LIKELIHOOD RATIO TEST

The likelihood ratio test is a test of a statistical hypothesis that uses the likelihood ratio as a test statistic. It is available in a broad class of hypothesis-testing

problems where the underlying statistical model involves a parametric family of distributions. Many well-known statistical tests are, in fact, likelihood ratio tests. In some cases, it has desirable optimality properties. For large samples, a convenient approximation is available for computing approximate p values, subject to some regularity conditions. In some less regular cases, approximate p values can be obtained via computer simulation.

Suppose that data $y = (y_1, y_2, \dots, y_n)$ are modeled as a realization of a random vector whose distribution depends on unknown parameters $\theta = (\theta_1, \theta_2, \dots, \theta_k)$. If the distribution is discrete, let $f(x; \theta)$ denote the probability mass function; if continuous, let $f(x; \theta)$ denote the probability density function as a function of a real vector x and the unknown parameters.

The likelihood function is

$$L(\theta; y) = f(y; \theta);$$

that is, $f(x; \theta)$ is evaluated at the data and viewed then (primarily) as a function of the unknown parameters. When the distribution is discrete, this is precisely the probability of getting the observed data as a function of the parameters; in the continuous case, the interpretation is similar, so in a certain sense, larger values of the likelihood function indicate better agreement between parameters and data.

Let Θ denote the set of all possible parameter vectors under the model, and let Θ_0 denote the set of those parameter vectors in Θ permitted under the hypothesis (this hypothesis is sometimes called the null hypothesis). Also, let Θ_1 denote the alternative, that is, the set of those parameter vectors in Θ not permitted under the hypothesis. The likelihood ratio is defined in several different but essentially equivalent ways. One is

$$\Lambda = \frac{\sup_{\theta \in \Theta} L(\theta; y)}{\sup_{\theta \in \Theta_0} L(\theta; y)}.$$

Because larger likelihood means better agreement between parameters and data, the denominator measures the best agreement possible under the hypothesis. If the best agreement over all Θ is attained under

the hypothesis, $\Lambda = 1$. Otherwise, it is greater than 1, with better performance of the alternative over the hypothesis giving a bigger likelihood ratio. Thus, larger values of L provide more evidence against the hypothesis.

An alternate definition is

$$\Lambda_1 = \frac{\sup_{\theta \in \Theta_1} L(\theta; \mathbf{y})}{\sup_{\theta \in \Theta_0} L(\theta; \mathbf{y})},$$

where the numerator measures only the best agreement under the alternative. Thus, $\Lambda = \max(\Lambda_1, 1)$, so when there is any evidence against the hypothesis, they coincide. The likelihood ratio is also sometimes defined as $1/\Lambda$ or $1/\Lambda_1$, in which case smaller values of the statistic provide more evidence against the hypothesis.

If two test statistics are increasing functions of one another, then because they always give the same p value, the tests based on them are equivalent. In many common problems, the likelihood ratio turns out to be an increasing function of a more familiar test statistic. Some examples are one-sample, two-sample, and regression t tests; analysis of variance F tests; and certain tests based on the mean of the data for binomial and Poisson models.

Power Properties

When the hypothesis and alternative each consists of a (different) single distribution, the likelihood ratio test is the most powerful test; no other test is more sensitive at detecting when the hypothesis is false. This optimality result is the essential message of the Neyman-Pearson Lemma. When the alternative and/or hypothesis consists of infinitely many points, the corresponding optimality result no longer holds in general, except in the special case when the underlying model forms a one-parameter exponential family and we are performing a one-sided test. In some other cases, the likelihood ratio test is the most powerful test among a larger group of sensible tests, but it is possible to construct examples where the likelihood ratio test has no power at all, so one should be careful in unusual situations. The book by Lehmann is a good reference for theoretical properties of the likelihood ratio test.

Calculating p Values

Once the value of the likelihood ratio statistic is obtained, the next step is to calculate the p value. In some cases, an exact p value can be computed, whereas in others, a large sample approximation is available, and in still others, computer simulation can be used to obtain an approximate p value.

If the statistic is an increasing function of another statistic with a known distribution under the hypothesis for which tail probabilities are available, we can convert to the appropriate scale and compute the p value directly. This is possible in many of the traditional tests already mentioned, where tabulated (or numerically computed) tail probabilities for distributions such as the normal, chi-squared, binomial, Poisson, F , and t distributions are readily available.

Large-Sample Behavior of $2 \log \Lambda$

In many models (those displaying so-called regularity), the maximum likelihood estimator is asymptotically normal. If so, and the hypothesis imposes m restrictions on possible values of θ , the asymptotic distribution of $2 \log \Lambda$ is a finite mixture of chi-squared distributions of the form

$$P\{2 \log \Lambda \leq x\} = \sum_{k=0}^m p_k P\{\chi_k^2 \leq x\},$$

where $P\{\chi_0^2 \leq x\} = 1\{x \geq 0\}$ is the degenerate distribution function at 0. In general, the mixing proportions p_k depend on the geometry of the model in a neighborhood of the true value θ_0 . However, under the additional condition that all points in Θ_0 are interior points of the model Θ , $p_0 = L = p_{m-1} = 0$ and $p_m = 1$, giving a pure χ_m^2 asymptotic distribution for $2 \log \Lambda$.

For the maximum likelihood estimator to be asymptotically normal, the information matrix $\mathbf{I}(\theta_0)$ must be nonsingular; here, θ_0 is the true value and $\mathbf{I}(\theta)$ has an (i, j) th element equal to

$$I_{ij}(\theta) = E \left(\frac{\dot{f}_i(\mathbf{X}; \theta) \dot{f}_j(\mathbf{X}; \theta)}{f(\mathbf{X}; \theta) f(\mathbf{X}; \theta)} \right),$$

where X has distribution $f(x; \theta)$ and $f(x; \theta) = (f_1(x; \theta), \dots, f_k(x; \theta))$ is a vector of partial derivatives of $f(x; \theta)$ with respect to components of θ .

As an example where the information matrix is singular, consider the contamination model $f(x; p, \theta) = \prod_{i=1}^n [(1-p)g(x_i; 0) + pg(x_i; \theta)]$. The 2×2 information matrix has a zero on the diagonal and on the off-diagonal at either $p = 0$ or $\theta = 0$, that is, when there is no contamination and so is singular. It is known that, for certain forms of $g(x; \theta)$ in this model, under the hypothesis of no contamination $2 \log \Lambda$ diverges very slowly to infinity as the sample size grows.

Parametric Bootstrap Approximate p Values

An approximate p value can be obtained through a parametric bootstrap procedure. The idea is that for two parameter values θ and θ' that are close together, the distribution of Λ when θ is the true value should be close to the distribution of Λ when θ' is the true value. Let $p(\lambda | \theta)$ represent the probability that Λ exceeds λ when θ is the true value, let λ_{obs} denote the observed value of Λ . Then the exact p value is

$$\sup_{\theta \in \Theta_0} p(\lambda_{\text{obs}} | \theta) \approx p(\lambda_{\text{obs}} | \theta_0) \approx p(\lambda_{\text{obs}} | \hat{\theta}_0(y)),$$

because for large samples, if the hypothesis is true, the restricted (to Θ_0) maximum likelihood estimate $\hat{\theta}_0(y)$ should be close to θ_0 . The probability $p(\lambda_{\text{obs}} | \hat{\theta}_0(y))$ is the parametric bootstrap approximate p value. In general, it is difficult to obtain directly, but can itself be approximated by computer simulation.

Using the Computer

Most of the standard tests that are also likelihood ratio tests, such as t tests, F tests, and so on, can be performed on a wide variety of mathematical and statistical software systems. Even most spreadsheet programs have a facility for performing elementary statistical tests of this nature.

In nonstandard cases, one can proceed using one of the statistical systems that have a built-in programming capability, allowing users to write programs in a

simplified programming environment to perform any statistical analyses not already available. For likelihood ratio tests, this generally requires the use of optimization routines. In such cases, add-on packages are often available for nonstandard models. For example, in the R software system, the add-on library MASS has a function `fitdistr` that fits various models to univariate data by maximum likelihood. We illustrate the use of this in the example below.

Example

The twelve numbers below give time in hours between failures of the air-conditioning equipment in a Boeing 720 jet aircraft, originally cited in an article by F. Proschan.

