A new vibration control device called a rotational inertia double-tuned mass damper (RIDTMD) is proposed in this paper. The device consists of a tuned mass damper (TMD) in which the typical viscous damper is replaced with a tuned viscous mass damper. The linear model for a single-degree-of-freedom structure incorporating an RIDTMD, the equations of motion in state-space representations, and the transfer function of the considered model are derived. The optimum design parameters of the system subjected to harmonic load are obtained by using a numeric technique, and the performance of the new device is compared with that of a traditional TMD in terms of frequency response. The strokes of auxiliary masses are also assessed. Based on the results, it is demonstrated that the RIDTMD is more effective than a TMD at the same mass ratio, particularly at excitation frequencies near resonance. Moreover, the suppression band is wider and the moving block stroke is nearly identical for both devices.

1. Introduction

Mitigating the dynamic response of civil engineering and mechanical structures to earthquakes, wind, and rotating machinery has drawn the interest of many researchers in recent decades. Several passive, semi-active, and active control devices have been developed. Among the available devices, a TMD is one of the simplest and most reliable, typically consisting of an auxiliary mass, a spring, and a viscous damper attached to the structure to be controlled.

Hermann Frahm proposed the dynamic vibration absorber [1], later called the TMD, in the 1900s. Since then, several variant forms of TMDs have been proposed in order to improve performance. The Multiple Tuned Mass Damper (MTMD) was proposed and investigated by Xu and Igusa [2] and subsequently studied by several researchers [3–10]. In general, MTMDs are more effective and robust in mitigating the oscillations of structures than a single TMD.

Another type of TMD is the so-called double tuned mass damper (DTMD) or series tuned mass damper. This damper consists of one larger mass block (i.e., a larger TMD) and one smaller mass block (i.e., a smaller TMD) connected in a series. Li and Zhu [11] conducted research on the performance of a DTMD using a novel optimum criterion.

The working principle of all types of TMDs consists of transferring the vibration energy of the primary structure to an auxiliary mass-spring system (i.e., a TMD) in order to effectively dissipate the energy into a suitable damper. In the case of a traditional TMD, that damper is a linear viscous damper. However, other types of dampers can be used.

More recently, Hwang et al. [12] proposed to control structural vibrations by means of a rotational inertia viscous damper (RIVD) utilizing a ball screw amplifying mechanism. The authors noted that the efficiency of the RIVD heavily depended on the lead of the ball screw; as the lead decreases, the effectiveness of the damper significantly increases. Moreover, the apparent mass of the controlled structure, which also depends on the lead of the ball screw, is increased due to the installation of the RIVD.

Ikago et al. [13], based on the concepts of Hwang et al. [12], developed and studied the tuned viscous mass damper (TVMD), which is essentially an RIVD in series with a spring. The resulting apparent mass-spring arrangement behaves as a supplemental tuned oscillator that magnifies the deformation of the damper, thereby improving the performance of the RIVD. It is important to highlight that both devices, the RIVD and the TVMD, are two-terminal devices. For this reason they need a fixed reference to react, unlike the TMD which does not have that disadvantage.
2. Mathematical models

2.1. TMD model

A schematic representation of a TMD coupled to an SDOF structure is shown in Fig. 1. The parameters $k_s$, $c_s$, and $m_s$ are the stiffness, damping factor and mass of the structure to be controlled, respectively. Similarly, $k_b$, $c_b$, and $m_b$ are the stiffness, damping factor and mass of the TMD, respectively. The variables $x_1$ and $x_0$ are the structure and TMD displacements, respectively; whereas $f$ and $x_g$ denote the external force and support acceleration applied to the structure. In this paper, the model developed by Den Hartog [15] is used.

2.2. RIDTMD model

Both the RIVD and the TVMD utilize a ball-screw mechanism that transforms an axial relative displacement into the rotational movement of a mass, which is in turn immersed in a viscous fluid that provides damping to the system [12]. The TVMD also includes a flywheel in order to increase its rotational moment of inertia and a secondary spring [13].

In this work, the damping of the RIVD is modeled by means of an axial dashpot [13] with an equivalent damping factor $c_s$ and the ball-screw mechanism is replaced with an equivalent pinion-rack mechanism in which the pinion radius $r$ occupies the same role as the screw lead. The considered RIVD model, incorporating a flywheel, is shown in Fig. 2.

