N/n$. The weight does not vary with i, all sample units receive the same weight. However, there are many situations in which it will be recognized that each sample unit does not necessarily represent the same number of population units. These situations are outlined below. In consequence, weights usually *do* vary across sample units.

Typically, the weight for each sample unit will be added to the survey data set as a variable. Then, the weight variable will be specified in analysis as an indicator of the contribution that will be made by that unit to an estimate. For example, a simple weighted mean (of a variable y, which takes the value y_i for unit i) will be calculated as:

$$\overline{y}_w = \frac{\sum_{i=1}^{n} w_i \times y_i}{\sum_{i=1}^{n} w_i}.$$

Reasons for Weighting

Disproportionate Stratification

A situation in which sample units obviously do not all represent the same number of population units is when the sample units have not been selected with equal probabilities. If disproportionate stratification has been used (such as oversampling units that belong to a small but important subgroup), then those sample units that had higher selection probabilities represent fewer population units. If there were H strata ($h = 1, \ldots, H$) and a simple random sample of n_h units were selected from stratum h, then each sample unit i in stratum h should receive the weight: $w_h = N_h/n_h$. Now, the weights vary across strata (in inverse proportion to the sampling fractions) but not between units within a stratum. Weights that are in inverse proportion to selection probabilities are often referred to as "design weights" or "sample weights."

Sampling Variance

With any kind of random sampling, units are selected on the basis of the outcome of some chance mechanism. In consequence, a sample may turn out to contain a higher proportion of one type of unit than another, just due to the play of chance (sampling variance). This may be known by reference to the characteristics of all units on the sampling frame, or by reference to some external source of data about the population. If the definition of "type" here is thought to be of relevance to the analysis, weights may be applied to correct the chance imbalance. For example, if the study population is known to contain 6000 women and 6000 men, but a simple random sample selected from it happens to contain 285 women and 315 men, it might be appropriate to give sample women a weight of 6000/285 and men a weight of 6000/315. These weights are identical in form to design weights, being $w_g = N_g/n_g$, where g ($g = 1, 2$) are the strata defined by sex. However, here the strata are not sampling strata (pre-strata). They are referred to as *post-strata* and weighting of this kind is known as *post-stratification* weighting. Weights are not inverse selection probabilities, but ratios of population size to sample size within post-strata. If disproportionate sampling has been used, post-stratification weights must be defined as the ratio of population size to design-weighted sample size, i.e.,

$$w_g = \frac{N_g}{\sum_{h=1}^{H} \left((N_h \times n_{gh}) / n_h \right)},$$

where n_{gh} is the sample size in the intersection of post-stratum g and pre-stratum h. In this case, the combined weight for each unit i in post-stratum g and pre-stratum h is $w_{gh} = w_g \times w_h$.

Nonresponse Error

Most surveys experience some greater or lesser degree of nonresponse. Nonresponse may cause the distribution of the responding sample (i.e., the sample for which data are available for analysis) to differ from that of the selected sample. This will happen if nonrespondents differ from respondents in terms of relevant characteristics. For example, suppose that a selected sample contains 400 employed people and 200 who are not employed (students, retired, etc.). If the response rate is 75% among the employed people but 90% among the others, the responding sample will contain 300 employed people and 180 others. The proportion of employed people is therefore lower in the responding sample (62.5%) than in the selected sample (66.7%). To correct for this differential nonresponse, employed respondents could be given a weight of 400/300 and other respondents a weight of 200/180. These weights are of the form $w_f = n_f/m_f$, where f ($f = 1, 2$) are the classes defined by employment status, and n_f is the number of units selected and m_f the number of units responding in class f. The classes are known as *nonresponse classes* and the weights are referred to as *nonresponse weights*. Nonresponse weights are ratios of selected sample size to responding sample size within classes, i.e., the reciprocal of the within-class response rate.

A combined weight for a unit in nonresponse class f, post-stratum g, and pre-stratum h is simply $w_{fgh} = w_f \times w_g \times w_h$.

Coverage Error

Sampling error and nonresponse error are two of the three main sources of errors of nonobservation on surveys. The third is coverage error. There are two types of such errors, under-coverage and over-coverage. Over-coverage exists when a sampling frame includes units that are not members of the study population. For any contacted sample unit, membership of the population can usually be established, so such units do not enter the responding sample (they are categorized as "ineligible"). Under-coverage exists when a sampling frame has imperfect coverage of the study population. If the omitted units have relevant characteristics that differ from those of the included units, then under-coverage introduces error. Weighting may be used to address the impact of under-coverage error, if population data is available superior to that available from the sampling frame. For example, if it is known that 1% of units are omitted from the frame in one geographic region, but 6% in another, then sample units in the two regions could be given weights of 100/99 and 100/94, respectively, to correct this imbalance. This might be thought to be an appropriate procedure if region is likely to be correlated with important survey measures.

Methods of Calculating Weights

Assumptions

Design weights, to deal with disproportionate stratification, are in some respects different in nature to the other three kinds of weights described in the previous section. Design weights are a direct consequence of the choice of sample design. In order to calculate them, it is necessary only to know the relative selection probability of each sample unit. With a well-defined probability sample design, it should not be problematic to establish the selection probability of each unit (though care may be needed if the design is multi-stage). Once the selection probabilities are known (an essential requirement for a probability sample design), the method of calculation of the weights is not controversial. No assumptions are required.

The other three reasons for weighting all aim to adjust for the potentially undesirable impacts of sources of survey error (coverage, sampling, nonresponse). By definition, it is not possible to know the impact of these error sources on survey estimates (because survey data is not obtained for units that are excluded from the frame, not sampled, or nonresponding). Instead, the impacts must be estimated using some kind of model. The model may be simple (as in the examples above) or complex, but any model involves assumptions. It is helpful to recognize the nature of assumptions that are typically made when calculating survey weights, as consideration of these assumptions should influence the choice of calculation method.

Most methods of calculating weights proceed in one of two ways. The first involves splitting the sample into weighting classes (also known as adjustment cells), calculating a weight for each class, and applying that weight to each sample unit in the class. The second involves estimating a propensity (to be included on the frame, to respond to the survey) using, for example, a logit or probit regression model and calculating a weight as the inverse of the model-estimated probability (of being included on the frame, or of responding to the survey). In either case, the weighting relies upon an assumption that the responding sample units within a class (or with a given set of characteristics that determine the estimated propensity) are similar in terms of survey measures to unobserved units in the class whose absence the weighting is intended to address (e.g., the nonresponding units in the case of nonresponse weighting). To the extent that the assumption is true, the weighting will tend to reduce the error of survey estimates. But, to the extent that differences remain between the observed units and corresponding unobserved units, error will remain in the survey estimates. Weighting therefore reduces, but does not remove entirely, the errors in question. The effectiveness of weighting depends on the extent to which the underlying assumptions are realistic.

A second assumption in the case of weighting class approaches for nonresponse is that units within a class all have the same underlying response probability and that these probabilities are independent. This is sometimes referred to as the response homogeneity group (RHG) model. That is, conditional upon membership of the weighting class, the data are missing completely at random (MCAR).

It should be noted that the nature of the fundamental assumption is different in the case of post-stratification, compared with weighting for under-coverage or nonresponse. Any differences between sampled units and not-sampled units within post-strata are solely due to random sampling variation. In other words, any errors present are variable errors rather than systematic ones. For any survey measure, the expected value is by definition the same for both sampled and nonsampled units. Post-stratification alone cannot therefore affect the bias of survey estimates, but it will tend to reduce standard errors (to the extent that post-strata are correlated with survey measures). Conversely, the processes that cause under-coverage and nonresponse are likely to be systematic (or at least to have substantial systematic components). Thus, the nature of the survey error that the weighting aims to address is a bias rather than variance. For the assumption to be realistic, the weighting classes should therefore account for the systematic aspects of the relevant process.

A final point to note about weighting to correct the effects of sampling variance, coverage bias or nonresponse bias, is that an assumption is made that the effect is the same on all survey estimates. Indeed, one of the main advantages of weighting is that a single solution can be used for all subsequent analysis and estimation, rather than having to deal with each estimate separately. This contrasts with imputation techniques, where the missing data mechanism can be specified differently for each data item treated. The limitation of this assumption, however, tends to become apparent at the stage of defining weighting classes or calibration constraints. What appears to be a good choice for one survey estimate may be clearly suboptimal for another. Compromises are necessary.

Sample-Based Methods

Sample-based methods are those that rely solely upon information internal to the sampling process and the selected sample. Design weights are by definition sample-based: they are constants determined by the design. Sample-based methods are also often used for nonresponse weighting. They cannot be used to weight for under-coverage or for post-stratification, as these require external population data (see the next section).

Sample-based nonresponse weighting methods typically involve splitting the selected sample into classes, observing the number of responding and nonresponding units in each class and then calculating a weight $w_f = n_f/m_f$ to be applied to each responding unit in class f, as described above. This will ensure that, after weighting, the distribution of the responding sample across the classes is the same as that of the selected sample. Classes can only be defined by variables that are available for all selected sample units. Such variables may come from the sampling frame (e.g., a register or administrative file), may be collected in the course of the survey process (e.g., by interviewer observation in the case of a personal interview survey), or may be linked to the sample from some external source (e.g., Census small-area data in the case of an address-based household survey). A key factor in the success of sample-based survey weighting is the identification and collection of data that may be useful for weighting at the sample selection and field work stages.

Sample-based weighting will be successful at reducing nonresponse bias if three criteria are met:

- Response rates (and therefore weights) must vary over the classes;
- The values of survey estimates (e.g., means, proportions, and regression coefficients) must vary over the classes;
- The values of survey estimates must be similar for both respondents and nonrespondents within each class.

The construction of the classes is therefore important. There are many different methods that can be used to construct sample-based classes. Often the classes are created based purely on intuition or some very limited theory of the likely correlates of nonresponse. Empirical methods can be used to construct classes that provide good discrimination in terms of response rates. Segmentation algorithms (exploiting tree-based methods such as classification tree and regression tree) can be used, with a dichotomous response/nonresponse indicator as the dependent variable. Alternatively, logistic regression can be used and classes created defined by bands of model-predicted response propensity. Sometimes, these methods are used in conjunction with analysis of the survey data that aims to assess the second of the three criteria listed above. The process can be iterative, with classes initially constructed based on the response rate criterion, then amended in the light of analysis of the survey data using the initial classes as a covariate, then perhaps amended again in the light of a reassessment of response rates based on the amended classes.

Other sample-based methods do not involve the construction of explicit classes. For example, a sample unit's weight might be defined as the reciprocal of its predicted response propensity from a logistic regression model of nonresponse. It is also possible to model response propensity using relevant survey process data, such as the number of calls needed to make contact with a sample member, the amount of elapsed time before a postal questionnaire was received, or some indicator of the amount of persuasion that was needed.

Population-Based Methods

Other weighting methods involve creating classes for which the number of population units is known, or can be well estimated. Each responding sample member can then be assigned a weight, $w_g = N_g/n_g$, as described above. It will be noted that if there is any frame under-coverage, this weight will adjust simultaneously for both under-coverage and sampling variance. In fact, it is more common for the weight to be calculated as $w_g = N_g/m_g$, thus also adjusting simultaneously for nonresponse.