3 5 7 18 43 85 91 98 100 130 230 487

If the failure rate is constant over time, then such times should follow an exponential distribution with density of the form $\theta e^{-\theta y}$, for $y > 0$. One way to test for constant failure rate is to embed the exponential densities in a larger model and test for exponentiality. One choice of larger model is the two-parameter family of gamma densities:

$$g(y; K, \theta) = y^{K-1} e^{-\theta y} \theta^K / \Gamma(K), \text{ for } y > 0.$$

Note that setting the shape parameter $\kappa = 1$ gives an exponential density. With κ fixed, $\log L(\kappa, \theta; \mathbf{y}) = \sum_i \log g(y_i; \kappa, \theta)$ is maximized at $\theta = \kappa / \bar{y}$, where $\bar{y} = \frac{1}{n} \sum_{i=1}^n y_i$ is the mean of the data. So if $\hat{\kappa}$ maximizes $\log L(\kappa, \kappa / \bar{y}; \mathbf{y})$, then the unrestricted maximum likelihood estimates are $(\hat{\kappa}, \hat{\kappa} / \bar{y})$, whereas the restricted estimates are $(1, 1 / \bar{y})$, and so $\log \Lambda = \log L(\hat{\kappa}, \hat{\kappa} / \bar{y}; \mathbf{y}) - \log L(1, 1 / \bar{y}; \mathbf{y})$.

There is no closed form for $\hat{\kappa}$; however, the maximization can be performed numerically, or we can use `fitdistr`:

```
> library(MASS)
> y <- c(3,5,7,18,43,85,91,98,100,130,230,487)
> mle <- fitdistr(y, "gamma")$estimate
> mle
      shape      rate
0.706796220  0.006537295
```

The R function `dgamma` computes the gamma density so the value of $\log \Lambda$ is given as follows:

```
> logNumer <- sum(log(dgamma(y,shape=mle[1],rate=
  mle[2]]));
> logDenom <- sum(log(dgamma(y,shape=1, rate=
  1/mean(y))));
> logLam <- (logNumer-logDenom)
> logLam
[1] 0.5494047
```

The chi-squared approximation to the p value is

```
> 1-pchisq(2*logLam,df=1)
[1] 0.2945276
```

Is the sample size large enough to trust this approximate p value? The parametric bootstrap is performed by repeating the steps above on simulated exponential samples, using the restricted maximum likelihood estimate as the rate, and computing the statistic for each simulated sample:

```
> logLamsim <- 0
> for(i in 1:1000){
+ ysim <- rexp(12,rate=1/mean(y))
+ mlesim <- fitdistr(ysim,"gamma")$estimate
+ logNumerSim <- sum(log(dgamma(ysim,shape=
  mlesim[1],rate=mlesim[2]]))
+ logDenomSim <- sum(log(dexp(ysim,rate=1/mean
  (ysim))))
+ logLamsim[i] <- (logNumerSim-logDenomSim)
+ }
> sum(logLamsim>logLam)
[1] 333
```

So, 333 of the 1,000 simulated versions of $\log \Lambda$ exceeded our observed value of 0.549, giving an approximate parametric bootstrap p value of 0.333, in reasonable agreement with the large-sample approximation of 0.295.

LIKERT SCALING

Likert scaling (also called the *method of summated ratings*) is a multiple-item procedure for measuring attitudes. Scales resulting from the Likert method consist of a set of statements (*items*) implying favorable or unfavorable reactions to the attitudinal object. Respondents indicate their agreement to each item on a response scale most frequently ranging from 1 (representing strong disagreement) to 5 (representing strong agreement). Respondents' ratings are then summed across all items on the scale (after having reverse coded negative items), resulting in a composite score that reflects the valence and extremity of attitudes toward the object. Typical instructions and sample items are provided in Figure 1.

History and Development

Rensis Likert, in collaboration with Gardner Murphy, began development of his method of summated ratings in 1929 in response to Louis L. Thurstone's *equal-appearing intervals method*. Despite the strengths of Thurstone's approach, the method was criticized for its unwieldiness. Specifically, the method required burdensome calculations in a time before the advent of computers and required a sample of participants to act as judges in the pretesting of potential items. As a result, creating scales using the

Thurstone method proved to be time-consuming. The method was also criticized by Likert and others for making a number of statistical assumptions that were unverified at the time (e.g., that the scale values of the items are independent of the attitudes of the pretesting judges). Likert developed his method with the goal of creating a reliable and valid attitude scaling procedure that was less time-consuming to construct and that did not require unnecessary assumptions. The procedure that Likert presented in 1932 has changed little throughout the years, apart from capitalizing on the statistical computation advantages offered by modern computers.

Constructing a Likert Scale

The first step in creating a Likert scale is to specify the attitudinal object. The more well-defined the subject under consideration is, the better. Once the attitudinal object has been determined, the researcher generates a pool of potential items. The aim of this phase is to create statements reflecting a broad diversity of viewpoints on the topic. Although belief or *cognitive* items (e.g., Items 1, 3, 4, and 6 in Figure 1) are most typical, feeling or *affective* items (e.g., Item 2) and behavioral tendency or *conative* items (e.g., Item 5) are also common. In contrast with some methods that use statements varying along the favorable-unfavorable continuum (e.g., Thurstone scaling), only statements that are clearly positive or negative (although not at the most extreme) should be selected for a Likert scale. The reasoning behind this recommendation is that extremely worded or neutral statements do not discriminate among respondents, that is, they do not distinguish people with very positive attitudes from people with moderately positive attitudes, negative attitudes, and so forth. Care should be taken to avoid biased or leading statements, extremely worded or neutral items, and items containing well-known facts.

The item pool usually consists of at least 25 statements, and can be as many as 50 or more. The primary reason for using multiple items rather than a single statement is that each statement may have ambiguities and subtle biases, leading people to respond in a certain way. By summing or averaging across multiple related items, the impact of biases and imperfections contained in individual items can be minimized. A secondary reason for using multiple items concerns breadth. Attitudes are often multifaceted, involving cognitions, emotions, and behavioral tendencies. A single item is unlikely to capture the full scope of the attitude in question; using multiple items potentially ameliorates this problem.

Once the researcher has generated an initial pool of items such as those illustrated in Figure 1, the third step in creating the scale is to administer the items to a sample from the population of interest.

The researcher has the respondents indicate their level of agreement to each item. Next, each item is scored for each respondent. For positive items, “strongly agree” receives five points, “agree” receives four, and so on; for negative items, the scoring is reversed. Although a 5-point response scale is most commonly employed in Likert scaling, 7-point scales are also common. Some researchers prefer to eliminate the middle, neutral category by using 4 or 6 points.

Next, each respondent’s scores are summed to obtain a total score for that individual. The highest possible score is five times the number of items, and indicates an extremely positive attitude. The lowest possible score is simply the number of items, and indicates an extremely negative attitude.

The final step in Likert’s method involves item analysis and elimination. The goal of this step is to determine which items adequately discriminate among individuals and to eliminate those that do not. Before the advent of computers, researchers commonly accomplished this task by testing whether there was a statistically significant difference between those with total scores in the top quartile and those with total scores in the bottom quartile on each particular item. With the wide availability of computers and statistical software packages, the preferred contemporary

method is to examine the correlations between respondents’ scores on individual items and their corrected total scores (i.e., the total score not including the item in question). The higher the *item-total score correlation*, the better the item is discriminating. The goal is to select items that each make a significant contribution to the variability within the total score. Items with low or no correlation with the total scores are regarded as poor items, because they contribute little to the variability in the overall score. These items do not display a strong relationship with the other items in the scale, and thus may assess a construct different from that intended by the researcher. As a result, they are discarded.

Table 1 displays hypothetical means, standard deviations, and item-total score correlations for our sample items. Examining the table, it can be seen that the mean scores for the first five items hover around the neutral point, and that the standard deviations are all in excess of one scale point, indicating a reasonable diversity of opinion among the respondents. However, the mean for the sixth item is rather low, indicating that most people strongly disagreed with this statement. In addition, the standard deviation is quite low, suggesting that the respondents in this sample did not vary greatly in their opinions. Both extreme means

and low variability are warning signs that an item does not discriminate well among respondents.

The next column displays the correlations between the items and the total scores. It can be seen that both the first and fourth items correlate highly and positively with the total score, and thus discriminate well among respondents. These items contribute significantly to the overall scores and should probably be retained. The second and fifth items correlate rather weakly with the total score, suggesting that they may be measuring something different from the other items, and are therefore eliminated. The third item is interesting in that it shows a moderate to strong correlation, but it is in the wrong direction. Thus, it is actually working *against* the discrimination desired by the researcher. This may indicate an error in scoring, and if this proves to be the case, the item can be rescored and retained. In some cases, negative correlations can result from poorly worded items that may imply something different from what was intended. If respondents consistently misunderstand a statement, an extremely low or negative correlation can result. In instances of this sort, the item may be discarded or subsequently corrected and allowed to remain in the scale if the item-total correlation is as expected. The sixth item, like the second and fifth, shows a rather weak correlation. In contrast, however, this is likely due to the extremity and low variability of the responses rather than (or in addition to) the item measuring something other than what the researcher intends.