The following relation holds for the pinion-rack arrangement sketched in Fig. 2:

$$\theta = \frac{1}{r}(x_1 - x_2)$$

in which $r$ and $\theta$ are the radius and the rotation angle of the pinion, and $x_1$ and $x_2$ are the displacements of each device end.

Fig. 3 shows an RIDTMD (i.e., a TMD using a TVMD) coupled to an SDOF system in which the moving block mass, the primary and secondary spring stiffness of the auxiliary system, and the equivalent damping factor of the RIVD are denoted by $m_1$, $k_1$, $k_2$, and $c_2$, respectively. The pinion, the immersed mass and the flywheel have their own translational masses, which are relatively small and can therefore be combined into $m_1$.

In the system sketched in Fig. 3, the potential and strain energies ($U$ and $T$), the dissipative function ($\delta W$), and the incremental work ($\delta W$) obtained when the external forces move through incremental displacements $\delta x_i$ ($i = 1, 2, s$) are expressed as follows:

$$U = \frac{1}{2} k_1 x_1^2 + \frac{1}{2} k_2 (x_1 - x_2)^2 + \frac{1}{2} k_3 (x_2 - x_3)^2$$

$$T = \frac{1}{2} m_1 \dot{x}_1^2 + \frac{1}{2} m_2 \dot{x}_2^2 + \frac{1}{2} m_3 \dot{x}_3^2 + \frac{1}{2} J_\theta \omega^2$$

$$\delta W = (f - m_v x_g) \delta x_3 - m_1 \dot{x}_1 \delta x_1 - m_2 \dot{x}_2 \delta x_2$$

$$\delta W = m_1 \dot{x}_1 \delta x_1 + (m_2 - m_3) \delta \dot{x}_1 + m_3 \delta \dot{x}_2$$

in which $f$ is the sum of the pinion, immersed mass, and flywheel rotational moments of inertia; $m_v$ is the rack mass (which is neglected in this research); and $x_3$ is the displacement in the degree-of-freedom $i$ ($i = 1, 2, s$).

From expressions (1–5), and from defining the apparent mass as $m_a = J \omega^2$, the equations of motion are obtained as follows [16]:

$$k_1 (x_1 - x_i) + c_2 (x_1 - x_2) + m_2 \ddot{x}_2 + f$$

$$k_1 (x_1 - x_i) + c_2 (x_1 - x_2) + m_2 (\ddot{x}_2 - \ddot{x}_3) + m_1 \ddot{x}_1 = -m_3 \ddot{x}_2$$

$$k_2 (x_2 - x_i) + c_2 (x_2 - x_1) + m_2 (\ddot{x}_2 - \ddot{x}_3) + m_1 \ddot{x}_1 = 0$$

To find the transfer function of the system, the resulting system of differential equations is represented in state-space [17] as follows:

$$\ddot{x}(t) = A \ddot{x}(t) + B u(t)$$

$$y(t) = C \ddot{x}(t)$$
where \( \mathbf{q} = [x' \ x'' \ x''']^T \) is the state vector, in which \( x = [x_1 \ x_2 \ x_3]^T \); \( u \) is the system input load; \( y \) is the system output, i.e., the studied variable; \( \mathbf{B} \) is the input matrix, which is determined by the applied load type; \( \mathbf{C} \) is the output matrix, which depends on the selection of the studied variable; and \( \mathbf{A} \) is the state matrix, which is given as follows:

\[
\mathbf{A} = \begin{bmatrix} 0_3 & \mathbf{I}_3 \\
-M\mathbf{C} & -M^{-1}\mathbf{K} \end{bmatrix}
\]  

(11)

where \( 0_3 \) and \( \mathbf{I}_3 \) are zero and identity 3 × 3 matrices, respectively, and \( \mathbf{M}, \mathbf{C} \) and \( \mathbf{K} \) are the mass, damping and stiffness matrices, respectively, as defined below.