Aside from the definition of the weights, two important distinctions can be made between sample-based and population-based methods. The first is the ability of population-based methods to simultaneously adjust for multiple error sources (sampling error, coverage error, nonresponse error). This is usually viewed as an advantage. The second is that sample units are allocated to classes on the basis of their survey responses (or other unit-level data, such as information from the sampling frame), whereas the numerators for the weights usually come from an external source. This is usually viewed as a disadvantage of population-based methods.

The disadvantage lies in the potential for misclassification. Any differences between the survey data and the population data, in the definitions used, the point in time to which the data refer, the method of collecting the data, etc., could potentially result in units appearing in one class in the numerator and a different class in the denominator. If such misclassifications are systematic in any way, then the weighting can actually increase bias rather than reduce it (or, introduce one sort of bias while reducing another sort). It is necessary to consider carefully the potential scope for misclassification and its likely nature. For example, it may be preferable to create classes based on a variable that is only weakly related to survey variables but believed to be insensitive to differences in the population and survey data collection methods (e.g., age and gender for a survey of individuals) rather than one which might be much more strongly related to survey variables but liable to be sufficiently sensitive to data collection methods to cause systematic misclassification (e.g., ethnic group).

Calibration Methods

Calibration refers to a class of methods that produce weights that obey some calibration constraint(s). Understanding of the statistical properties of these methods was developed during the 1990s. During this same period, the development of powerful and flexible software to implement the methods contributed to a rapid growth in the popularity and use of calibration methods.

Post-stratification is one example of a calibration method, the constraint being that the weights must result in weighted post-stratum sample sizes equalling post-stratum population sizes. Thus, if there are H post-strata, there are H calibration constraints. Another possibility is to define the constraints in terms of continuous variables, such as stratum population totals, X_h, or means, $\bar{X}_h$. A common example occurs in business surveys, where the $\{X_h\}$ may be total production (or turnover, or employment), in a stratum perhaps defined by industry sector, the data typically coming from a business register. This is equivalent to ratio estimation (where the weights are typically implicit to the estimation process and the choice of auxiliary variables may be estimate-specific), which can therefore be thought of as a type of calibration. Raking (also known as the raking ratio method, or rim weighting) also falls within the class of calibration methods. Raking is an iterative procedure whereby the responding sample is weighted in turn to two or more different sets of comprehensive and mutually exclusive classes. A stopping rule, usually based upon changes in the weights or in the weighted sample sizes, determines when the iterations are complete. Typically, the different sets of classes are defined as categories of a number of different variables. Thus, the method ensures that the marginal distributions of each variable (but not necessarily the joint distributions) equal the population distribution. Raking enables calibration to multiple variables in situations where post-stratification to the full cross-classification of the variables would be undesirable due to small cell sizes and in situations where the joint population distribution is unknown.

For any type of calibration, some auxiliary data are required to determine the calibration constraints. One advantage of calibration methods for large survey organizations—especially national statistical institutes—is that the use of the same constraints across multiple surveys ensures coherence of the outputs from these surveys, at least in terms of the variables that define the constraints. For example, all national social surveys can be seen to be based on the same age × sex × region breakdown.

The calibration approach requires two main inputs. The first is a set of pre-weights. These are typically the design weights, but could equally be combined design and nonresponse weights, for example. The second is the set of calibration constraints. An algorithm is then used to identify a set of calibration weights that are as similar as possible to the pre-weights while also meeting the calibration constraints. This is achieved by minimising a distance function between the pre-weights and the calibration weights. There is a range of software available to calculate calibration weights.

Combining Methods

It is common, and often desirable, to combine more than one weighting method on a single survey. For example, one could use sample-based class weighting methods for nonresponse, using design weights as pre-weights for the nonresponse analysis, and subsequently carry out post-stratification, using the (design + nonresponse) weights as pre-weights (see Fig. 1). This can be an appropriate way of making the best use of available auxiliary information if different information is available at the level of the selected sample and the population. The calibration approach is often viewed as a natural extension of this idea, combining both design weights and calibration constraints in a standard way. In fact, it is not necessary that the pre-weights in a calibration approach are the design weights. Some researchers have developed nonresponse weights (which themselves may use design weights as pre-weights) and then used those as the calibration pre-weights. There may be advantages in this approach if there are auxiliary data available for the selected sample that are not available at population level to form the calibration constraints. Typically, for many surveys, for example in public-use survey data files, the final weight is the product of three weights: design, nonresponse adjustment, and post-stratification (or calibration) weights.

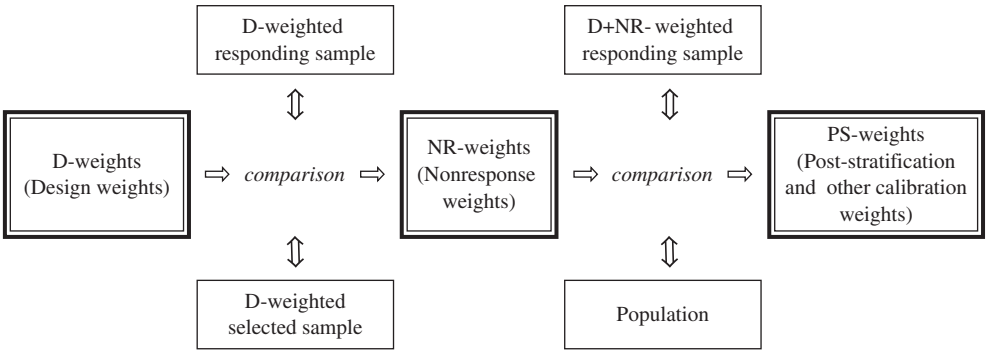

Figure 1 A typical weighting process.

Design-Based and Model-Assisted Methods

The "design-based" and "model-assisted" approaches to inference from survey data are often thought of as two rival schools of thought. In reality, pure design-based inference is only possible in the complete absence of any survey errors other than random sampling variation. In other words, for example, there must either be no nonresponse or nonresponse must be completely random. In any realistic situation, inference relies upon some model(s), though these are often not stated explicitly. Estimation using only design weights makes implicit assumptions (models) about the nature of nonresponse error and coverage error, for example. The development of weights to deal with these sources of error merely makes the models explicit.

Using Weights in Analysis

Impact of Weights

In the case of nonresponse weights particularly (but also design weights), there is a trade-off to be made between the variance and bias of estimates. Variability in the weights will tend to increase the variance of estimates, so the weighting will only be successful at reducing mean square error if this is outweighed by the reduction in bias. The impact of weights on the variance of estimates can be measured by the design effect due to weighting. The squared coefficient of variation of the weights, plus one, provides an approximation to this design effect, under the simplifying assumption that population variance (of the survey measure) does not vary across weighting classes.

It is common for researchers to assess variation in weights and to consider whether the consequent increase in variance is acceptable relative to the expected bias reduction. If it does not appear acceptable, large weights may be trimmed by some more or less arbitrary method, or some weighting classes combined. An important consideration is that bias, unlike variance, acts independently of sample size, so controlling the range of weights tends to be a more important consideration for surveys with small samples than for surveys with large samples.

Types of Weights

Sometimes, survey data sets will contain more than one weight variable, corresponding to multiple purposes or types of analysis. For example, in longitudinal surveys, respondents to wave t may be assigned a cross-sectional weight (for estimates relating to the cross-sectional population at time t) and one or more longitudinal weights (for estimates relating to longitudinal populations at time t and one or more previous time points). On other occasions, data sets may contain component weights (e.g., a design weight, a nonresponse weight, a post-stratification weight, and/or other calibration weight), which must be used in combination. It is not unusual for confusion about the status of weight variables to result in incorrect analysis. On the other hand, provision of multiple weights can often improve the quality of analysis and provide important information for more sophisticated users.

Documentation of Weights

To avoid confusion of the sort mentioned above, it is important that the origin, meaning, and purpose of each weight added to a data set is fully documented. This is an important element of the task of survey documentation and directly affects the usability of survey data. Quality of documentation varies greatly and there are no generally agreed standards.

Applying Weights

Historically, much descriptive estimation based on survey data has used unweighted data. Objections to the use of weights were both practical (it takes time and effort to

develop weights) and ideological (the calculation of weights requires reliance on assumptions that may not be justifiable). Such objections were particularly common in situations where design weights were equal (or almost equal) for all sample units. Of course, ignoring nonresponse involves the stronger assumption that data are missing completely at random (MCAR). The arrival of increased computing power and flexible software addressed many of the practical objections, while the ideological objections were addressed by an increased understanding of the role of weighting and the broader context of statistical inference. By the late 1980s, weighting was usual practice for most public sector social surveys. For analytical estimation, practice remains divided in terms of using weights that are typically developed primarily for descriptive purposes. Alternatives to weighted analysis are to incorporate weighting and calibration variables as covariates in the analysis (not always possible for all analysts) or to model substantive outcomes and missing data outcomes simultaneously.

To use weights in any statistical analysis, the contribution of each responding unit to an estimate should be weighted by the appropriate weight. This is conceptually equivalent to counting each responding unit w_i times when constructing the estimate. In most statistical software packages this is easily achieved by specifying the weight variable prior to specifying the estimation to be carried out. There are, however, differences between packages in the way that weights are treated. Also, some packages allow user specification of how the weights should be treated. The differences do not usually affect point estimates (of means, proportions, correlation coefficients, regression coefficients, etc.) but can have a large impact on estimates of standard errors (and consequently hypothesis testing and model fitting). It is therefore important that weights are specified correctly by users. When analysis is carried out using weighted data it is common practice to report both weighted and unweighted sample sizes. This provides the reader with some information on both the relative precision of estimates (e.g., for subgroups) and the relative contribution of subgroups to estimates for larger domains, including the total study population.

Mental Health: Evidence and Research, World Health Organization, Geneva, Switzerland

Glossary

health A state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.

health care setting Setting in which services are provided to a population to maintain health and prevent and cure diseases.

human immunodeficiency virus (HIV) The virus that causes acquired immune deficiency syndrome (AIDS).

quality of life Individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns.

World Health Organization United Nations technical agency responsible for health.

The World Health Organization Quality of Life (WHOQOL) instruments assess respondents' perception and subjective evaluation of various aspects of the quality of life. They are designed to measure quality of life related to health and health care. The instruments have been developed within cross-cultural multicenter projects. Experts and lay health care users in each center have been involved in this process to produce reliable and valid instruments applicable across cultures. There are four WHOQOL instruments: WHOQOL-100, a 100-item generic quality of life assessment instrument; WHOQOL-BREF, a 26-item brief version of the generic WHOQOL-100; WHOQOL-HIV, a specific module to assess quality of life in persons who are HIV-positive; and WHOQOL-SRPB, a specific module to assess the spiritual, religious, and personal belief component in quality of life.