After analyzing the remaining 34 items, the researcher must decide which items to keep and which to discard. In general, the items with the highest item-total score correlations are usually kept, and these items should have reasonable variability (as indicated in our example by standard deviations). Care should be taken to maintain a balance of positive and negative items, because respondents may have a greater tendency to agree with items than to disagree (this is known as *acquiescence bias*). As well, enough items should be included in the final version of the scale to maintain adequate reliability (often measured by Cronbach's alpha). In this example, the researcher obtains a scale consisting of 10 positive and 10 negative items. The recomputed item-total score correlations in

the refined scale (as illustrated in the final column of Table 1) should be fairly similar to those in the original scale. The result of the procedure is usually a succinct, easy-to-administer, reliable, and valid attitude measure that is ready for application (and cross-validation) on other samples.

Evaluating the Likert Procedure

The reliability and validity of Likert's method has been demonstrated many times in the years since its conception. Mueller, for example, confirmed the method's validity and obtained very high interitem and test-retest reliabilities. However, the method is not without its limitations. One disadvantage of Likert scaling is that it creates a scale that is *object specific*. That is, the scale resulting from the procedure is valid only as a measure of attitudes toward the object for which it is intended. In contrast, *semantic differentials*, another type of multiple-item scaling, produce general measures that can be used with little or no alteration for a broad variety of attitudinal objects. Another criticism is that Likert's method assumes unidimensionality. It attempts to rate individuals on a single dimension of favorability; however, subsequent analyses sometimes reveal multiple dimensions. Finally, like many self-report attitude measures, the actual "neutral" point is unknown in the Likert method because this point is unlikely to correspond precisely to the midpoint of the resulting scale. This is only a problem if one is attempting to determine whether an individual respondent's score falls in an objectively favorable or unfavorable dimension; it is not of concern if one's intention is to compare the mean attitude scores of two or more groups, or to compare the mean attitude change resulting from an experimental manipulation.

Despite its limitations, the Likert procedure is generally regarded as a reliable and valid approach to measuring attitudes that is simpler to implement than the Thurstone procedure. Likert's method remains a popular and widely used method of attitude measurement.

LILLIEFORS TEST FOR NORMALITY

The normality assumption is at the core of a majority of standard statistical procedures, and it is important to be able to test this assumption. In addition, showing that a sample does not come from a normally distributed population is sometimes of importance per se. Among the many procedures used to test this assumption, one of the most well known is a modification of the Kolmogorov-Smirnov test of goodness of fit, generally referred to as the *Lilliefors test for normality* (or Lilliefors test, for short). This test was developed independently by Lilliefors and by Van Soest. The null hypothesis for this test is that the error is normally distributed (i.e., there is no difference between the observed distribution of the error and a normal distribution). The alternative hypothesis is that the error is not normally distributed.

Like most statistical tests, this test of normality defines a criterion and gives its sampling distribution. When the probability associated with the criterion is smaller than a given α level, the alternative hypothesis is accepted (i.e., we conclude that the sample does not come from a normal distribution). An interesting peculiarity of the Lilliefors test is the technique used to derive the sampling distribution of the criterion.

In general, mathematical statisticians derive the sampling distribution of the criterion using analytical techniques. However, in this case, this approach fails, and consequently, Lilliefors decided to calculate an approximation of the sampling distribution by using the Monte Carlo technique. Essentially, the procedure consists of extracting a large number of samples from a normal population and computing the value of the criterion for each of these samples. The empirical distribution of the values of the criterion gives an approximation of the sampling distribution of the criterion under the null hypothesis.

Specifically, both Lilliefors and Van Soest used, for each sample size chosen, 1,000 random samples derived from a standardized normal distribution to approximate the sampling distribution of a Kolmogorov-Smirnov criterion of goodness of fit. The critical values given by Lilliefors and Van Soest are quite similar, the relative error being of the order of 10^{-2} .

According to Lilliefors, this test of normality is more powerful than other procedures for a wide range of nonnormal conditions. Dagnelie indicated, in addition, that the critical values reported by Lilliefors can be approximated by an analytical formula. Such a formula facilitates writing computer routines because it eliminates the risk of creating errors when keying in the values of the table. Recently, Molin and Abdi refined the approximation given by Dagnelie and computed new tables using a larger number of runs (i.e., $K = 100,000$) in their simulations.

Notation

The sample for the test is made of N scores, each of them denoted X_i . The sample mean is denoted M_X and is computed as

$$M_X = \frac{1}{N} \sum_i^N X_i, \quad (1)$$

the sample variance is denoted

$$S_X^2 = \frac{\sum_i^N (X_i - M_X)^2}{N - 1}, \quad (2)$$

and the standard deviation of the sample, denoted S_X , is equal to the square root of the sample variance.

The first step of the test is to transform each of the X_i scores into z scores as follows:

$$Z_i = \frac{X_i - M_X}{S_X}. \tag{3}$$

For each Z_i score, we compute the proportion of score smaller or equal to its value: This is called the *frequency associated* with this score and it is denoted $\mathcal{S}(Z_i)$. For each Z_i score, we also compute the probability associated with this score if it comes from a “standard” normal distribution with a mean of 0 and a standard deviation of 1. We denote this probability by $\mathcal{N}(Z_i)$, and it is equal to

$$\mathcal{N}(Z_i) = \int_{-\infty}^{Z_i} \frac{1}{\sqrt{2\pi}} \exp \left\{ -\frac{1}{2} Z_i^2 \right\}. \tag{4}$$

The criterion for the Lilliefors test is denoted L . It is calculated from the z scores, and it is equal to

$$L = \max_i \{ |\mathcal{S}(Z_i) - \mathcal{N}(Z_i)|, |\mathcal{S}(Z_i) - \mathcal{N}(Z_{i-1})| \}. \tag{5}$$

So L is the absolute value of the biggest split between the probability associated with Z_i when Z_i is normally distributed, and the frequencies actually observed. The term $|\mathcal{S}(Z_i) - \mathcal{N}(Z_{i-1})|$ is needed to take into account that, because the empirical distribution is discrete, the maximum absolute difference can occur at either endpoint of the empirical distribution.

The critical values are given by Table 2. L_{critical} is the critical value. The null hypothesis is rejected when the L criterion is greater than or equal to L_{critical} .

Numerical Example

As an illustration, we will look at an analysis of variance example for which we want to test the so-called normality assumption, which states that the within-group deviations (i.e., the residuals) are normally distributed. The data are from Abdi and correspond to memory scores obtained by 20 subjects who were assigned to one of four experimental groups (hence,

five subjects per group). The score of the s th subject in the a th group is denoted $Y_{a,s}$, and the mean of each group is denoted M_a . The within-group mean square $MS_{S(A)}$ is equal to 2.35, and it corresponds to the best estimation of the population error variance.

	<i>G. 1</i>	<i>G. 2</i>	<i>G. 3</i>	<i>G. 4</i>
	3	5	2	5
	3	9	4	4
	2	8	5	3
	4	4	4	5
	3	9	1	4
Y_a	15	35	16	21
M_a	3	7	3.2	4.2

The normality assumption states that the error is normally distributed. In the analysis of variance framework, the error corresponds to the *residuals*, which are equal to the deviations of the scores to the mean of their group. So, in order to test the normality assumption for the analysis of variance, the first step is to compute the residuals from the scores. We denote X_i the residual corresponding to the i th observation (with i going from 1 to 20). The residuals are given in the following table:

Y_{as}	3	3	2	4	3	5	9	8	4	9
X_i	0	0	-1	1	0	-2	2	1	-3	2
Y_{as}	2	4	5	4	1	5	4	3	5	4
X_i	-1.2	.8	1.8	.8	-2.2	.8	-2	-1.2	.8	-2

Next we transform the X_i values into Z_i values using the following formula:

$$Z_i = \frac{X_i}{\sqrt{MS_{S(A)}}}, \tag{6}$$

because $MS_{S(A)}$ is the best estimate of the population variance, and the mean of X_i is zero. Then, for each Z_i value, the frequency associated with $\mathcal{S}(Z_i)$ and the probability associated with Z_i under the normality condition $\mathcal{N}(Z_i)$ are computed [we use a table of the normal distribution to obtain $\mathcal{N}(Z_i)$]. The results are presented in Table 1.

Notes: N_i stands for the absolute frequency of a given value of X_i , F_i stands for the absolute frequency associated with a given value of X_i (i.e., the number of scores smaller than or equal to X_i), Z_i is the z score corresponding to X_i , $\mathcal{S}(Z_i)$ is the proportion of scores smaller than Z_i , $\mathcal{N}(Z_i)$ is the probability associated with Z_i for the standard normal distribution, $D_0 = |\mathcal{S}(Z_i) - \mathcal{N}(Z_i)|$, $D_{-1} = |\mathcal{S}(Z_i) - \mathcal{N}(Z_{i-1})|$, and max is the maximum of $\{D_0, D_{-1}\}$. The value of the criterion is $L = .250$.