For convenience, the following parameters are introduced:

\[
\begin{align*}
\mu_1 &= \frac{m_1}{m} \quad \mu_2 = \frac{m_2}{m} \quad \mu_{21} = \frac{m_2}{m_1} \quad \xi_1 = \frac{c_1}{2\omega_1 m_1}; \\
\xi_2 &= \frac{c_2}{2\omega_2 m_2}; \\
\omega_1 &= \sqrt{k_1/m_1}; \quad \omega_2 = \sqrt{k_2/m_2}
\end{align*}
\]

The matrices \( \mathbf{M}, \mathbf{C} \) and \( \mathbf{K} \) can then be written as follows:

\[
\mathbf{M} = m_1 \begin{bmatrix} 1 & 0 & 0 \\
0 & \mu_1 + \mu_2 - \mu_2 \\
0 & -\mu_2 & \mu_2 \end{bmatrix}
\]

(12)

\[
\mathbf{C} = m_1 \begin{bmatrix} 2\xi_1\omega_1 & 0 & 0 \\
0 & 2\mu_1\omega_1\omega_2 & -2\mu_2\omega_1\omega_2 \\
0 & -2\mu_2\omega_1\omega_2 & 2\mu_2\omega_2 \end{bmatrix}
\]

(13)

\[
\mathbf{K} = m_1 \begin{bmatrix} \omega_1^2(1 + \mu_1 x_1^2 + \mu_2 x_2^2) & -\mu_1 \omega_2 x_1 x_2 & -\mu_2 \omega_1 x_1 x_2 \\
-\mu_1 \omega_2 x_1 x_2 & \mu_1 \omega_1 x_1^2 & 0 \\
-\mu_2 \omega_1 x_1 x_2 & 0 & -\mu_2 \omega_2 x_2^2 \end{bmatrix}
\]

(14)

If an external dynamic force is applied to the structure (e.g., wind load or unbalanced rotating machinery), then \( \mathbf{B} \) is given by expression (15) and \( u = f \). If support acceleration is employed as an input (e.g., seismic load), then \( \mathbf{B} \) is given by (16) and \( u = x_2 \).

\[
\mathbf{B}_l = \begin{bmatrix} 0_{3 	imes 1} \\
-M^{-1} \begin{bmatrix} 1 \\
0 \\
0 \end{bmatrix} \end{bmatrix}
\]

(15)

\[
\mathbf{B}_s = \begin{bmatrix} 0_{3 	imes 1} \\
-M^{-1} \begin{bmatrix} m_1 \\
m_1 \\
0 \end{bmatrix} \end{bmatrix}
\]

(16)

Based on the above definitions, and taking into account that the system is linear and time-invariant, the generic transfer function (TF) and the frequency-response function in displacement are given, respectively, by the following expressions [17]:

\[
H(s) = \frac{\mathbb{Y}(s)}{\mathbb{U}(s)} = \mathbf{C}(s\mathbf{I}_6 - \mathbf{A})^{-1}\mathbf{B}
\]

(17)

\[
H(j\omega) = H(s)|_{s=j\omega}
\]

(18)

in which \( s \) is the Laplace variable, \( \omega \) is the circular frequency, \( j = \sqrt{-1}, \mathbf{I}_6 \) is a \( 6 \times 6 \) identity matrix, \( \mathbb{Y}(s) \) is the Laplace transform of the system output, and \( \mathbb{U}(s) \) is the Laplace transform of the system input.

In this research, the following TFs are used:

\[
H_l(s) = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}(s\mathbf{I}_6 - \mathbf{A})^{-1}\mathbf{B}_l
\]

(19)

\[
H_{l1}(s) = \begin{bmatrix} -1 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}(s\mathbf{I}_6 - \mathbf{A})^{-1}\mathbf{B}_l
\]

(20)

\[
H_{l2}(s) = \begin{bmatrix} -1 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}(s\mathbf{I}_6 - \mathbf{A})^{-1}\mathbf{B}_l
\]

(21)

To study the dynamic response of an RIDTMD, three main engineering parameters were selected. Specifically, two traditional responses of TMD-controlled structures are considered: structural displacement and auxiliary mass stroke. Moreover, an RIDTMD is a two-degree-of-freedom device, two strokes must be studied.

If the output variable is the displacement of the structure (i.e., \( y = x_1 \)), then the TF is given by (19). In a similar way, if the output variable is the stroke of the moving block (i.e., \( y = x_2 - x_1 \)), then the TF is given by (20), and if the output variable is the stroke of the rack (i.e., \( y = x_2 - x_3 \)), then the TF is given by (21).

Of course, many other TFs can be proposed for study. However, the study of structural displacement and auxiliary mass stroke is very common in existing literature. The structural displacement is the factor that designers strive to reduce in order to extend the structure’s life. Additionally, the auxiliary mass stroke is also important because the required space for the installation of the control device is dependent on it.