Rationale for the Development of Quality of Life Instruments

The World Health Organization (WHO) initiated the development of international quality of life assessment instruments in the 1990s for several reasons. First, because health, according to WHO's constitution, is "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity," there is a need to go beyond morbidity and mortality and to assess disability, functioning, perceived health, and quality of life. Second, most measures of health status have been developed in a single cultural setting, and the adaptation of these measures for use in other settings is time-consuming and often unsatisfactory. Third, the increasingly mechanistic model of medicine, concerned largely with the eradication of disease and symptoms, reinforces the need to introduce broader, humanistic concerns into

health care. WHO's initiative to develop a quality of life instrument therefore arises from a need for a genuinely international measure of quality of life—taking into account sociocultural diversities—and from commitment to the promotion of a holistic approach to health and health care.

Quality of life: WHO's Concept and Definition

Due to the lack of a universally agreed upon definition of quality of life, the first step in the development of the WHO Quality of Life (WHOQOL) instruments was to define the concept. In 1995, WHO defined quality of life as "individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns." It is a broad-ranging concept, incorporating the person's physical health, psychological state, level of independence, social relationships, personal beliefs, and relationship to salient features of the environment. This definition highlights the view that quality of life refers to a subjective evaluation, which includes both positive and negative dimensions and which is embedded in a cultural, social, and environmental context.

Given that quality of life is a multidimensional construct to be amenable to measurement, it is necessary to identify various components of quality of life. Consultations and investigators from field centers proposed several broad domains assumed to contribute to an individual's quality of life. Each domain was further divided into a series of specific areas (facets and subdomains; Table I). This hierarchical structure of the WHOQOL allows for a quality of life profile of respondents with domain and facet scores.

Table I Composition of the Generic WHOQOL-100: Six Domains and 25 Facets

Domain I: Physical	1. Pain and discomfort
	2. Energy and fatigue
	3. Sleep and rest
Domain II: Psychological	4. Positive feelings
	5. Thinking, memory, learning, and concentration
	6. Self-esteem
	7. Bodily image and appearance
	8. Negative feelings
Domain III: Level of independence	9. Mobility
	10. Activities of daily living
	11. Dependence on medication and treatment
	12. Work capacity
Domain IV: Social	13. Personal relationships
	14. Practical social support
	15. Sexual activity
Domain V: Environmental	16. Physical safety and security
	17. Home environment
	18. Financial resources
	19. Health and social care: availability and quality
	20. Opportunities for acquiring new information and skills
	21. Participation in and new opportunities for recreation/leisure
	22. Physical environment
	23. Transport
Domain VI: Spiritual, religious, and personal beliefs	24. Spiritual, religiousness, and personal beliefs
General facet	25. Overall quality of life and general health perceptions

WHOQOL-100: Generic Quality of Life Assessment

The first WHOQOL instrument to be developed was the WHOQOL-100. The procedure for the development was as follows. First, focus groups were run in several field centers (Bangkok, Bath, Madras, Melbourne, Panama, St. Petersburg, Seattle, Tilburg, and Zagreb) to (i) examine the meaning, variation, and perceptual experience of the quality of life construct in different locations of the world and (ii) test the face validity and comprehensiveness of initial WHOQOL domains and facets, which had been proposed by an international group of experts. Participants in these focus groups were mostly individuals from the general population in contact with health care providers. The data from the focus groups revealed that within each cultural settings quality of life cannot be easily described in terms of one or several words or phrases; rather, it is the breadth and content of quality of life that characterize it. Moreover, it was found that the issues raised by participants in focus groups mostly reflected the issues covered in the WHOQOL domain and facet structure proposed by experts in an initial meeting, but modifications to the facets nevertheless proved necessary.

The next step was to provide a definition for each facet. This consisted of a conceptual definition, a description of various dimensions along which rating can be made for a facet, and a listing of some example situations or conditions that might specify various levels of intensity of a facet. Definitions of each facet were translated into the language of the field centers following a standardized WHOQOL translation method, which is an iterative process of forward and backward translation complemented by review by monolingual focus groups and bilingual experts.

The translated facet definitions were discussed in further focus group work in the field centers. Focus group participants included inpatients, outpatients, informal caregivers, health personnel, and persons from the general population. The focus groups involved (i) discussion on how different facets affect quality of life, (ii) consideration of how to ask about the facets, (iii) rating the "importance" of each facet on a 5-point scale, and (iv) other issues considered important by participants to quality of life. On the basis of the focus groups in different countries, the WHOQOL facet structure was revised.

A question-writing panel was assembled in each of the field centers. Questions formulated in the local language were translated in English to develop a global item pool of approximately 1800 questions. After identifying semantically equivalent and poorly formulated questions, the pool was reduced to approximately 1000 questions. The principal investigator in each of the field centers rank ordered the questions for each facet according to "how much it tells you about a respondent's quality of life in your culture." From the combined rankings for all centers, 235 questions were selected for the WHOQOL pilot instrument. Five-point semantic differential response scales were derived for each of the instrument's language versions according to standardized methodology.

Pilot testing involved the administration of the 235 questions to 250 health care users and 50 healthy respondents in each of the 15 culturally diverse field centers ($N = 4500$). A series of frequency, reliability, inter-item correlation, interfacet, and discriminant validity analyses were run on the pilot data (i) at the level of individual centers, (ii) summarized across individual centers, and (iii) on the pooled global data. The final selection of items took into account a number of desirable features of the facets and items, including the goal of having four items per facet (the minimum number required for scale reliability analyses), the degree of conceptual overlap between items (which was minimized insofar as possible), and the findings of aforementioned psychometric analyses. The resulting 100-item instrument, called the WHOQOL-100, has since been shown to be reliable and valid for use in diverse cultures. The instrument has 24 specific facets (distributed in six domains) as well as 1 general quality of life facet (Table I). The WHOQOL-100 is available in more than 40 languages and available at the following Web site: http://www.who.int/evidence/assessment-instruments/qol.

WHOQOL BREF: Brief Generic Quality of Life Assessment

Although the WHOQOL-100 is a detailed assessment instrument of individual facets relating to quality of life, it may be too lengthy for use in large epidemiological studies or clinical trials in which quality of life is only one variable of interest. In such instances, an assessment tool will be more likely incorporated into studies if it is brief. The WHOQOL-BREF was therefore developed, which is much shorter but still provides summary scores at the domain level. To maintain comprehensiveness in the abbreviated version, one item from each of the 24 WHOQOL-100 facets was included. On the basis of multivariate, psychometric analyses of new and existing data sets, a 26-item scale was developed consisting of one item from each of the 24 facets plus two general items covering overall quality of life and general health. The items were regrouped into four domains: physical health, psychological aspects, social relationships, and environment. Domain scores produced by the WHOQOL-BREF correlate very highly with domain scores of the WHOQOL-100. The WHOQOL-BREF thus performs as a brief quality of life measure.

WHOQOL-HIV: Quality of Life Assessment for Persons with HIV

The WHOQOL-100 and WHOQOL-BREF are generic instruments designed to assess quality of life among people with a variety of health problems. However, people with specific health problems tend to have additional quality of life concerns. For this reason, the WHOQOL Group encouraged the development of disease-specific WHOQOL modules that would be administered with the generic instruments to assess disease-specific quality of life concerns. WHO started by organizing the development of a specific WHOQOL module for use among people with HIV/AIDS. Although increasingly research has been focusing on minority populations in the United States, there had been no instruments to assess the quality of life of people living in developing countries, where the vast majority of people with HIV/AIDS live and where quality of life concerns may be different. HIV-specific instruments developed for use in U.S. and European contexts are difficult to adapt and use in low-income countries.

The WHOQOL-HIV was developed as follows. A consultation of international experts was convened to review the suitability of the generic WHOQOL for assessing people with HIV. Additional facets were proposed to address specific concerns of people living with HIV/AIDS. Focus groups were then conducted at six culturally diverse centers. Participants comprised people with HIV/AIDS, informal caregivers, and health professionals. The aims were to review the adequacy of the WHOQOL-100 for assessing people with HIV/AIDS and to generate additional facets and items for a pilot module. A total of 115 items were proposed, covering 25 new facets for

assessment of quality of life specific to living with HIV/AIDS. The new facets included symptoms of HIV, body image, sexual activities, work, social inclusion, disclosure, death and dying, and forgiveness. In a pilot study, 900 people from six culturally diverse sites completed the WHOQOL-100 along with 115 HIV-specific items. Respondents were HIV asymptomatic, HIV symptomatic, people with AIDS, or asymptomatic without HIV/AIDS. Using standard WHOQOL development methodology, a series of psychometric analyses were conducted—including frequency, interitem correlations, reliability, and multidimensional scaling—to select the best items from the pilot module. This resulted in the selection of 20 items covering 5 new facets for inclusion in a field trial of the WHOQOL HIV module (Table II). The field trial involved administering the WHOQOL HIV field test module to 1334 people with HIV/AIDS from seven culturally diverse centers (Australia, Brazil, Italy, Thailand, Ukraine, and two centers in India—Bangalore and New Delhi). Experience with the module demonstrated good reliability and good discriminant validity, with poorest quality of life found for those who reported being the least healthy. The module provides a means for quality of life assessment for HIV/AIDS in diverse cultural settings. The WHOQOL-HIV is available at http://www.who.int/mental_health/resources/evidence_research/en.

WHOQOL-SRPB: Spirituality, Religion, and Personal Beliefs as Components of Quality of Life Assessment

Traditionally, generic assessments of quality of life do not routinely address specific aspects of religion, spirituality, or existential well-being. However, there is increasing evidence that peoples' beliefs may be important contributors to quality of life. Spirituality may be especially important in particular cultural and ethnic groups. For this reason, WHO developed a WHOQOL module for assessment of spirituality, religion, and personal beliefs (SRPB) in different cultures using standard WHOQOL instrument development methodology. Briefly, an international consultation was conducted to generate potential facets related to SRPB. Experts in the field participated, representing major religions of the world, as well as participants

Table II Additional WHOQOL-HIV Facets and Items[a]

Symptoms
1. How much are you bothered by any unpleasant physical problems related to your HIV that you may have?
2. To what extent do you fear possible future (physical) pain?
3. To what extent do you feel any unpleasant physical problems related to your HIV infection prevent you from doing things that are important to you?
4. To what extent are you bothered by fears of developing any physical problems?
Social inclusion
5. To what extent do you feel accepted by the people you know?
6. How often do you feel that you are discriminated against because of your health condition?
7. To what extent do you feel accepted by your community?
8. How much do you feel removed/alienated/emotionally distant from others/those around you?
Forgiveness
9. How much do you blame yourself for your HIV infection?
10. How bothered are you by people blaming you for HIV status?
11. How guilty do you feel about being HIV positive?
12. To what extent do you feel guilty when you need the help and care of others?
Fear of the future
13. To what extent are you concerned about your HIV status breaking your family line and your future generations?
14. To what extent are you concerned about how people will remember you when you are dead?
15. To what extent does any feeling that you are suffering from fate/destiny bother you?
16. How much do you fear the future?
Death and dying
17. How much do you worry about death?
18. How bothered are you by the thought of not being able to die the way you would want to?
19. How concerned are you about how and where you will die?
20. How preoccupied are you about suffering before dying?