The value of the criterion is

$$L = \max_i \{|\mathcal{S}(Z_i) - \mathcal{N}(Z_i)|, |\mathcal{S}(Z_i) - \mathcal{N}(Z_{i-1})|\} = .250. \quad (7)$$

Taking an α level of $\alpha = .05$, with $N = 20$, we find that the critical value is $L_{critical} = .192$ (as found in Table 2). Because L is larger than $L_{critical}$, the null hypothesis is rejected and we conclude that the residuals in our experiment are not distributed normally.

Numerical Approximation

The available tables for the Lilliefors test for normality typically report the critical values for a small set of alpha values. For example, the present table reports the critical values for $\alpha = [.20, .15, .10, .05, .01]$. These values correspond to the alpha values used for most tests involving only one null hypothesis, because this was the standard procedure in the late 1960s. The current statistical practice, however, favors multiple tests (maybe as a consequence of the availability of statistical packages). Because using multiple tests increases the overall Type I error (i.e., the familywise Type I

error or α_{PF}), it has become customary to recommend testing each hypothesis with a corrected α level (i.e., the Type I error per comparison, or α_{PC}) such as the Bonferroni or Šidák corrections. For example, using a Bonferroni approach with a familywise value of $\alpha_{PF} = .05$, and testing $J = 3$ hypotheses requires that each hypothesis is tested at the level of

$$\alpha_{PC} = \frac{1}{J} \alpha_{PF} = \frac{1}{3} \times .05 = .0167. \quad (8)$$

With a Šidák approach, each hypothesis will be tested at the level of

$$\begin{aligned} \alpha_{PC} &= 1 - (1 - \alpha_{PF})^{\frac{1}{J}} \\ &= 1 - (1 - .05)^{\frac{1}{3}} = .0170. \end{aligned} \quad (9)$$

As this example illustrates, both procedures are likely to require using different α levels than the ones given by the tables. In fact, it is rather unlikely that a table could be precise enough to provide the wide range of alpha values needed for multiple testing purposes. A more practical solution is to generate the critical values for any alpha value, or, alternatively, to obtain the probability associated with any value of the Kolmogorov-Smirnov criterion. Such an approach can be implemented by approximating the sampling distribution “on the fly” for each specific problem and deriving the critical values for unusual values of α .

Another approach to finding critical values for unusual values of α is to find a numerical approximation for the sampling distributions. Molin and Abdi proposed such an approximation and showed that it was accurate for at least the first two significant digits. Their procedure, somewhat complex, is better implemented with a computer and comprises two steps.

The first step is to compute a quantity, A , obtained from the following formula:

$$A = \frac{-(b_1 + N) + \sqrt{(b_1 + N)^2 - 4b_2(b_0 - L^{-2})}}{2b_2}, \quad (10)$$

Notes: The intersection of a given row and column shows the critical value $L_{critical}$ for the sample size labeling the row and the alpha level labeling the column. For $N > 50$, the critical value can be found by using $f_N = \frac{83+N}{\sqrt{N}} - .01$.

 \end{aligned}
 \tag{11}$$

The second step implements a polynomial approximation and estimates the probability associated to a given value L as

$$\begin{aligned}
 Pr(L) \approx &-.37782822932809 + 1.67819837908004A \\
 &-3.02959249450445A^2 + 2.80015798142101A^3 \\

 &+0.00069650013110A^8 - 0.00011872227037A^9 \\
 &+ 0.00000575586834A^{10}.
 \end{aligned}
 \tag{12}$$

For example, suppose that we have obtained a value of $L = .1030$ from a sample of size $N = 50$. (Table 2 shows that $Pr(L) = .20$.) To estimate $Pr(L)$, we need first to compute A , and then use this value in Equation 12. From Equation 10, we compute the estimate of A as

$$\begin{aligned}
 A &= \frac{-(b_1 + N) + \sqrt{(b_1 + N)^2 - 4b_2(b_0 - L^{-2})}}{2b_2} \\
 &= \frac{-(b_1 + 50) + \sqrt{(b_1 + 50)^2 - 4b_2(b_0 - .1030^{-2})}}{2b_2} \\
 &= 1.82402308769590.
 \end{aligned}
 \tag{13}$$

Plugging in this value of A in Equation 12 gives

$$Pr(L) = .19840103775379 \approx .20.
 \tag{14}$$

As illustrated by this example, the approximated value of $\Pr(L)$ is correct for the first two decimal values.

Figure 1 is a line chart illustrating the cost of homes (principal place of residence) and cottages in the past 5 years. This graph was created using Excel. Note that even though the graph is made of discrete sets of data points, a trend is implied.

The following are recommendations for creating a line chart:

1. Gridlines help the reader estimate the value of the points.
2. The x - and y -axes are clearly labeled.
3. A legend is necessary when more than one line is presented.
4. The legend may be placed outside or inside the chart.
5. Each line is different as well as the points that make up each line in order to easily distinguish one trend from the other.
6. Too many lines (particularly if they overlap) would make the chart difficult to read.

Line charts are ideally used to demonstrate trends for data and to show how one variable is affected by another variable. Data points are connected by lines. A minimum of three points is required to make a line.

LINEAR REGRESSION

Linear regression is a powerful tool for testing theories about relationships among observables, and it is also useful for researchers interested in the predictive power of a set of variables. The terms *linear regression analysis* and *general linear model* are often used in the same contexts. The general linear model (GLM) is a broad class of interrelated statistical procedures focusing on linear relationships among variables or variable composites. The term *linear* is used because these techniques can be represented visually by plotting one variable against another on two-dimensional charts and using mathematical formulae for determining

where to draw one or more lines that will represent the relationships visually among the variables.

Regression analysis is the most broad, or general, form of the GLM. Hence, regression analysis forms the basis for many other statistical techniques, or, stated differently, a number of other common statistical procedures (e.g., analysis of variance, analysis of covariance, t test, Pearson product-moment correlation, Spearman rho correlation) are all specially designed versions of regression analysis. Furthermore, regression serves as a general framework for understanding a host of related multivariate statistics, most generally subsumed under canonical correlation analysis. An excellent nontechnical introduction to linear regression is provided by Schroeder, Sjoquist, and Stephan, and additional useful information may be found on the Web site of the Multiple Linear Regression Special Interest Group of the American Educational Research Association (<http://www.coe.unt.edu/mlrv/>).

Simple Linear Regression

Simple linear regression examines the relationship between two variables, one of which is referred to as the predictor variable (i.e., the variable that usually precedes the other), and the other of which is referred to as the criterion variable (i.e., the variable that the researcher is interested in explaining, predicting, or better understanding). Because simple regression results provide an understanding of the patterns of relationships between the two variables of interest in a given context, we often use the term *prediction* in describing the relationship. The procedure is called “simple” because it includes only one predictor variable.

As in studies employing Pearson product-moment correlation (r), the linear relationship between the predictor (X) and the criterion (Y) variables can be shown on a two-way scatterplot. A line of best fit drawn through the scatterplot is called the *regression line*, and the statistic representing the relationship between the two sets of points is called multiple R . In Pearson product-moment correlation, the coefficient r is used to show the strength and directionality of a relationship between two variables. A value of r close to zero

indicates a low or negligible correlation between two variables, whereas a value closer to 111 indicates a more appreciable amount of correlation between the variables. Negative r values depict inverse relationships between variables, whereas positive r values depict direct relationships. Multiple R is very similar to the Pearson r with the exception that it is always positive in value ($0 \leq R \leq 1$) because of a set of variable weights developed as part of the analysis. Because there is only one predictor in simple linear regression, R will be equivalent to the absolute value of the Pearson correlation coefficient ($|r|$) between the two variables.

Predictive Equations

Predictive equations are used to determine the degree of accuracy in prediction for any given observation in the regression data set. The predictive equation in simple linear regression applies both additive (a) and multiplicative (b) weights to one variable (the predictor variable, X) so as to “reproduce” maximally the other variable (the criterion, or dependent variable, Y). The predicted Y score (\hat{Y} , or “Y-hat”) for each observation in the sample is derived from this predictive equation. The simple regression equation (“regression of Y on X ”) is

$$\hat{Y} = a + bX. \quad (1)$$

This equation is the mathematical formula for a straight line. Hence, the visual resulting from the formula is called the *regression line*. Because \hat{Y} is the predicted estimate of Y , this is often represented in the formula as follows:

$$Y \leftarrow \hat{Y} = a + bX. \quad (2)$$

Error Scores

It is important to note that the \hat{Y} values are based on the *average* goodness of prediction across Y scores in the entire data set. Thus, some \hat{Y} values will be better approximations of their corresponding Y than others. The accuracy of prediction for any given case in the

analysis can be found by subtracting \hat{Y} from Y . The difference is the *error of prediction* (Y_e):

$$Y_e = Y - \hat{Y}. \quad (3)$$

Assumptions in Simple Linear Regression

As with any statistical procedure, simple regression analysis is based on certain assumptions about the data. As noted in various treatises on regression analysis, these assumptions include, but are not limited to, the following:

1. Simple linear regression analysis assumes that all of the variables are normally (or at least quasi-normally) distributed.
2. Regression analysis also assumes that the sample employed is randomly drawn from (or at least representative of) the population of interest.
3. Simple linear regression further assumes that a straight line will be the best way to capture the nature of the relationship between the two variables of interest. Forcing regression lines on data relationships that are curvilinear will lead to a misunderstanding about the relationship between the predictor and criterion variables.
4. Regression also is based on the assumption of “homoscedasticity” (i.e., that the conditional distribution of the Y_e scores for each value of X is an approximately normal distribution). This is also called the *constancy of error variance assumption*.