For convenience, the dynamic magnification factor (DMF), which provides a dimensionless assessment of the dynamic response of the structure, is defined as follows:

\[
\text{DMF} = k_b\|H_l(j\omega)\|
\]

(22)

### 3. Optimization

To conduct a meaningful comparative assessment between the TMD and the RIDTMD, and because their performances are strongly dependent on the design parameters, an optimization procedure is required in each case.

#### 3.1. TMD optimization

The optimal parameters \( k_b \) and \( c_b \) that minimize the peak of the frequency-response function in displacement of the structure under harmonic force load are found by using Warburton’s formulae [18] for mass ratios \( \mu = m_b/m \) of 1%, 5% and 10%. The optimal parameters are shown in Table 1 in a normalized form.

#### 3.2. RIDTMD optimization

In this case, the same structural mass to auxiliary mass ratios \( \mu_1 \) of 1%, 5% and 10% and the apparent mass to auxiliary mass ratios \( \mu_2 \), of 1%, 5%, 10%, 15%, 20%, 25% and 30% are considered. Note that the mass ratio of the RIDTMD (i.e., \( \mu_1 \)) has the same practical meaning as the mass ratio of the traditional TMD (i.e., \( \mu \)) because both denote the relative mass added to the structure due to the installation of the control device. Conversely, \( \mu_2 \) can be adjusted without altering the device weight; for instance, it can be modified by varying the fly-wheel radius.

![Table 1](image-url)
The design parameters to be optimized are \( k_1 \), \( k_2 \), and \( c_2 \). The optimization problem is then stated as follows:

\[
\begin{align*}
\text{minimize} & \quad \{ J_0 \} \\
\text{subject to} & \quad 0 < k_1 \leq k_{1n}, 0 < k_2 \leq k_{2n}, \quad 0 < c_2 \leq c_{2n}, \quad \omega \in \Omega \nonumber
\end{align*}
\]

in which \( k_{1n} \), \( k_{2n} \), and \( c_{2n} \) are constants, and \( J_0 \) is the cost function defined as follows:

\[
J_0 = \max_{\omega \in \Omega} ||H_1(j\omega)||
\]

where \( \Omega \) denotes the range of possible exciting frequency \( \omega \).

The optimized parameters are shown in Tables 2–4 in normalized form. Bold font cells refer to the cases in which the structure which is controlled with an optimum TMD displays the lowest response. Note that, in such cases, the primary subsystem \( (k_1, m_1) \) is tuned slightly below the natural frequency of the structure, whereas the secondary subsystem \( (k_2, m_2) \) is tuned slightly above the natural frequency of the structure. It can also be seen that \( \alpha_1 \) and \( \alpha_2 \) approach one when \( \mu_1 \) approaches zero.

Table 4 shows that, for some smaller apparent mass to auxiliary mass ratios \( \mu_{21} \), the optimum damping ratio is greater than one (i.e., an over-critically damped case). Accordingly, the secondary subsystem does not oscillate and the RIDTMD behaves similar to a TMD. It is important to note that the minimum of \( J_0 \) occurs when the damping ratio is minimal.

4. Performance assessment

4.1. Effect of apparent mass to auxiliary mass ratio \( \mu_{21} \)

To compare the effectiveness of the RIDTMD with respect to that of the TMD, the performance index \( R \) is defined as follows:

\[
R = \max_{\omega \in \Omega} \frac{\text{DMF}_{(\alpha_j)(j\omega)}}{\text{DMF}_{(\alpha_j)(j\omega)}}
\]

in which \( \text{DMF}_{(\alpha_j)(j\omega)} \) is the DMF of the structure which is controlled with an optimum RIDTMD (Section 3.2), and \( \text{DMF}_{(\alpha_j)(j\omega)} \) is the DMF of the structure which is controlled with an optimum TMD (Section 3.1).

The dependence of \( R \) on \( \mu_{21} \) for systems provided with a TMD and an RIDTMD with the same mass ratios \( \mu_1 \) and \( \mu \) is displayed in Fig. 4. It is observed that the RIDTMD outperforms the TMD by approximately 20% in terms of performance index \( R \). It is important to highlight that, in order to achieve the peak magnitude of the optimal RIDTMD with a 5% mass ratio \( \mu_1 \), a traditional TMD would need a mass ratio \( \mu \) of 7.9%, resulting in a 58% increase in \( m_0 \). Although the RIDTMD outperforms the TMD for all the studied values of \( \mu_{21} \), \( R \) displays the minimum values for \( \mu_{21} \) between 10% and 15%.