[a] Facet scores are calculated as average scores across four items.

who did not profess any religious faith. Various facets were generated and then reviewed by focus groups in 15 centers (Egypt, Brazil, Uruguay, Argentina, Spain, Italy, the United Kingdom, Lithuania, Turkey, Israel, India, Malaysia, Thailand, China, and Japan). A total of 92 focus groups at these sites involved input from 701 people. The aim of the focus groups was to ensure the applicability of the suggested facets to quality of life and to generate items for inclusion in a questionnaire. Based on the qualitative data and the quantitative importance ratings, the relevance of 15 facets was confirmed. For each of these facets, 7 items were generated. The WHOQOL-SRPB pilot module thus consisted of 105 items, which were added to the WHOQOL-100 during pilot testing. Using standard WHOQOL instrument development methodology, the 15-facet pilot module was reduced to an 8-facet, 32-item SRPB module for field testing (Table III). The facets address spiritual connection, experiences

Table III SRPB Facets and Corresponding Items[a]

Connectedness to a spiritual being or force	
1.	To what extent does any connection to a spiritual being help you to get through hard times?
2.	To what extent does any connection to a spiritual being help you to tolerate stress?
3.	To what extent does any connection to a spiritual being help you to understand others?
4.	To what extent does any connection to a spiritual being provide you with comfort/reassurance?
Meaning of life	
5.	To what extent do you find meaning in life?
6.	To what extent does taking care of other people provide meaning of life for you?
7.	To what extent do you feel your life has a purpose?
8.	To what extent do you feel you are here for a reason?
Awe	
9.	To what extent are you able to experience awe from your surroundings (e.g., nature, art, and music)?
10.	To what extent do you feel spiritually touched by beauty?
11.	To what extent do you have feelings of inspiration/excitement in your life?
12.	To what extent are you grateful for the things in nature that you can enjoy?
Wholeness and integration	
13.	To what extent do you feel any connection between your mind, body, and soul?
14.	How satisfied are you that you have a balance between mind, body, and soul?
15.	To what extent do you feel the way you live is consistent with what you feel and think?
16.	How much do your beliefs help you to create coherence between what you do, think, and feel?
Spiritual strength	
17.	To what extent do you feel inner spiritual strength?
18.	To what extent can you find spiritual strength in difficult times?
19.	How much does spiritual strength help you to live better?
20.	To what extent does your spiritual strength help you to feel happy in life?
Inner peace/serenity/harmony	
21.	To what extent do you feel peaceful within yourself?
22.	To what extent do you have inner peace?
23.	How much are you able to feel peaceful when you need to?
24.	To what extent do you feel a sense of harmony in your life?
Hope and optimism	
25.	How hopeful do you feel?
26.	To what extent are you hopeful about your life?
27.	To what extent does being optimistic improve your quality of life?
28.	How able are you to remain optimistic in times of uncertainty?
Faith	
29.	To what extent does faith contribute to your well-being?
30.	To what extent does faith give you comfort in daily life?
31.	To what extent does faith give you strength in daily life?
32.	To what extent does faith help you to enjoy life?

[a] Facet scores are calculated as a average scores across four items.

of awe and wonder, wholeness and integration, meaning of life, spiritual strength, inner peace/serenity/harmony, hope and optimism, and faith. The SRBB module should be administered together with the WHOQOL-100 or WHOQOL-BREF. The WHOQOL-SPRB is available at http://www.who.int/mental_health/resources/evidence_research/en.

Use of WHOQOL Instruments

The WHOQOL instruments are being applied throughout the world in various ways. The WHOQOL is frequently included in epidemiological surveys and randomized clinical trials. The WHOQOL-BREF is used as a routine outcome measure for health issues ranging from pain management and cancer treatment to severe depression. The WHOQOL is also used to study the quality of life concept in greater depth. Finally, the WHOQOL is used in training and program evaluation efforts to focus attention on health-related issues beyond mortality and morbidity.

Glossary

culture A word used by Herder, and later widely adopted in the social sciences generally, referring to the corpus of beliefs of a community concerning customs, morals, religions, myths, and the arts; for Herder, the written literature of a (literate) community was a reflection of its culture.

experimental psychology That branch of psychology concerned mainly with the influences of physical stimuli on events taking place within the mind and body of a single individual; experimental psychologists usually believe that data collected in a laboratory can be organized within a scientific framework that includes hypotheses framed in physiological and/or mathematical terms.

social psychology That branch of psychology concerned mainly with the influences of other people on the events taking place within the minds and bodies of one or more individuals; research involving investigative manipulations of the behavior of individuals who are members of small groups is often described nowadays, particularly in North America, as being an aspect of "experimental social psychology."

Volk Herder's word for a group of people united in terms of a common culture.

Völkerpsychologie A term invented by Lazarus and Steinthal, and quickly adopted by Wundt, that referred to the scientific attempt to provide a history of the means whereby a *Volk* attained its culture.

Wilhelm Maximilian Wundt (1832–1920), at Leipzig in 1879, founded the first Institute of Experimental Psychology in a university setting. But, throughout his career, he struggled to be clear himself about the relationship between "experimental psychology" (which for him overlapped extensively with "physiological psychology") and *Völkerpsychologie* (his word for something only approximating the modern expression "social psychology," as will be explained below). The former is concerned with scientific accounts of what transpires within an individual's mind during a particular window of time (which might last only seconds), while the latter is concerned with scientific accounts of what transpires within and between groups composed of individuals. This explains why a distinction has been made between "intra-individual" and "inter-individual" psychology in the headings listed above.

Introduction

Wundt was born on August 16, 1832, in the small town of Neckarau, near Mannheim, Germany; his father was a Lutheran minister who moved from Neckarau when Wundt was one year old to various positions before settling more permanently in Heidelsheim in central Baden from 1836–1844. When Wundt was aged 14, he entered the Gymnasium (a high school for students intending to go to university) in nearby Heidelberg, and in 1851, at the age of 19, he spent a year studying medicine at the University of Tübingen before returning to Heidelberg to take up full-time medical studies at the university there. While still a student, he published an article (on salt concentration in the urine), and his Ph.D. dissertation, on neurophysiology, was defended in 1856 while he was gaining medical experience in Karlsruhe. There he also served briefly as a research assistant to Ewald Hasse before moving to Berlin to study physiology with J. Müller (1801–1858) and E. du Bois-Reymond (1818–1896). He then returned to Heidelberg to study with H. von Helmholtz (1821–1894). There, he wrote a second thesis (*Habilitation*) in 1857 that allowed him to present lectures on physiology at Heidelberg. In the following year, he

entered Helmholtz's service as a research assistant; he worked with Helmholtz from 1858 to 1863.

He was to stay in Heidelberg for a total of 17 eventful years, from 1857 to 1874. Not only did he work with Helmholtz, but he was promoted from *Privatdozent* (a rank allowing him to give lectures but not be on full-time faculty) to *ausserordentlicher Professor* (roughly, associate professor on full-time faculty) teaching anthropology and medical psychology, a rank he held from 1864 to 1874. In addition, he participated actively in the politics of the country then known as Baden, whose legislative offices were in Heidelberg; he was embroiled in the question of German unification, because Baden, in 1864, when Wundt was elected to the Baden legislature, was undecided as to whether to confederate with Saxony, Bavaria, Prussia, and other German-speaking countries.

However, he left politics after four years, partly because he found that political bickering was so time-consuming and enervating that he preferred to make his life's goal one of academic, rather than political, achievement. In 1872, at the age of 40, he married Sophie Mau (born January 23, 1844, in Kiel; died April 15, 1912, in Leipzig). In 1874, he was called to be *ordentlicher Professor* (roughly, full professor and chairman of a department) at the University of Zürich in Switzerland, but this turned out to be a temporary position prior to Wundt's receiving the call to be *ordentlicher Professor* at the University of Leipzig. At Zürich, his title had been that of Professor of Inductive Philosophy; at Leipzig, his title was that of Professor of Philosophy. His academic career at Heidelberg had included the teaching of anthropology and medicine. The possession of such an unusually well-rounded background of knowledge was exceptionally useful when it came to his appealing to the authorities at Leipzig for the foundation of his Institute of Experimental Psychology.

During his years at Heidelberg, he may have formulated, independently of Helmholtz, the idea that most of our perceptions are based on unconscious inferences. But Wundt's major achievement was to have written two books on psychology that were unusually far-reaching in scope. The first was his *Beiträge zur Theorie der Sinneswahrnehmung* (Contributions to the Theory of Sense Perception) of 1862, a work whose Introduction delineates a plan for a future science of psychology, one that would include *Völkerpsychologie*. The second was his *Vorlesungen über die Menschen und Tierseele* (Lectures on Human and Animal Psychology) of 1863, a work in two volumes, the second of which included the longest discussion of *Völkerpsychologie* in his early writings. It is important to note that neither book has been translated into English, although in 1961, Shipley translated the Introduction to the *Beiträge*. The *Vorlesungen* did come out in a second edition almost 30 years later and was translated by Creighton and Titchener, but the second edition was radically different from the first edition and omitted almost all reference to *Völkerpsychologie*.

Wundt's Early Views on Intra-Individual and Inter-Individual Psychology

Wundt's early views on the nature of psychology cannot be properly evaluated without some knowledge of the historical background with respect both to intra-individual and inter-individual psychology against which he himself evaluated his own contributions. With respect to intra-individual psychology, there are many secondary sources, including the work of Boring and Murray, that describe how research on sensation and perception by E. H. Weber (1795–1878), G. T. Fechner (1801–1887), F. C. Donders (1818–1889), and, of course, Helmholtz provided the catalytic impulse that transformed armchair psychology, with its tradition going back through the associationists to Descartes and Aristotle, into the kind of experimental psychology that Wundt himself would propagate once installed at Leipzig. Wundt also acknowledged the importance of the well-intentioned mathematical psychology of J. F. Herbart (1776–1841); Herbart's system was an analogy in mental science to Newton's system in physical science. But when Wundt described Herbart's intra-individual psychology in the first edition (1874) of his great textbook, the *Grundzüge der physiologischen Psychologie* (Principles of physiological psychology), he criticized it, on mathematical grounds, so harshly that Wundt probably helped to make Herbart's mathematical psychology unfashionable for the whole of the 20th century.

Wundt's views on inter-individual psychology, as crystallized in his changing conceptions of the role of *Völkerpsychologie* vis-à-vis psychology as a whole, were initially based on some conceptions of group psychology put forward by T. Waitz (1821–1864), H. Steinthal (1823–1899), and M. Lazarus (1824–1903), who in turn professed themselves to have been favorably influenced by Herbart. The details of Herbart's influence on Waitz, Steinthal, and Lazarus have been provided by Ribot and by Danziger; it should be noted that Lazarus and Steinthal invented the word *Völkerpsychologie* and used it in the title of a new journal, the *Zeitschrift für Völkerpsychologie und Sprachwissenschaft* (Journal of *Völkerpsychologie* and Language Theory), that they founded in 1859. It is not well known that Herbart tried to extend the mathematical psychology that he had worked out for intra-individual psychology to the psychology of groups.