Multiple Linear Regression

Multiple linear regression is an extension of simple regression with the difference being the number of predictor variables employed. Multiple regression analyses will include at least two predictor variables (X_1, X_2, \dots, X_k). The linear equation for multiple regression is simply an extension of the simple regression equation:

$$Y \leftarrow \hat{Y} = a + b_1X_1 + b_2X_2 + \dots + b_kX_k. \quad (4)$$

Notice that there is a single additive (a) weight (or constant) for the equation and that each of the predictor variables (X_1 to X_k) has its own multiplicative (b) weight.

Multiple linear regression allows the researcher to look simultaneously at a host of predictor variables of interest and to examine the collective ability of these variables to predict the criterion variable. The multiple linear regression equation shown in Equation 4 above simply combines all of the predictor variables into one composite variable (\hat{Y}), and this composite variable then serves as a single (synthetic) predictor variable representing the host of predictors. Once the researcher determines the degree of multiple correlation (R) between the composite of predictor variables and the criterion variable, methods are then typically employed to understand further the complex set of relationships among the variables.

Holzinger and Swineford collected data on 24 tests of ability from 301 middle school students. A multiple linear regression example using scores on two of these tests (word meaning and word recognition) as predictor variables and scores on a third test (paragraph completion) as the criterion variable will be used here to illustrate the interpretation of results of a regression analysis. All output was generated using SPSS software. Linear regression results and a scatterplot depicting the relationship between Y and \hat{Y} appear in Figure 1 and Figure 2, respectively.

The two predictor variables collectively account for 50.7% ($R^2 = .507$) of the variance in the criterion variable. The analysis of variance breakdown indicates that the relationship between the predictor and criterion variables (i.e., the regression sum of squares) is statistically significant at the .001 level.

Correlations, Weights, and Coefficients in Linear Regression

Linear regression yields a variety of statistical indices that aid in making interpretations of the data. We discuss here three types of indices commonly used in social science literature employing regression analyses, namely, correlations, weights, and structure coefficients.

Correlations

There are essentially two types of correlations that one might generate and interpret when conducting a regression analysis, namely, simple correlations

(Pearson r values) and the multiple correlation (R). Pearson r is used to express a simple linear relationship

between two variables of interest, whereas R , as previously indicated, expresses the relationship between

the composite of predictor variables and the single criterion variable. In the simple regression case, only one Pearson r can be generated, and the value of this r will be the same as the multiple R (except, possibly, for the sign of the r coefficient). In the two-predictor (multiple linear regression) case illustrated here, there are three different r values: (a) correlation between X_1 (word recognition) and Y (paragraph comprehension), (b) correlation between X_2 (word meaning) and Y , and (c) correlation between X_1 and X_2 . Correlations among these three variables and the \hat{Y} generated by the analysis appear in Figure 3.

Figure 3 Correlations Among Word Recognition, Word Meaning, Paragraph Comprehension, and Predicted Value

Simple correlations between each of the predictors and the criterion variable should be reported routinely in regression studies. Based on these values, the researcher might determine whether a variable should be discarded prior to conducting the regression analysis (e.g., in the case in which the correlation with the criterion variable is nearly zero). We wish to warn, however, that this should not be simply a “fishing expedition” designed to select a set of promising variables from an array of variables for which the researcher just so happens to have data. Variables should always be selected for consideration in an analysis because they have theoretical importance, not because they are available. In the present example, word meaning is clearly the better predictor of paragraph completion.

Examining the correlations (r_s) between each pair of predictor variables also can be useful. These values help the researcher to determine the degree to which the predictors are collinear with one another. Collinearity introduces a variety of problems into the regression analysis, most of which are associated with the derivation of the statistical weights for the various predictor variables. When collinearity exists, the statistical weights yielded by the regression analysis will not be uniquely determined. Furthermore, including two predictor variables in the regression analysis that are nearly perfectly collinear (i.e., that are correlated

at or near 1.0) is not sensible considering that, once one of the variables is included, the second variable will offer no information that is not already provided by the first. In the present example, the correlation among the predictors is only .172, indicating that collinearity is not a major problem with this data set.

Once the Pearson r_s have been consulted (and, if necessary, variables have been eliminated from the analysis), the regression analysis is then conducted. The most important correlational statistic yielded by the regression analysis is multiple R . The squared value of multiple R (R^2) represents the statistical effect size, and, as noted previously, it can be interpreted as a percent of relationship between the predictor variable set and the criterion variable. In the absence of other information, R^2 , along with the total sum of squares and the sample size, provides enough information to calculate an F statistic used in testing for statistical significance. As previously noted, the R^2 for this analysis is large and statistically significant.

Weights

Unstandardized and standardized weights yielded by the analysis appear in Figure 4. The unstandardized a and b weights yielded by the regression analysis each can be useful in interpreting the results. The multiplicative weight (b) used in the equation is also

called the *slope* and the *regression coefficient*. The additive weight (a) is also called the *Y-intercept*, the *constant*, and the *regression constant*. The a weight represents the point at which the regression line will cross the y -axis (the value of y when $x = 0$); hence, the a weight estimates the value of the dependent variable when all predictors have a value of zero. The value of the b weight indicates the number of units that the criterion value is predicted to change if the given predictor variable is increased by one unit. If the b weight is negative, the value of the predicted dependent variable will decrease by b units when x is increased by one unit. Conversely, if b is positive, the value of the predicted dependent variable will increase when x is increased. In the present example, the b weight for word meaning (i.e., .313) is appreciably larger than that for word recognition (i.e., .032).

If all of the variables in the analysis are standardized (i.e., converted to z scores), the regression equation for k variables takes the following form:

$$z_y = \beta_1 z_{x1} + \beta_2 z_{x2} + \dots + \beta_k z_{xk} + e. \tag{5}$$

Note that with standardized data, there is no longer an additive weight (e in the equation represents the error [Y_e] score, not a statistical weight). The beta (β) weights shown in Equation 5 are also known as *standardized regression coefficients* and are often used over the b weights derived using the raw data because it is easy when comparing betas to make direct comparisons as to the relative amount of weight each variable is being assigned. The b weights, on the other hand, are not as easily comparable as they are affected by the metric in which the particular predictor

variable is measured. Note that the β for word meaning is more than six times larger than that for word recognition.

Regression Structure Coefficients

As explained by Thompson and Borrello, a structure coefficient (r_s) is the correlation between each of the predictors and \hat{Y} . For the present example, r_s values are shown in the last column of the correlation matrix presented previously. Structure coefficients express the degree of relationship of a predictor with the predicted values of the dependent variable, or, stated differently, express the degree to which a given predictor is “reproduced” in the computation of \hat{Y} . In the simple regression case, the structure coefficient for the single predictor is |1.00|, considering that the \hat{Y} is simply a linear transformation of the predictor. In multiple regression, structure coefficients are often larger for some predictors and smaller for others. In the present example, the structure coefficient for word meaning is .99, indicating that the variable is almost perfectly correlated with \hat{Y} . Word recognition has a much smaller structure coefficient ($r_s = .31$).

Consultation of Beta Weights and Structure Coefficients

There is a tendency for researchers to use beta weights when assessing variable contributions in linear regression. As noted earlier, these are the statistical weights applied to the standardized predictor variables in a regression. Although it seems logical to conclude that a larger beta weight implies a greater

contribution, this is not necessarily the case. This is particularly problematic when predictor variables are collinear. In fact, in cases in which collinearity among predictors is moderate to large, beta weights are extremely subject to distortion and can lead to erroneous conclusions about the importance of variables. By contrast, regression structure coefficients are not as prone to distortion. Therefore, in determining which variables are most instrumental in regression, structure coefficients generally provide more reliable evidence than do beta weights.

LOGISTIC REGRESSION ANALYSIS

Logistic regression is a flexible tool when one variable is identified as the response (dependent) variable and it is categorical. Contingency table analysis and loglinear models can handle only categorical variables, which becomes a constraint when both categorical and continuous variables should be included in a model. Also, most of the time, researchers are interested in a particular variable as the response. More importantly, the total number of variables that can be handled by a contingency table will easily reach a limit—a table with five variables and each variable having only two values will have $2^5 = 32$ cells. Unless for a very large sample, many cells will have very few cases.