![Fig. 4. R vs \( \mu_{21} \) for TMDs and RIDTMDs with the same \( \mu = \mu_1 \).](image)

It should be noted that, if a disk-shaped flywheel with radius \( 2r \) is used, then the mass of the flywheel is 0.5\( \mu_{21}m_1 \). Consequently, the assumption that the mass of the flywheel can be part of, and therefore be lumped into, \( m_1 \) is true. Moreover, for the optimized value of \( \mu_{21} = 10\% \) the flywheel mass is much less than \( m_1 \) (only the 5% of \( m_1 \)), as compared to the improvement in performance.

4.2. Structure response in frequency domain

It is important to show the performances of both optimum devices (RIDTMD and TMD) in terms of DMF (see Eq. (22)) for frequencies around resonance.

The Suppression Band (SB) is defined as the frequency range in which the structure controlled by the device (either TMD or RIDTMD) outperforms an uncontrolled structure. Fig. 5 shows the SBs of both devices. Note that there are undesirable zones where both a TMD-controlled and uncontrolled structure outperforms an RIDTMD. These undesirable zones can be defined approximately for frequency relations below 0.9 and over 1.1. However, this is not an actual disadvantage of RIDTMD because such undesirable zones can be avoided with a proper tuning of the device.

The DMF of the systems provided with an RIDTMD and a TMD in the frequency ratio range of 0.5–1.5 and mass ratios \( \mu = \mu_1 \) of 5% are displayed in Fig. 5. It is noted that the structure provided with an RIDTMD has a considerably smaller DMF (approx. 20% smaller peaks) and wider SB (approx. 40% wider) than the structure provided with a TMD. The latter is because the frequency-response curve of the RIDTMD is flatter than that of the TMD.
of the RIDTMD of 1%, 5% and 10%, the re-

tions of the auxiliary mass of the TMD.

4.3. Device strokes

Because shorter strokes are desirable from a practical point of view, in this subsection the TMD and RIDTMD strokes are assessed by means of the following indicators (see Eqs. (20), (21)):

\[
J_b = \max_{\omega \in \Omega} \frac{|H_0(j\omega)|}{|H_0(j\omega)|} \quad \text{(26)}
\]

\[
J_j = \max_{\omega \in \Omega} \left| \frac{H_0(j\omega)}{H_0(j\omega)} \right| \quad \text{(27)}
\]

in which \(H_0(j\omega)\) is the frequency-response function in the displacements of the auxiliary mass of the TMD.

Considering the mass ratios \(\mu\) and \(\mu_1\) of 1%, 5% and 10%, the results of the stroke assessments are presented in Table 5. It is observed that both the TMD and RIDTMD have nearly identical peak strokes. Conversely, the stroke of the rack is considerably larger than that of the auxiliary mass; however, this fact does not induce problems in practical applications because of the relatively small volume of the rack.

5. Conclusions

This paper proposed a device for vibration control (RIDTMD) in which the viscous linear damper of a traditional TMD is replaced with a TVMD. The advantages of the RIDTMD with respect to a traditional TMD are displayed in terms of DMF on SDOF systems under harmonic excitation.

The most important findings are listed below:

- The frequency-response curve of the RIDTMD is flatter than that of the TMD. Consequently, the peak of the DMF of the structure provided with an RIDTMD is approximately 20% lower and the SB is 40% wider than that of the structure provided with a TMD, with both having identical mass ratios and nearly identical auxiliary mass strokes.
- The apparent mass to auxiliary mass ratio \(\mu_{21}\) of the RIDTMD plays a relevant role in the RIDTMD performance setting. The highest effectiveness is achieved for \(\mu_{21}\) at approximately 10% for a typical mass ratio \(\mu_1\) (e.g., 1–5%).
- For the optimum \(\mu_{21}\), the mass of the rotational inertia is significantly small compared to the TMD mass. Then, with a quite simple addition to the traditional TMD, a significant improvement in performance is obtained.
- In general, the value of \(\mu_{21}\) that minimizes the response of the structure also minimizes the optimum damping ratio \(\zeta_s\).

The device proposed in this paper (RIDTMD) could also be used in multi-degree-of-freedom (MDOF) structures. If the excitation and the structure are such that one mode of the structure is substantially more participating than the others, and the RIDTMD is properly tuned, one can expect to obtain similar results to the SDOF structural case. However, further study must be conducted in order to assess the performance of an RIDTMD in MDOF structures with many participating modes.