Herbart called the science concerned with people behaving in groups *Staatswissenschaft*, that is, a science

concerned with the state. Nowadays, such a title might be found in a book of readings concerning political science rather than social psychology. Nevertheless, it was Herbart's belief that his intra-individual psychology could be carried over, *mutatis mutandis*, from the individual to the group, and, for Herbart, it was difficult to disentangle group behavior from political behavior. The subject matter of *Staatswissenschaft* concerned groups that ran the gamut from being hierarchically organized, with extreme power being given to the people at the top of the hierarchy, to being disorganized, with nobody having any real power.

Herbart's mathematical psychology, as applied to the behavior of political groups, extended the "statics" and "mechanics" of the individual mind to the state itself. Any state is composed of many individuals who are mainly competing rather than cooperating; at any moment in historical time, a condition of equilibrium will be arrived at in which the majority of individuals are able to combine their competitive and altruistic inclinations. But disequilibrium can easily be introduced into the system by political unrest, outside invasion, or new ideologies, and peace will only be re-achieved when a new equilibrium condition is arrived at, one that will be attained when some unruly individuals are temporarily or permanently deprived of power within the group. Moreover, just as individual ideas within an individual's mind can either remain independent of each other or fuse with each other, so individuals within a group can remain independent of each other or fuse into subgroups ("pressure groups" or "break-away groups," as we might now say).

Wundt, in his 1862 Introduction to the *Beiträge*, began his discussion of the psychology of groups (calling it, in agreement with others, "sociology") by saying that the best way of collecting the relevant data was to use a broadened method of observation. But the "broadened method," he maintained, would not include the Newton-like equations proposed by Herbart. Wundt claimed that sociology had been created "by an extension of the results of the psychological observation of the individual, to the lives of the nations. Now, however, this science has gradually begun to free itself from the basis on which it rests, and to establish its own foundation. This foundation consists in the determination of a great number of facts through *statistics*."

By "statistics" in this sentence, Wundt meant the collection of data that provided evidence for the relative frequency of physiological characteristics (e.g., measurements of chest girth) or major life events (e.g., divorce) associated with individuals within a group. For example, by 1862, data had been collected on the frequency of suicides, not only within a given nation, but also within given age ranges, genders, seasons of the year, and so on. The person most responsible for collecting such data was the mathematician L. A. Quetelet (1796–1874), who obtained much of his data from census information collected by the Belgian government. Quetelet argued that many data sets concerning individuals showed a symmetric variability around a common arithmetic mean and were probably distributed, therefore, in a Gaussian manner. Quetelet thus provided a methodology that served as a background for the introduction not only of descriptive, but also of inferential, statistics into the social sciences. Wundt, along with Lazarus and Steinthal, was indirectly responsible for the relegation of Herbart's views on the social sciences into near oblivion. Wundt also played a small but important part in ensuring that Quetelet's views about the importance of arithmetic means led to those means' being adopted as the most widely used measures of central tendency in reports concerning groups.

It might be noted that Fechner in 1897 would later maintain, contrary to Quetelet, that the measure of central tendency that best described many collectives was the mode, rather than the mean. It might also be noted that, as will be described below, Wundt's moving away from conceiving groups as political entities led him to a pre-Herbartian conception of groups as cultural entities.

Wundt's Career at Leipzig

When Wundt arrived in Leipzig in 1875, he was riding the crest of a newly acquired fame resulting from the success of his 1874 textbook of physiological psychology. The first edition of this book was concerned not only with describing the latest knowledge about the nervous system and the brain but also with describing new trends in experimental psychology, including psychophysics, studies of sensory perception, and research on reaction time. Wundt's textbook went through a total of six editions between 1874 and 1908–1911, but only the first volume of the fifth edition was made available in English. In the third edition, published in 1887, at the height of the Institute's fame, there is no reference to *Völkerpsychologie* in the index.

It was probably his graduate students who suggested to Wundt that the classroom he had been given in one of the buildings on the Leipzig campus serve as the foundation of an expanded teaching laboratory. This provided the seed that led Wundt to apply for an Institute (German, *Seminar*) to be devoted to experimental psychology in particular. Such an arrangement would allow more graduate students to study with Wundt, and Wundt himself then also receive financial support from the University to reimburse teaching and research personnel, as well as to purchase apparatus and supplies. All his earlier research had been self-funded. The impetus that an Institute would give to the furtherance of experimental research would also provide material for a journal for the dissemination of this research; the first issue of his new journal *Philosophische Studien* appeared in 1881, and the third

issue included a report of the first Ph.D. dissertation defended at the Institute, namely, that of M. Friedrich in 1883.

Wundt's subsequent career was devoted to the expansion of the Institute (by the early 1880s, it had grown from one classroom to about seven, and in 1896, the Institute was moved to occupy the whole floor of a new building); to the development of the journal (in 1901, its name was changed to *Psychologische Studien*); to the teaching of practical classes in experimental psychology (following a trend in the science departments of many German universities, a trend quickly imitated in other countries); to the cordial reception of foreign visitors (who would study the "new psychology," as it came to be called); and to the continuation of his writings, both on philosophy and on psychology. The main works that occupied his final two decades at Leipzig included the sixth edition of his textbook, the writing of his autobiography (published in 1920), and the first of the many editions of his multivolume work entitled *Völkerpsychologie* that appeared between 1900 and 1920.

Following his retirement from teaching in 1917, Wundt died in his home on August 31, 1920. He was preceded in death by his wife by eight years; she had borne three children, Eleonora (born 1876), Max (born 1879), and Lilli (born 1880, who died at age four). Wundt received many honorary degrees; these are listed by Meischner and Eschler.

Wundt's Original Research Contributions: Intra-Individual Psychology

This section will be short, partly because there are many secondary sources available that discuss Wundt's contributions to experimental psychology, and partly because the focus of the present article is on his contributions to social measurement. Nearly all of the research performed at Leipzig was carried out in the context of practical classes or dissertations. With respect to practical classes, Wundt would think of several research projects and allow small groups of graduate students, led by a more experienced student or research assistant, to carry out these projects, making use of the equipment Wundt had acquired. With respect to dissertations, these could be experimental or philosophical, and dissertations of both kinds appeared, in condensed form, in *Philosophische Studien* or, after 1901, in *Psychologische Studien*. The research contributions of Wundt himself that are best remembered today are his tridimensional theory of feeling and his analyses of the psychological processes involved in the perception of very briefly presented visual information. Murray has described Wundt's attempt to integrate the natural sciences (*Naturwissenschaften*) with the human sciences (*Geisteswissenschaften*) and has summarized Wundt's views on the dangers of introspection as a scientific method, his views on "psychic causality," his so-called "structuralism," and his contributions to "voluntarism" as an approach to psychology. His attempt to integrate the sciences included the incorporation of both physiological psychology and *Völkerpsychologie* into a general science of mind and behavior.

Wundt's Original Research Contributions: Inter-Individual Psychology

Wundt wrote little on *Völkerpsychologie* during the first half of his 41-year residence at Leipzig (from 1879 to 1900). There was, however, one article in *Philosophische Studien* in which Wundt (1886) stressed that the psychological laws determining the behavior of groups were not necessarily of the mechanical kind associated with Herbart, but were laws that were relatively independent of the physiological events taking place in the brains of individuals and more dependent on physical events that determined the environment, including the linguistic environment in which an individual found himself. But, in the course of writing the various editions of his books on logic and on ethics, Wundt kept up with new findings reported by anthropologists and others exploring as yet unknown corners of the world, and in particular, he kept track of data concerning the languages, customs, morals, myths, laws, and religious beliefs of the peoples indigenous to those regions. All this information would find its appropriate place in the major work of the last half of his stay at Leipzig, namely, the *Völkerpsychologie*.

The story of the various parts and editions of this work is extremely complicated; we cut through the tangle to say that in the final publication of the book in 10 volumes, Volumes 1 and 2 were concerned with Language and were translated into English in 1973. Volume 3 was concerned with Art, Volumes 4, 5, and 6 with Myth and Religion, Volumes 7 and 8 with Society, Volume 9 with Law, and Volume 10 with Culture and History. However, Volumes 1 to 6 represented third or second editions of earlier parts of the *Völkerpsychologie*, and Volumes 7 to 10 appear to have been first editions. To add to the confusion, Wundt published a separate one-volume work in 1912 entitled *Elemente der Völkerpsychologie: Grundlinien einer psychologischen Entwicklungsgeschichte der Menschheit* (Elements of *Völkerpsychologie*: Outlines of a psychological history of the development of mankind).

This book was translated into English by Schaub in 1916, with the main title rendered as *Elements of Folk*

Psychology, a translation that was acceptable in Schaub's time, but is now seriously misleading. This is because the expression "folk psychology" has taken on a new meaning in the final decades of the 20th century. It is found in books on the philosophy of mind and refers to the preconceptions that ordinary people have about how the mind works. Nowadays, a reasonable translation of *Völkerpsychologie*, as used by Wundt, might be "the psychology of peoples." It is not to be translated as social psychology; some of the most widely read books of the early 20th century that contained the words social psychology in the title, such as the textbooks of Allport, McDougall, and Thouless, referred nowhere to Wundt's *Völkerpsychologie*. Nor is it to be translated as "cross-cultural psychology," which usually deals with topics such as adaptations by individual groups to emigration, or the effects on indigenous peoples of new technologies.

One of Wundt's own definitions of *Völkerpsychologie*, as given in the Introduction to the first edition of Volume 1, was as follows:

> *By this term, we can denote that mixture of actual observations, received theories, and putative facts of which the representatives of individual scientific disciplines avail themselves when they are unable to offer an appropriate psychological interpretation [for their data].*

This definition almost moves *Völkerpsychologie* out of the realm of psychology and into the realms of archeology, anthropology, and history itself.

Three main comments can be made about the multivolumed book entitled *Völkerpsychologie*. First, in his resistance to a Herbartian approach, Wundt actually moved to a position that had been expressed by writers prior to Herbart who had been concerned with the evolution of human thought. Danziger has explained how the term *Volk* was given life in Germany in the writings of J. G. Herder (1744–1803), for whom a *Volk* was a group united, not so much in terms of a political power hierarchy, or even in terms of a legislated system of moral rules, but in terms of what Herder called a "culture." In Herder's view, the language common to the group provided a medium that bonded the separate elements of that culture. Many answers to traditional philosophical questions concerning morality, truth, and art were thereby embedded in the culture of a community, and Herder had himself believed that those answers in turn depended on the physiological characteristics of, and environmental influences on, the individuals in that community. Wundt's emphasis on the linguistic, artistic, mythic, religious, and moral determinants of the evolution of the mentality of a community at any period in its historical development is coherent with Herder's definition of a culture as being identifiable with the mentality of a *Volk*. Wundt's return to Herder's notion of a cultural community had also been anticipated by azarus and Steinthal, according to Danziger.