Logistic regression is better equipped than ordinary regression for modeling on a categorical response variable. The simplest categorical variable has only two different values (“dichotomous” or “binary”), such as pass or fail. A variable with multiple values without any order is multinomial, and a variable with multiple ordered values is multiordinal. Different logistic regression models should be used according to the measurement nature of the response variable. Here, the focus is on logistic regression with a binary response variable. There can be as many explanatory (independent) variables as needed, and they can be either continuous or categorical.

Several problems will arise if we still use ordinary regression analysis when the response variable is categorical. Consider the following simple linear regression model:

$$Y_i = \alpha + \beta X_i + \varepsilon_i.$$

Note that Y can take only two possible values, say, 1 and 0, which will put a constraint on its predicted values. That is, this model will generate many predicted values that are neither 1 nor 0. And this will cause another problem when there is more than one explanatory variable. Any one of the explanatory variables may explain the majority of the very limited variation of the response variable, leaving little room

for others. In addition, the distribution of the error terms cannot be normal because the terms have only two possible values: when $Y = 1$, $\varepsilon = 1 - \alpha - \beta X$, and when $Y = 0$, $\varepsilon = -\alpha - \beta X$. Another assumption to be violated is constant error variance—the variance of X will change at different levels of X (formal expressions omitted).

These problems arise because the relationship between X and Y is not linear anymore. A transformation is needed on the categorical response variable so that it can be predicted by a linear relationship with the explanatory variables. Several transformations have been suggested, but statisticians have found the logit transformation very useful.

Odds and the Logit Transformation

In essence, logistic regression does not directly model on the value of the response variable, but on the probability that a particular value occurs. Let π be the probability that a value occurs; then $1 - \pi$ is the probability that it does not occur. The odds is the ratio of these two probabilities:

$$Odds = \frac{\pi}{1 - \pi}.$$

After taking the natural logarithm of the odds, a linear relationship between the transformed variable and the explanatory variables can be established, which is called the logistic transformation, or logit, for short:

$$\text{logit}[\pi] = \ln\left(\frac{\pi}{1 - \pi}\right).$$

The Simple Logistic Regression Model

This model has only one explanatory variable:

$$\ln\left(\frac{\pi}{1 - \pi}\right) = \alpha + \beta X.$$

The coefficient β can be interpreted in several ways. First, following the usual interpretation in ordinary

regression, we can say that with a one-unit change of X , the natural log of odds shall change by β . To many people, however, “log odds” does not make much intuitive sense.

The second interpretation comes after taking the antilog, $\frac{\pi}{1-\pi} = e^{\alpha+\beta X} = e^{\alpha}(e^{\beta})^X$. It says that with a one-unit change of X , the odds will change multiplicatively by e^{β} .

Further calculations may lead to a third interpretation. When $X = 1$, $\frac{\pi}{1-\pi} = e^{\alpha+\beta} = e^{\alpha}(e^{\beta})$. When $X = 0$, $\frac{\pi}{1-\pi} = e^{\alpha}$. The difference (or the change) of the two odds is $e^{\alpha}(e^{\beta} - 1)$. Because e^{α} is constant, $e^{\beta} - 1$ represents the change of odds. This can be written as $\% \Delta = (e^{\beta} - 1) * 100$, where Δ is the change of the odds. With a one-unit change in X , the odds will change by $\Delta\%$.

Note that these are the interpretations when X is continuous. When it is categorical, the change of odds becomes the odds ratio. Suppose X has only two values, 0 and 1. Again, when $X = 1$, $\frac{\pi}{1-\pi} = e^{\alpha+\beta} = e^{\alpha}(e^{\beta})$, and when $X = 0$, $\frac{\pi}{1-\pi} = e^{\alpha}$. This time, the change is measured by the ratio rather than the difference between the two odds, or the odds ratio, $\frac{e^{\alpha}(e^{\beta})}{e^{\alpha}} = e^{\beta}$, which is also used in the aforementioned second interpretation. This is why computer programs like SPSS automatically produce e^{β} , but one should note that its interpretation changes according to whether X is continuous or categorical.

An Example

A survey was conducted on local residents’ support for the adoption of renewable energy in a British town. Part of the results are shown in Table 1 with 50 cases and three variables.

Let π = the probability that a resident supports renewable energy, X_1 = the resident’s annual household income in thousand pounds, and $X_2 = 1$ if the respondent owns a property and 0 if not.

We can have two simple logistic regression models, each with a different explanatory variable:

$$\ln\left(\frac{\pi}{1-\pi}\right) = \alpha + \beta X_1 \text{ and } \ln\left(\frac{\pi}{1-\pi}\right) = \alpha + \beta X_2.$$

Here are the SPSS procedures: Analyze → Regression → Binary Logistic. Bring in “support” as the dependent variable. Then, for the first model, put “income” as a covariate (because it is continuous). For now, there is no need to change other default settings, so click OK.

a. Variable(s) entered on step 1: ownership, income.

According to the output in Table 2, we have

$$\ln\left(\frac{\pi}{1 - \pi}\right) = 0.569 - 0.002 * \text{Income}.$$

The last column in the output shows the value of e^β , 0.998. With a one-unit change of income (1,000 pounds), the odds change by almost 1. The percentage of change (decrease) of the odds is $(0.998 - 1) * 100$, or 0.2%, showing nearly no effect of income on the probability of supporting renewable energy.

The number under “Wald” is equal to $(\hat{\beta}/ASE)^2$, where $\hat{\beta}$ is the estimated coefficient and ASE stands for asymptotic standard error, especially calculated for nonnormally distributed variables. When the sample size is large (say, more than 100), the Wald statistic has a chi-squared distribution with 1 degree of freedom. We can use it to test the null hypothesis $\beta = 0$. For this model, the Wald statistic is 0.02. Therefore, the probability of not rejecting the null hypothesis is very high (0.886). We do not have enough evidence for rejecting the hypothesis that income has no effect on the probability of supporting renewable energy.

The explanatory variable in the second model, property ownership, is categorical. In using SPSS, remember to click the “Categorical” button and put “ownership” into the “Categorical Covariates” box.

Based on Table 3, the model is

$$\ln\left(\frac{\pi}{1 - \pi}\right) = -0.262 + 1.312 * \text{ownership}.$$

The last column of Table 3 shows that the odds ratio is 3.714. In other words, the odds of support for property owners is about 3.7 times of the odds of support for non-property owners. The effect is also statistically significant, with a p value of 0.031, smaller than the usual threshold of 0.05. Thus, we will reject the null hypothesis that ownership has no effect.

We can also construct a 95% confidence interval for the odds ratio. First, calculate the confidence interval for β : $(1.312 - 1.96 * 0.608, 1.312 + 1.96 * 0.608)$, or (0.12, 2.50). The confidence interval for the odds

ratio is $(e^{b-z*SE}, e^{b+z*SE}) = (e^{0.12}, e^{2.5}) = (1.13, 12.18)$. The further away the odds ratio is from 1, the more considerable the effect. Therefore, ownership has a considerable and significant effect on the probability of supporting renewable energy.

Multiple Logistic Regression Model

This is a natural extension of simple logistic regression with two or more explanatory variables. Here is a model without interaction term:

$$\ln\left(\frac{\pi}{1 - \pi}\right) = \alpha + \beta_1 * \text{Income} + \beta_2 * \text{ownership}.$$

SPSS output is shown in Table 4.

Because the effect of income remains insignificant after controlling that of ownership, we may want to use the simple model with ownership only. This can be confirmed by comparing the $-2 \log$ likelihood values from the two models (Table 5).

These values are an overall measurement of the difference between the observed values and the

predicted values, which indicate the performance of the models. It is clear that by adding income to the simple logistic regression model with ownership only, the predicted values become closer to the observed values, but not very much (formal procedures are omitted here). Logistic regression does not have something like the R^2 in ordinary regression. The Cox & Snell R Square and the Nagelkerke R Square were thus invented to give people a sense of the model performance.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Ferris, K. R., Jackofsky, E. F., & Breckenridge, B. G. (1986). Evidence for a curvilinear relationship between job performance and turnover. *Journal of Management*, 12(1), 105–111.

Regression, in general, is a technique for predicting an outcome based on a variety of variables, alone and in combination with one another. In this study, the researchers investigated the possibility of a curvilinear relationship between job performance and turnover in two diverse employee groups, using samples of 169 male accountants and 107 owner-operator truck drivers. Measures of performance for the two samples were obtained from company records. Testing for a curvilinear effect within each sample was done by regressing performance and the performance squared term on turnover, and confirming the findings by using **logistic regression**. The resulting standardized regression equations were plotted for each sample, using scores one to three standard deviations above and below the mean of the independent variables. Results indicated that performance was related to turnover in a curvilinear fashion in both professional and nonprofessional samples.