Second, Wundt's *Völkerpsychologie* differed both from Herbart's system and from modern psychological systems, such as behaviorism and Gestalt psychology, insofar as each of these last three systems is mainly concerned with the scientific description and prediction of behavioral and mental events in terms of measurements, such as the strength or duration of stimuli, the degree to which wholes subsume parts, and the latency or vigor of vocal or motor responses. These schools are not particularly interested in the contents of thoughts or in the qualitative (as opposed to quantitative) nature of responses. It is in fact possible, as Karl Bühler suggested, to divide systems of psychology into two kinds, one concerned with the contents of thoughts of individuals and one that is relatively unconcerned with contents and more concerned with providing a general scientific context appropriate to a mental science. In modern times, psychoanalysis is the school most representative of the first kind of system, and behaviorism is the school most representative of the second kind of system.

Wundt's *Völkerpsychologie* clearly can be classified as an example of the first kind of system, and Herbart's as an example of the second kind. But modern social psychology and cross-cultural psychology, along with modern sociology, contain investigations of both kinds; for example, the degree of successful adaptation by immigrants to new cultures varies not only with quantitative determinants such as the length of stay since their arrival in the new culture, but also with qualitative determinants such as the country of origin of the immigrants, their first language, and the generation (first or second) of immigrant. Research investigations like these are difficult to classify neatly under either of Bühler's headings. The fact that Wundt's *Völkerpsychologie* is so relentlessly content-bound as to be difficult to fit into any system that attempts quantification of its data has pushed it to the sidelines of the history of the social sciences.

Third, one can flip through the pages of any of the volumes of the *Völkerpsychologie*, or of the single-volumed *Elements of Folk Psychology*, and find very few numbers and certainly no equations or formulas. Wundt's early enthusiasm for the collection of statistical data *à la Quetelet* appears to have been replaced by a principled concern with qualitative matters when he came to write the *Völkerpsychologie*. As a consequence, he still wished to determine the general causes ("scientific laws") that would explain his data. In fact, he developed the theory that the evolution of a culture went through several separate stages from the primitive to the sophisticated; for example, he saw the history of a religious system as developing from fear-inspired nature worship, through a stage of demon worship followed by a stage of hero worship, to its final appearance in a polytheistic or monotheistic form of god or goddess worship. He also developed the theory that the evolution of language went

through a mimetic phase prior to its speech phase. The data on which he based these theories are assembled in the multi-volumed *Völkerpsychologie*; his schematic outline of the history of the evolution of religious, moral, family, and legal systems within cultures was provided in the one-volume work entitled, in English, *Elements of Folk Psychology*.

Wundt's Influence on Social Measurement

Although Wundt played a part in encouraging the collection of statistical data as one of the responsibilities of a social scientist, his own contribution to social psychology was to have emphasized the importance of cultural beliefs in determining the behavior and thinking patterns of an individual member of that culture. As a consequence, Wundt played little part in the advancement of experimentation as a method in social psychology, or in the advancement of the use of correlational techniques as adjuncts both to descriptive and to inferential statistics, or in the advancement of any approach to sociology or social psychology based on an ideology. In the laboratory, he encouraged his students to analyze their data in a quantitative manner, including the calculation of measures of variability, as well as of central tendency, and he admired Fechner's use of Gaussian assumptions in the calculation of absolute or differential thresholds in tasks involving sensory discriminations. But even though, in his Introduction to the *Beiträge*, Wundt had forcefully advocated his view that the data of experimental psychology should include the data of child psychology, animal psychology, and *Völkerpsychologie*, he himself only investigated the last of these in detail and then in such a way that he made little use of the descriptive statistics that he himself had recommended in that Introduction. Wundt's contribution to social measurement was that he laid a solid grounding for the institutionalization, within academia, of the mental sciences alongside the physical and natural sciences. Once this had been achieved, the way had been paved for the institutionalization, within academia, of social psychology, cross-cultural psychology, the psychology of religion, and other branches of psychology concerned with the behavior of individuals within groups.

Glossary

autoregressive model A time-series model in which the value of a series at time t depends on its past values, together with a random disturbance. A second-order autoregressive model is thus $y_t = a_1 y_{t-1} + a_2 y_{t-1} + e_t$, $t = 1, \ldots, T$.

correlation coefficient A statistical measure of the degree of association or covariation between two series. A value of $+1$ indicates perfect positive association, -1 indicates perfect negative association, and 0 indicates complete independence.

first-differencing The construction of a time series based on changes (or differences) in level from one period to the next, in the form $z_t = y_t - y_{t-1}$. Higher order differencing may also be employed.

multiple regression A statistical model in which the values for a dependent variable (y) are explained as a function (usually linear) of several exogenous or causal variables (x_1, x_2, x_3, etc.) and a random disturbance term: $y_t = b_0 + b_1 x_{t1} + b_2 x_{t2} + b_3 x_{t3} + e_t$, $t = 1, \ldots, T$.

partial correlation A correlation between two variables after the roles of other influencing factors have been taken into account, or "partialled out."

George Udny Yule (1871–1951), British statistician, was one of the key innovative figures in the generation of the work of Karl Pearson, William Sealy Gosset (who used the pseudonym "Student"), and Ronald A. Fisher, who constructed the basis of statistical theory in the early 20th century. Yule worked closely with Pearson on correlation and regression in the 1890s, but soon established an independent role. He contributed seminal ideas in several arenas related to the growth of quantitative social science. His work on multiple regression and correlation was applied to social policy questions and he formulated the first use of conditioning on exogenous variables to assess policy instruments. His work was also formative in the development of time-series analysis, in autoregressive and differenced series, as a precursor of modern cointegration analysis. His work on contingency table analysis broke free of Pearson's biometric framework, and again laid key foundations for later work.

Biography and Major Contributions

George Udny Yule was born in Scotland in 1871, into a family with deep Scottish roots and a scholarly tradition. Yule is a Scottish surname and Udny was a family name ultimately deriving from a place in Aberdeenshire. George Yule's grandfather had been a Persian and Arabic scholar, his father produced a definitive edition of Marco Polo's travels, and both his father and uncle (an administrator in India) received knighthoods. Yule was educated at Winchester, which placed strong emphasis on classical scholarship, and Yule's later facility at writing Latin verses about the theory of small samples must derive from these years. But it was science and engineering that appealed to the young man, and he went on to study engineering at University College, London University, graduating in 1890 at age 19. He then spent 2 years in the engineering workshops before a spending a year doing research on the physics of electrical waves with Professor Heinrich Herz in Bonn, Germany. Yule's first published papers (at the age of 22) were on this physics research, but in the summer of 1893, he returned to London and changed his research field to statistics.

Yule became a demonstrator (assistant) to Karl Pearson, a Professor of Applied Mathematics at University College, and remained in this position until 1899. Pearson was then at his most innovative, constructing measures of statistical inference to implement Francis Galton's

ideas on correlation and inheritance. During the 1890s, Yule was a close collaborator with Pearson, making advances in net or partial correlation, multiple correlation, and regression. Although Yule had the title of Assistant Professor, his salary was extremely low, and early in 1899, he left for an administrative post with a London examination board. However, from 1902 to 1909, he also held a (part-time) Newmarch Lectureship in Statistics, and also took on other work. The year 1912 was a turning point for Yule; he was appointed a lecturer in statistics at Cambridge University, and he remained there for the rest of his career (apart from civil service for 4 years during World War I). He was elected a Fellow of the Royal Society in 1922, and President of the Royal Statistical Society from 1924 to 1926. He retired at age 60 with heart problems, but continued to do a research until his death in 1951.

Although he was a close associate of Pearson during the 1890s, Yule soon established his own directions, independent of his biometrically oriented mentor. The two men were joint authors on only one paper. Yule became interested primarily in social, economic, and epidemiological applications of statistical methods, and these required assumptions and perspectives different from those of biometrics. Yule developed such methods, and in doing so, clashed with his mentor several times. After he left University College in 1899, he and Pearson followed independent agendas. Yule and Pearson had very different personalities and interests. Yule was an individual research worker: he had no interest (or aptitude) for setting up a laboratory, establishing a journal, gathering acolytes, and running a directed research program, all of which Pearson did. Nor did Yule find Pearson's biometric (and eugenic) program appealing. Yule had diverse interests and sought to develop and apply statistical theory to problems as they came to hand, rather than to be more narrowly focused. Indeed, he once described the academic scientist's role as a "loafer in the world," detached and free from narrow, applied ties. In Yule's case, this was a very fruitful process. Although Yule was an individual researcher, he was also a keen contributor to scientific societies. Most notable was his participation in the Royal Statistical Society in London, which he joined in 1895. This society had a long tradition of using numerical data and quantitative methods to examine social problems, and it brought Yule into contact with civil servants and social scientists. The society's journal became the major outlet for Yule's scientific papers.

Yule made significant contributions in several different areas. The three arenas in which his contributions "made a difference" in the development of quantitative social research were multiple regression modeling, the study of contingency tables, and time-series analysis. The three themes correspond roughly to three periods in his research career: multiple regression, in the last decade of Victorian England; contingency tables, in the first decade of the new century; and time-series analysis, during the 1920s. In each arena, Yule made progress by recognizing the need to relax one or more of the assumptions that underlay the biometric approach to statistical inference, and to construct more appropriate probability tools. (Pearson's seminal work had been closely based on assumptions of multinormal frequency distributions together with independence among interval-scale observations; such assumptions were reasonably appropriate for his applications, i.e., measuring physical characteristics of plants, animals, or people, but they did not work for many socioeconomic applications or for other nonexperimental situations, such as time-series observations of physical phenomena.) Yule's major papers on contingency tables and time-series analysis have been reprinted, but his early regression papers have not.

Yule's intellectual contributions were recognized at the time of his work; through his publications and his direct influence in bodies such as the Royal Statistical Society and the International Statistical Institute, his contributions diffused throughout the world of early quantitative social science in the decades from 1910 to 1940. Though some of the methods have been overtaken by later work, some of his work still has a fresh, "modern" feel to it, and is still relevant.

Multiple Regression

Historians of statistics agree that Yule played a very significant role in the development of statistical methods in the 1890s. John Aldrich writes that "Karl Pearson and G. Udny Yule developed the main interpretations of correlation used by statisticians for the last century or so" and "Between them they made correlation analysis." For Stephen M. Stigler, it is Yule who puts the final keystone, the reintegration of correlation and regression into least-squares theory, into place: "Only one important step remained to be taken in 1895, a step crucial to the completion of the larger program that Galton had launched. Before two years had passed G. Udny Yule was to take that step."

The empirical context for Yule's statistical applications was English Poor Law policy. The 19th-century Poor Law was a tough policy dealing with those unable to support themselves through illness, unemployment, or old age: the workhouse or, for those unable to work, the closed asylum awaited these unfortunate Englishmen. This fate was what was called "in-relief." By the latter 19th century, considerable assistance was being provided by some Poor Law Unions in the form of "out-relief," which was assistance in the home, mainly for the elderly and ill, and there was a very active political debate on "pauperism," as poverty was then termed, a debate with echoes in recent

welfare policies. One strand argued that out-relief encouraged pauperism, whereas others argued there was no relationship. In a paper in the *Economic Journal*, Yule employed data for over 500 spatial units (Poor Law Unions) in England in 1871 and 1891 to test the relationship, using the (brand new) correlation coefficients: for 1871, the correlation between out-relief and pauperism was 0.262 (probable error, 0.025), and for 1891, the correlation was 0.388 (error, 0.022).