LOGLINEAR ANALYSIS

There are two general types of variables in a numeric data set, continuous (or quantitative), such as annual income, and categorical (or qualitative). Categorical variables themselves have two types, nominal, such as gender, and ordinal, such as levels of education. For a particular analysis, there may be a combination of different types of variables, which, to a large extent, determines the choice of statistical techniques. Loglinear analysis is used when (a) all the interested variables are categorical and (b) the objective is to find out which one of the interactive relationships among the variables can best explain the observed frequencies rather than explain one variable's variation with other variables. Because data with categorical variables can be presented in a contingency table, loglinear analysis is sometimes called *multiway frequency analysis* (MFA). It is also a multivariate version of chi-square analysis, dealing with variations and interactions between three or more categorical variables. Unlike in ordinary regression analysis, in loglinear analysis none of the variables is treated as a dependent variable. Rather, it is the cell count that is to be explained. Logistic regression should be used if a dependent variable is assigned and it is categorical.

Like chi-square analysis, loglinear analysis does not make any specific assumptions of distributions in the population. It only assumes that observations are independent. There is a potential problem, however, with analyzing frequencies: Especially for a small data set, some frequencies can be very small or even zero, making it very difficult to assess the reliability of results. Therefore, it is usually required that (a) there be at least five times as many cases as the number of cells in a table, and (b) when examining two variables at a time, there be an expected frequency (to be explained below) of greater than one for all cells and an expected frequency of five or more in 80% of the cells. Empty cells are usually replaced with 0.5 to avoid using the meaningless 0 as a denominator. Obviously, this is arbitrary, so a better strategy is to combine some categories in order to increase the number of cases in a particular cell.

An Example

Table 1 contains results from a survey on the students in a university. There are three categorical variables: level of study (undergraduate or postgraduate), nationality (American or international), and part-time employment during term time (employed or unemployed). The objective is to find out which model of the relationships between the variables can best predict the observed cell frequencies.

We shall use SPSS 12 to carry out the following analysis. Because the entry of cross-tabulated data is different from the entry of individual-level data, it is necessary to show all the steps here. The first is to create the variables in the “Variable View”: level of study (1 = undergraduate, 2 = postgraduate); nationality (1 = American, 0 = international); employment (1 = part-time employed, 0 = not part-time employed); and frequency. (Coding values can be different.) Then go to the “Data View” to key in the coding values and frequencies. Now you should have what is shown in Figure 1.

The last step is very important: Do *not* forget to go to Data → Weight Cases → Select “Weight case by” and bring in the variable “Frequency.” To check whether the data have been correctly entered, reproduce the table by the following procedures: Analyze → Descriptive Statistics → Crosstabs and move “Nationality” as the row variable, “Employment” as the column variable, and “Level of study” as the “Layer 1 of 1” variable. The output is shown in Table 2.

Table 2 also shows the expected values. SPSS can calculate them after you click “Cells” and select

“Expected” below “Counts.” Below is the formula for calculating the expected value of a particular cell:

$$\text{expected frequency} = \frac{\text{column total} \times \text{row total}}{\text{overall total}}.$$

For example, the first expected frequency, 34.8, is the result of $(42 \times 112)/135$.

The Loglinear Model

The basic idea of loglinear analysis is to compare the observed frequency of a cell with its expected frequency, that is, the frequency expected to be purely by chance. Here is the logic: The bigger the difference between the two frequencies, the less likely it is that the difference arises from chance; in other words, the more likely it is that the difference is an effect of interactions between the variables. If the frequencies are purely due to chance, then there should be no or little variation across the rows or columns. Thus, the row totals and column totals at the margin (marginal totals) should be sufficient for determining the frequency in each cell. Therefore, by measuring how far away the observed frequencies are from the expected frequencies, we have a basis for discovering which variables and their interactions can best predict the observed frequencies.

The effect of each variable is decomposed into the effect of its own (the main effect) and the effect of its interactions with other variables (the interaction effects). These effects are then connected in a linear fashion to predict the log transformation of the observed frequencies, hence the phrase “loglinear analysis.” Different combinations of the effects lead to different models.

For the above example,

F_{ijk} is the cell frequency,

λ^x is the effect of level of study,

λ^y is the effect of nationality,

λ^z is the effect of employment status,

λ is the baseline effect (when all other effects are zero).

Here are some of the possible models:

1. $\log F_{ijk} = \lambda + \lambda^x + \lambda^y + \lambda^z$, which includes only the main effects and is based on the theory that all variables are mutually independent.
2. $\log F_{ijk} = \lambda + \lambda^x + \lambda^y + \lambda^z + \lambda^{xy} + \lambda^{xz} + \lambda^{yz}$, which includes both the main effects and the interaction

effects of all pairs of variables, suggesting that the association between any two variables remains the same at each level of the third variable.

3. $\log F_{ijk} = \lambda + \lambda^x + \lambda^y + \lambda^z + \lambda^{xy} + \lambda^{xz} + \lambda^{yz} + \lambda^{xyz}$, which includes all the possible effects and is thus called the saturated model.

Note the hierarchical structure in the models. If a higher order interaction term is included, then all the lower order interactions and the main effects should be included.

Our objective is to make an informed decision on which of these models we should use for predicting the observed cell frequencies. The saturated model is of little use because it virtually says, “All effects matter.” Like any modeling process, we aim to find a model that is parsimonious, statistically rigorous, and substantively meaningful. Let’s focus on the first two criteria and leave the third to the researcher. We are searching for a model that fits two requirements: (a) It must have the least number of effects (or parameters), and (b) the difference between the observed frequencies and the expected frequencies must not be statistically significant. The difference is measured by

either the likelihood ratio chi-square (G^2) or Pearson's chi-square (X^2):

$$G^2 = 2 \sum (\text{observed}) \log \left(\frac{\text{observed}}{\text{fitted}} \right)$$

$$X^2 = \sum \frac{(\text{observed} - \text{fitted})^2}{\text{fitted}}$$

G^2 is usually preferred because of its mathematical robustness.

As an interactive procedure, model selection usually starts with the saturated model, eliminates the highest order of interaction term, and then compares the new model with the saturated model; if the new model is still not good enough, the selection moves on to eliminate another effect, and so on (so-called stepwise backward elimination).

Here are the SPSS steps: Analyze → Loglinear → Model Selection, then bring the three categorical variables into "Factor(s)." Define the range of each variable: for level of study, key in 1 for minimum and 2 for maximum; for nationality and employment, key in 0 for minimum and 1 for maximum. Click OK to obtain the results. (Technical details of how to calculate the effects have been omitted.)

Results and Interpretations

Limited space does not allow all SPSS outputs to be shown here. For this example, there are four steps, and only the last one is presented in Table 3.

What we are looking for is the evidence of statistical significance after each effect term is removed. If the removal of a particular effect will make a statistically significant difference on the fitness of the model to the observed data, this effect will be retained in the model; otherwise, it will be removed in the next step. The process stops when all of the effects are statistically significant, which is indicated by the p values. For this example, two terms are kept in the final step—the interaction effect between study level and employment, and nationality. This is so because the p values are 0.0138 and 0.0000, respectively, meaning that the probability of the

values predicted by the model being equal to the observed data is very low if the term is removed. Therefore, our statistical analysis ends with the following model:

$$\log F_{ijk} = \lambda + \lambda^X + \lambda^Y + \lambda^Z + \lambda^{XZ}.$$

LONGITUDINAL/REPEATED MEASURES DATA

Longitudinal/repeated measures data arise in situations where we have multiple measures on a subject taken over time (growth over time) or a change under different treatment conditions. A simple example of longitudinal research design is when the research setting involves multiple follow-up measurements on a random sample of individuals, such as their achievement, performance, or attitude, over a period of time with logically spaced time points. Researchers across different disciplines have used different terms to describe the analysis of data obtained from repeatedly observing the same subjects. Some of the terms they have used are *longitudinal data analysis*, *within-subjects design*, *repeated-measures design*, *growth modeling*, *multilevel growth modeling*, or *individual change model*.

The simplest form of a repeated measures design is a *one-way repeated measures design*, *one-way repeated measures ANOVA design*, or *within-subjects repeated measures design*, when repeated measures on a dependent variable are observed either over time

(e.g., time, grade level) or under different treatment conditions (different type of medication for long-term illness). These times, grade levels, or treatment conditions serve as the repeated measures independent variables in the analysis.

More complex repeated measures designs have at least one between-subjects factor (e.g., gender, ethnicity) in addition to having repeated measures as within-subjects factors (e.g., time). These repeated designs with both within-subjects factors and between-subjects factors are called *repeated measures ANOVA with between-subjects factors designs* or *factorial repeated measures designs*. Below, a detailed description, assumptions, a hypothetical data set, and SPSS analysis and results of only the one-way repeated-measures ANOVA design are provided because of space limitations.

One-Way Repeated Measures ANOVA Design

In the one-way ANOVA design, all subjects are measured on all levels of the repeated measures independent variable (e.g., time or treatment conditions). Table 1 shows the representation of five subjects (S_1, S_2, S_3, S_4, S_5) in a one-way design with three time points (T_1, T_2, T_3).