Yule did not argue that there was a causal relationship, only an association, and, in response to criticisms from Charles Booth, a wealthy businessman-*cum*-sociologist and devotee of Auguste Comte, Yule recognized the need to take account of other factors, giving him the perfect opportunity to deploy his new tools of multiple and partial correlation. In 1896, Yule wrote that "the proper method to be employed is, it seems to me, that of 'multiple correlation.' This method enables us to deal with facility with three variables, and if need be with more, and to form coefficients of correlation between any two of the variables while eliminating the effect of variations in the third (or others). Such 'net [partial] coefficients' will probably play an important part in future statistical researches." Here his work introduced the concept of controlling for the effects of other influential variables or effects when assessing the association between two variables, a concept that has proved vital to statistical analysis in general and to the nonexperimental social sciences in particular. If such effects were not taken into account, there was a real risk of spurious correlations (or "illusory correlations," as Yule termed them) appearing. Yule began his 1897 paper *On the Theory of Correlation* by stating that "The investigation of causal relations between economic phenomena presents many problems of peculiar difficulty, and offers many opportunities for fallacious conclusions. Since the statistician can seldom or never make experiments for himself, he has to accept the data of daily experience, and discuss as best he can the relation of a whole group of changes; he cannot, like the physicist, narrow down the issue to the effect of one variation at a time. The problems of statistics are in this sense far more complex than the problems of physics."

In tackling the issues of multivariate relationships, Yule broke away from Pearson's assumption of multivariate normality. Instead, Yule framed his analysis within the method of least squares, long established in astronomy and elsewhere as a theory of errors. In *The History of Statistics: The Measurement of Uncertainty before 1900*, Stigler captured the importance of Yule's move: "The paper had a new and broader outlook that at once put the developing theory of correlation in a perspective from which it could deal with the problems of the social sciences and reconciled it formally with the traditional method of least squares from the theory of errors. As such Yule's work marked the completion of a final stage in the development of what could be called Galton's program and formed a cap on nineteenth-century work on statistics for the social sciences."

A further paper in 1899 took Yule's work forward into an explicitly causal framework, presenting the multiple regression model and applying it to the social problem of pauperism. In the latter decades of Victorian England, the levels of pauperism had been falling markedly. Now Yule saw that the real test of explanation was whether changes in the explanatory factors could explain such changes in pauperism. The paper jumps straight into a multicausal approach: "The various causes that one may conceive to effect changes in the rate of pauperism may for clearness be classified under some five heads," which were (1) policy or administration; (2) economic conditions (wages, trade levels, employment), (3) social or industrial character (including density), (4) moral character (such as crime, education, illegitimacy), and (5) the age distribution. In practice, Yule only had data available to take some of these factors into account. For rural regions for the decade 1871–1881, Yule's multiple regression equation was as follows: percentage change in pauperism = $-27.07 + 0.299$ (percentage change in out-relief ratio) + 0.271 (percentage change in proportion old) + 0.064 (percentage change in population). Yule was then able to argue that the coefficient for the out-relief ratio ($+0.299$) "gives the change due to this factor when all the others are kept constant." The model thus assesses the role of the policy instrument, conditioning on what today would be called the other exogenous variables. Yule recognized that his analysis was still susceptible to the omitted factors that he was unable to measure: "there is still a certain chance of error depending on the number of factors correlated both with pauperism and with the proportion of out-relief which have been omitted, but obviously this chance of error will be much smaller than before." In hindsight, with the benefits of a century of subsequent statistical research, it is possible to identify further gaps and limitations in Yule's statistical analysis (such as outliers, spatial autocorrelation, and possible endogeneity of the measure of policy). But it is the remarkable quality and depth of the work that stands out. As Stigler commented, "the paper was in its way a masterpiece, a careful, full-scale, applied regression analysis of social science data."

Contingency Tables

The second arena in which Yule made a contribution to quantitative social research was the analysis of categorical variables and contingency tables. The statistical advances of the 1890s, including Yule's own work, had focused on interval or continuous-scale variables, but by the turn of the century, attention was also being given to attribute or

categorical variables. Yule gave the example of mortality from some disease with and without the administration of a new antitoxin: an individual died or lived, had the antitoxin or did not, but there were no continuous scales of variation involved. In other cases, as Yule noted, there might be gradation possible, but the actual data were categorical (blind or not blind, deaf or not deaf). For the two-category, two-variable case, a simple contingency table (as in Table I) can represent the data: thus a is the number of people who had the antitoxin and survived, c is those who had antitoxin but still died, and $a+c$ is the total number of people who had the antitoxin; b and d are defined similarly for the "no antitoxin" groups, and N $(=a+b+c+d)$ gives the total number of people involved. How were correlations or other measures of association to be constructed for such cases?

Yule and Pearson came up with different perspectives on this situation, leading to serious, and sometimes intense, controversy, described in the literature as "the politics of the contingency table." Pearson wanted to treat all such categorical data as simplifications from an underlying normal frequency distribution, so accommodating them within his biometric correlation frame. This is plausible for some cases, but not for others, such as Yule's mortality example. By contrast, Yule took the categories as given, and attempted to construct measures of association relevant to the actual case. A coefficient, calculated directly from the table, should be zero if the two attributes were independent of each other, +1 or −1 if, and only if, they were completely associated in a positive or negative sense. Yule's Q-coefficient, defined as $Q=(ad-bc)/(ad+bc)$, did this, but it had no special justification, and other measures, equally valid, could be constructed but did not always give identical inferences. The controversy between Yule and Pearson, and that between their allies, was seen as exemplary of a deeper division in terms of attitudes to the biometric program and eugenics. This perhaps overinterprets the differences, but certainly it reflected Yule's more pragmatic, flexible approach to inference and Pearson's allegiance to the model of normal frequency distribution.

Both perspectives had their supporters. Pearson's measures were adopted within the emerging field of psychometrics whereas Yule's measures became popular in sociology. The field of contingency table and categorical data analysis has moved on a long way since this early work, and overall has built on Yule's insights rather than on Pearson's more rigid assumptions.

Table I A Simple Two-by-Two Contingency Table

Outcome	*Antitoxin*	*No antitoxin*	*Total*
Survived	a	b	$a+b$
Died	c	d	$c+d$
Total	$a+c$	$b+d$	N

Time-Series Analysis

Yule's third major contribution was to the development of time-series analysis. By the first years of the 20th century, there was recognition that correlating two sets of time-series observations could give rise to apparently significant, but spurious, results. If the two series both followed similar trending or oscillatory paths, then, inevitably, they would appear correlated. Several ways around this were suggested, such as first-differencing the series or removing the trend by linear or polynomial regressions and then correlating the residuals. As David Hendry and Mary Morgan have noted, "This trial and error approach was not matched by any deep understanding of statistical theory." It also drew implicitly on the model of spurious correlation being generated by an omitted "third" variable, in this case, "time": partial out the time factor and the genuine correlation could be retrieved. Yule reviewed the various approaches in a paper in 1921, finding the field confused in aims and methods and demonstrating that random variations could give rise to the apparent correlations.

These issues occupied Yule during the 1920s, and he produced seminal papers rejecting the earlier perspective. Two papers in particular, in 1926 and 1927, were influential, and these were both reprinted in Hendry and Morgan's *The Foundations of Econometric Analysis*, in which they noted that, in contrast to previous students of this problem, Yule's work was "informed by an understanding of statistical theory which was amongst the best of his generation." Yule rejected the argument that the source of the problem was that the variables were correlated with time. Instead, he argued that the problem arose because the observations were correlated with previous values in the same series, and that the changes in the observations were also correlated with previous values of changes. In other words, it was the internal dynamics of the time series that generated what Yule termed "nonsense correlations." Yule's 1926 paper on nonsense correlations begins with an example: for England in the period 1866–1911, the proportion of Church of England marriages to all marriages and the standardized death rate have a correlation coefficient of +0.9512. Yule makes the following comments:

> *Now I suppose it is possible, given a little ingenuity and goodwill, to rationalize very nearly anything. And I imagine some enthusiast arguing that the fall in the proportion of Church of England marriages is simply due to the Spread of Scientific Thinking since 1866, and the fall in mortality is also clearly to be ascribed to the Progress of*

Science; hence both variables are largely or mainly influenced by a common factor and consequently ought to be highly correlated. . . . But most people would, I think, agree with me that the correlation is simply sheer nonsense; that it has no meaning whatsoever; that it is absurd to suppose that the two variables in question are in any sort of way, however indirect, causally related to one another.

Yule investigated correlations between two unconnected time series under three different assumptions: when the individual series are (a) random, (b) random in first differences (which Yule termed "conjunct," to denote series for which all serial correlations were positive), and (c) random in second differences. In modern econometric parlance, these are series integrated of orders 0, 1, and 2, respectively. Classical sampling theory for correlation is valid for the random case a, and Yule's simulations demonstrated this, but not for the other models. Model b generated a much more dispersed distribution (so that "no correlation" would commonly be rejected), and model c generated a U-shaped distribution of correlations, with most values close to either $+1$ or -1. Series of type c Yule labeled "dangerous." To produce these results, Yule engaged in substantial Monte Carlo simulation of the distributions. With the very limited calculator assistance available in the 1920s, the work must have taken Yule many weeks, locked away in his study in Cambridge. Hendry and Morgan were able to replicate his results closely, but using modern computing equipment.

In his paper of the following year, as part of an investigation of Alfred Wolfer's sunspot cycle series, Yule introduced the autoregressive model (though Yule did not used the this term), in second-order form: $y_t = a_1 y_{t-1} + a_2 y_{t-1} + e_t$, where y_t is the series, a_1 and a_2 are autoregressive parameters, and e_t is a random disturbance. He demonstrated how such autoregressive models could generate oscillatory sequences, and also gave the random component what has been called "an active role as a disturbance term," showing how the random disturbances played a central role in the dynamics. They were not simply fluctuations around the oscillations, but could alter the phase and amplitude. Yule neatly used the analogy of a pendulum in a room: "Unfortunately boys get into the room and start pelting the pendulum with peas, sometimes from one side and sometimes from the other. The motion is now affected, not by superimposed fluctuations, but by true disturbances, and the effect on the graph will be of an entirely different kind. The graph will remain surprisingly smooth, but the amplitude and phase will vary continually." Judy Klein, in *Statistical Visions in Time. A History of Time Series Analysis, 1662–1938*, stated that "This work became the foundation for modern time series analysis. It was the first complete formulation of what was later to be called a stationary stochastic process of the autoregressive type. It was also the first instance in which an error term (e) was used to signify random disturbance in a relationship, not just errors in measurement." Other statisticians, such as Ragnar Frisch, Helen Walker, and Herman Wold, elaborated on these ideas, which lie at the heart of both time-series analysis and econometrics. Yule never went beyond the model for a single series to propose a model for bivariate series, and he commented "It is quite beyond my abilities, but I hope that some mathematician will take it up." It can be argued that a full analysis had to await Clive Granger's development of cointegrated time series in the 1980s.

Legacy

Perhaps inevitably, as with other pioneers of quantitative social research, Yule's name appears today only rarely in contemporary textbooks, but his work has been receiving increasing recognition in histories of statistics and econometrics. It is especially the classic time-series papers that are reprinted. Yule's multiple regression work received shorter shrift: when Alan Stuart and Maurice Kendall came to assemble a selection of Yule's papers for a retrospective collection in 1971, they did not include any of these papers. Commenting on the problems of selection from Yule's wide range, they noted that "It was with reluctance that we omitted Yule's pioneering work on pauperism, which is still of methodological interest to sociologists." In case this is read as dismissing obscure work with backhanded praise, it is worth quoting Kendall from his 1951 obituary article on Yule: "the value of some of his contributions has been lost to view in sheer virtue of their success; for example, his work on correlation and regression is now such standard practice that only a student of history would consult the original papers." This is very true: the methods developed and applied by Yule were formative in demonstrating how statistical modeling could be relevant to the nonexperimental context of social and economic analysis. Many of his methods are still in use, and elsewhere his insights have been built up and extended. Yule's remarkable achievement was to make these significant contributions to three different arenas of statistical modeling.

Former head of AASHTO

Robert J. Franzese
University of Michigan

Doug Frechtling
George Washington University

David A. Freedman
University of California, Berkeley

Linton C. Freeman
University of California, Irvine

Kim Fridkin
Arizona State University

Michael Friendly
York University

Michelle L. Frisco
Iowa State University

Lance D. Fusarelli
Fordham University

Sam Gaertner
University of Delaware

Michael Gaffikin
University of Wollongong

Norman Gall
University of Calgary

Xiaohong Gao
ACT Inc.

Tommy Garling
Göteborg University

Gerald Gates
US Census Bureau

Andrew Gelman
Columbia University

Richard Gelpke
University of Massachusetts at Boston

Arthur Getis
San Diego State University

Gerd Gigerenzer
Max-Planck-Institute für Bildungsforschung

Nigel Gilbert
University of Surrey

Jean Giles-Sims
Texas Christian University

Jeff Gill
University of Florida

David Gillespie
Washington University

Mike Gillespie
University of Alberta

Garret Glasgow
University of California, Santa Barbara

Jean Berko Gleason
Boston University

Jack Goldstone
University of California, Davis

Hongmian Gong
Hunter College, CUNY

Michael Goodchild
University of California, Santa Barbara

Linda Gottfredson
University of Delaware

Ivor Grattan-Guiness
Middlesex University at Enfield

William W. Graves, IV
University of North Carolina at Charlotte

Ann Green
Yale University

Christopher Green
York University

F. Green
University of Kent at Canterbury

Michael Greenacre
University of Pompeu Fabra

William Greene
New York University

Lee-Anne Greer
East Prince Mental Health

Henrich Greve
Norwegian School of Management BI

Daniel Griffith
Syracuse University

Eve Gruntfest
University of Colorado

Feng Gu
Boston University

Peter Guarnaccia
Rutgers University

Guang Guo
University of North Carolina

Peter Guth
US Naval Academy

James Guthrie
Vanderbilt University

Darrene Hackler
George Mason University

Donald Haider-Markel
University of Kansas

Stephen Hall
Imperial College, University of London

Ronald Hambleton
University of Massachusetts

David Hand
Imperial College

John Hand
University of North Carolina at Chapel Hill

Hans-Tore Hansen
University of Bergen

Brad Hanson
CTB/McGraw-Hill

Sandra Lee Harding
Queensland University of Technology

Wynne Harlen
University of Bristol

James W. Harrington
University of Washington

Richard Harris
University of Bristol

Harm't Hart
University of Utrecht

David Harvey
University of Nevada, Reno

Philip Haynes
University of Brighton

David Healy
University of Wales College of Medicine

Don Hedeker
University of Illinois at Chicago

Willem Heiser
Universiteit Leiden

Paul Herrnson
University of Maryland

Miguel Hernan
Harvard School of Public Health

Frederick Hess
University of Virginia

Ben Highton
University of California, Davis

Travis Hirschi
University of Arizona

Dick Hobbs
University of Durham

Ken Hodges
Claritas

John Hodgson
University of Alberta

Nancy Hoffart
Northeastern University

Howard Hogan
Census Bureau

Herbert Hoijtink
University of Utrecht

Darryl J. Holman
University of Washington, Seattle

Robert D. Hoppa
University of Manitoba

Ruth Horowitz
New York University

Ann Howard
University of North Carolina at Chapel Hill

Youqin Huang

Janice Huber
St. Francis Xavier University

Martina Huemann

John Hughes
Lancaster University

Hiddo A. Huitzing
University of Groningen

Gary Hunt
University of Maine at Orono

Mike Hutchinson
Australian National University

Paul Huth
University of Michigan

John Iceland
University of Maryland

Simon Jackman
Stanford University

Bruce A. Jacobs
University of Texas

Paul T. Jaeger
Florida State University

Craig R. Janes
University of Colorado at Denver

Maria Anna Jankowska
University of Idaho

Robin Jarrett
University of Illinois, Urbana

Eric Jensen
University of Idaho

Steve Jex
University of Wisconsin at Oshkosh

Peter Johnstone
Invermay Agricultural Centre

Dean H. Judson
US Census Bureau

William Kalsbeek
Iowa State University

Alan Karr
National Institute of Statistical Sciences

Elihu Katz
University of Pennsylvania

Kimberly Kempf-Leonard
University of Texas at Dallas

David Kenny
University of Connecticut

Shahjahan Khan
University of Southern Queensland

Doug Kiel
University of Texas at Dallas

Philip Kilbride
Bryn Mawr College

Gary King
Harvard University

Jean A. King
University of Minnesota

Maryon F. King
Southern Illinois University

Ann Marie Kinnell
University of Southern Mississippi

Rob Kitchin
National University of Ireland

Kim Kleinman
Missouri Botanical Garden

John Knodel
University of Michigan

Martin Knott
London School of Economics

Thorbjørn Knudsen
University of Southern Denmark

Timothy Kohler
Washington State University

Peter Koltnow
Former head of American Highway Users Alliance

Lyle Konigsberg
University of Tennessee, Knoxville

Aryeh Kosman
Haverford College

J. Morgan Kousser
California Institute of Technology

Herbert Kritzer
University of Wisconsin

David Kronenfeld
University of California, Riverside

Richard Kulka
Research Triangle Institute

Mei-Po Kwan
The Ohio State University

Seppo Laaksonen
Statistics Finland

Peter A. Lachenbruch
Division of Biostatistics/OBE/CBER zHFM-215

Partha Lahiri
University of Maryland

Johanna Laiho
Statistics Finland

Sanford Lakoff
University of California, San Diego

Rajav Lal
Harvard Business School

Kenneth Land
Duke University

Edward L. Lascher
California State University Sacramento

Diane Leach
National Institute of Child Health and Human Development

Amy E. Learmonth
Rutgers University

Michel Lebas
HEC School of Management, Paris

Dartmouth

Ann Ledwith
University of Limerick

Robert D. Lee
Pennsylvania State University

F. K. Lehman
University of Illinois

James Lepkowski
University of Michigan

Susan C. Levine
University of Chicago

Michael Lewis-Beck
University of Iowa

Loet Leydesdorff
Amsterdam School of Communications Research

Rebecca Li
College of New Jersey

Donald Lien
University of Texas at San Antonio

J. Robert Lilly
Northern Kentucky University

Mike Linacre
University of Sunshine Coast

John Loehlin
University of Texas at Austin

Enrique Lopez-Bazo
University of Barcelona

J. Dennis Lord
University of North Carolina at Charlotte

Johann Louw
University of Cape Town

Thomas R. Loveland
EROS USGS Data Center

Patricia Lovie
Keele University

Karen Luftey
University of Minnesota

Steven Lukes
New York University

Guanzhong Luo
Murdoch University

Armando Machado
Universidade do Minho

Colleen MacQuarrie
University of Prince Edward Island

M. Eileen Magnello
Wellcome Trust Centre at UCL

Michael Malbin
SUNY-Albany in Washington

Mary Malina
Naval Postgraduate School

George Marcoulides
California State University—Fullerton

Melvin Mark
Pennsylvania State University

Tony Marley
McGill University

Bernard Marr
Cranfield University

Beth Marsh
Duke University

Lawrence Marsh
Notre Dame University

Jim Marston
University of California, Santa Barbara

Luis Martins
Georgia Institute of Technology

Geoffrey Maruyama
University of Minnesota

Richard O. Mason
Southern Methodist University

Robert Mason
Oregon State University

Christina Mauleon
Chalmers University of Technology

Scott E. Maxwell
University of Notre Dame

Lorraine Mazerolle
Griffith University

George McCall
University of Missouri, St. Louis

Charles R. McClure
Florida State University

James H. McDonald
University of Texas at San Antonio

Doris McGartland-Rubio
University of Pittsburgh

W. Scott McGraw
Ohio State University

University of Illinois, Chicago

Stanley A. Mulaik
Georgia Institute of Technology

Wendy Myrvold
University of Victoria

Joan Naymark
Target Corporation

Andy Neely
Cranfield University

Marc Nerlove
University of Maryland

Bill Nichols

Roy A. Nielsen
University of Oslo

Bryan Norton
Georgia Institute of Technology

João Arriscado Nunes
University of Coimbra

Edward J. O'Boyle
Louisiana Technical University

Robert O'Brien
University of Oregon

Barbara Ohlund
University of Nebraska-Lincoln

Morton O'Kelly
Ohio State University

J. Keith Ord
Georgetown University

Bruce Owens
Wheaton College

R. Kelley Pace
Louisiana State University

Kavita Pandit
University of Georgia

Cynthia Parshall
University of South Florida

Diane Paul
University of Massachusetts

Lynn Paxson
Iowa State University

Joseph Pear
University of Manitoba

Leonard I. Pearlin
University of Maryland

Eric Pels
Free University, Amsterdam

Andrew Penner
University of California, Berkeley

Charles Perrings
University of York

Richard Perry
San Jose State University

David Peterson
Texas A&M University

Michael P. Peterson
University of Nebraska at Omaha

Trond Peterson
University of California, Berkeley

E. Pitacco
Università degli Studi di Trieste

Barbara Plake
University of Nebraska

David Plane
University of Arizona

Jennifer Platt
University of Sussex

Leonard Plotnicov
University of Pittsburgh

Andrew Plunkett
Manchester Metro University

John Polk
University of Illinois, Urbana-Champaign

Bruce Pollack-Johnson
Villanova University

Henry Pollakowski
Massachusetts Institute of Technology

Timothy Pollock
University of Maryland

Gerald M. Pomper
Rutgers University

Paula Popovich
Ohio University

Ted Porter
University of California, Los Angeles

Emil Posavac
Loyola University

Stanley Presser
University of Maryland

Kenneth Prewitt
Columbia University

Kevin Quinn
University of Washington

Jeff Rachlinski
Cornell Law School

Charles Ragin
Arizona State University

Senta Raizen
National Center for Improving Science Education

Uday Rajan
Carnegie Mellon

Suparna Rajaram
SUNY-Stony Brook

Nambury Raju
Illinois Institute of Technology

James Ramsay
McGill University