Table 1 One-Way Repeated Measures Design

	Time		
	T_1	T_2	T_3
S_1	S_1	S_1	S_1
S_2	S_2	S_2	S_2
S_3	S_3	S_3	S_3
S_4	S_4	S_4	S_4
S_5	S_5	S_5	S_5

Source of Variance in One-Way Repeated Measures Design

In this design, total variability (SS_{Total}) in the measured dependent variable is partitioned into a part due to time (SS_{Time}), a part due to subjects ($SS_{Subjects}$), and

error ($SS_{Time \times Subject}$), which is an interaction between subject and time. Thus,

$$SS_{Total} = SS_{Time} + SS_{Subjects} + SS_{Time \times Subject} \quad (1)$$

The associated degrees of freedom in this design are partitioned as

$$df_{Total} = df_{Time} + df_{Subjects} + df_{Time \times Subject} \quad (2)$$

where total degrees of freedom are the total number of measurements ($N = T \times S$) minus one. So,

$$df_{Total} = N - 1. \quad (3)$$

The degrees of freedom for time effect are the number of measurements over time and are represented as

$$df_{Time} = T - 1. \quad (4)$$

The degrees of freedom for subjects effect are the number of subjects minus one and are represented as

$$df_{Subjects} = S - 1. \quad (5)$$

The degrees of freedom for the error term are

$$df_{Time \times Subject} = (T - 1)(S - 1). \quad (6)$$

The corresponding mean squares (MS) are calculated by dividing sum of squares (SS) by their associated degrees of freedom (df). Thus,

$$MS_{Time} = SS_{Time} / df_{Time}, \quad (7)$$

$$MS_{Subjects} = SS_{Subjects} / df_{Subjects}, \quad (8)$$

$$MS_{Time \times Subject} = SS_{Time \times Subject} / df_{Time \times Subject}. \quad (9)$$

The F ratio for testing the null hypothesis that $\mu_{T1} = \mu_{T2} = \dots = \mu_{Tj}, j = 1, 2, \dots, T$ time points is the ratio of MS_{Time} and $MS_{Time \times Subject}$. Thus,

$$F = MS_{Time} / MS_{Time \times Subject}, \quad (10)$$

with $df = (T - 1), (T - 1)(S - 1)$.

Assumptions

Three assumptions underlie the one-way repeated measures design:

1. Measurements for each time point are normally distributed.
2. Subjects are independent.
3. The variances of the differences between each pair of levels of the repeated measures factor are equal. This assumption is called the “sphericity assumption,” and it is tested using Mauchly’s test. A significant Mauchly’s test indicates that the assumption of sphericity is not met. Violating this assumption inflates Type I error rate.

Analysis of Hypothetical Repeated Measures Data

Table 2 presents a small hypothetical data set in which five first-grade students are tested weekly for 3 weeks on their vocabulary learning in terms of the number of words they learn each week. The research question of interest is whether or not, on average, first-grade students’ vocabulary learning changes over the 3 weeks. Similarly, is there growth in first-grade students’ vocabulary learning over the 3 weeks?

The above hypothetical data values are entered in the SPSS data editor, where each line of data represents a subject and contains three columns of sequential dependent variable values (e.g., number of words learned each week) for each level of the repeated-measures independent variable (e.g., week1, week2, week3). To analyze these data, select the General

Linear Model option from the analysis tab of SPSS. Next, select the Repeated Measures submenu window and define “week” as the within-subjects factor. You can also request Descriptive Statistics, Eta-Square (estimate of the repeated measures effect size), Mauchly’s Test of Sphericity, and Power from the Options window.

Table 3 shows the means, standard deviations, and number of data points (subjects) in each level of the within-subjects factor (week).

The results of analyzing these hypothetical data indicate that the Mauchly’s test of sphericity is not significant (Mauchly’s $W = .918$, approximate chi-square value = .255, $df = 2$, $p = .880$). Thus, assuming sphericity, the partial eta-square value is .972 with observed power of 1.0. Also, because the assumption of sphericity is met, the results of the analysis for testing the null hypothesis of no differences between population means over the 3-week period ($H_0: \mu_{w1} = \mu_{w2} = \mu_{w3}$) using the ANOVA tests with Type III sum of squares (SS) and mean squares (MS) for within-subjects and between-subjects effects are summarized in Table 4. The results of testing the week variable reveal that there are significant differences in the means of the number of words learned over the 3-week period ($SS = 32.4$, $df = 2$, $MS = 16.2$, $F = 216$, and $p = .000$).

SPSS output also provides three alternatives for testing the same hypothesis (equality of the means over time) when the Mauchly’s test of sphericity assumption is violated. The first alternative is using the multivariate tests (e.g., Pillai’s Trace, Wilks’s Lambda, Hotelling’s Trace, Roy’s Largest Root). The second alternative is using the Greenhouse-Geisser, Huynh-Feldt, or lower-bound test adjustments. The third alternative is using a separate test of linear and

quadratic trends. Because the data in the above example support the sphericity assumption, we do not need to use any of these three alternatives.

Limitations of the Traditional Repeated Measures Analysis

The above-described simple repeated measures design and other, more complex designs require the availability of the complete data, where every individual has all the measurements for all the time points as well as equal time intervals. A common problem in analyzing repeated measures/longitudinal data is that the complete data for all measurements taken at different time points for all individuals may not be available for different reasons, such as absentee at the time of data collection, drop out from the study, or any other reason. Missing data for some individuals or variations in time between consecutive measurements pose a great complication using traditional repeated-measures statistical methods.

Hierarchical linear modeling (HLM) and multi-level analysis are alternative methods to overcome the limitations of the traditional repeated measures analysis. The HLM approach is generally more flexible than the traditional repeated measures analysis in terms of its data requirements because the repeated measurements are viewed as nested within the individual rather than as the same fixed set of measurements for all individuals. Thus, both the repeated measurements and the timing of measurements may vary randomly within subjects and across subjects. Also, HLM is capable of handling longitudinal data sets with more than two levels. For instance, repeated measures for each individual (level-1) are nested

within classroom levels (level-2), which in turn could be nested within school levels (level-3). In addition, HLM is flexible in terms of fitting a polynomial growth model to the longitudinal data, where the relationship between time and the repeated measures over time is not linear. Furthermore, it is able to fit a piecewise linear growth model to a longitudinal data set for comparing growth rates during two or more different longitudinal data collection periods. Finally, HLM can include level-1 time varying covariates in the repeated data set. For example, if the repeated measures data collection points are grades (e.g., Grades 3, 4, 5), we can add to the level-1 model the number of days the students were absent in each grade as a predictor.

LURIA NEBRASKA NEUROPSYCHOLOGICAL BATTERY

The extensive work of the Russian neuropsychologist A. R. Luria has long been recognized as a major contribution to clinical neuropsychology. However, his work was largely qualitative rather than quantitative in nature. The development of a standardized version of Luria's neuropsychological assessment procedures was an attempt to provide a version that could be used to generate both quantitative and qualitative information.

This undertaking was facilitated by the publication in 1975 of materials by Anne-Lise Christensen that were useful in developing the original standardized version of the Luria Nebraska Neuropsychological Battery (Form I) (LNNB). In addition, Luria summarized his investigative technique in an important paper

titled “The Neuropsychological Investigation of Patients With Localized Brain Lesions,” which was translated into English by Dr. Lawrence Majovski.

The resulting test consisted of 269 items in Form I or 279 items in Form II. The actual number of administered procedures for each form is more than 700, because many of the items include numerous repetitions of the specific procedures. In the LNNB, qualitative as well as quantitative observations are scored and used to interpret the results. The battery allows the user to make generally the same qualitative observations made by Luria and others, using more formal administration and scoring procedures. As with other, more qualitative methods, the test user is encouraged to administer each item flexibly and to continuously test the limits of the client’s cognitive abilities. The original scales for the LNNB were derived from Luria’s basic classification of his items into broad skill categories, such as motor, nonverbal auditory, visual-spatial, receptive language, and intellectual.

Form II of the battery was designed with several goals in mind. The first goal was to establish a parallel version of the battery that could be used for test-retest purposes. The second goal was to make available a set of stimulus cards that would have several advantages over the cards used in Form I. These advantages were (a) a larger size for clients with possible peripheral sensory deficits; (b) an organization that allows the examiner to use the cards more efficiently, thus reducing administration time; (c) reduction of the number of loose cards so as to further ease administration problems; (d) correction of some items that were either too difficult or too easy; (e) some changes in administration and scoring of the battery that increase the ability of the items to specify deficits

within particular areas; and (f) modifications in some items and stimuli to make the test material more familiar to users in the United States and Canada.

Since its introduction, the LNNB has generated several hundred research studies. It has been the subject of controversy from both qualitative theorists, who see the battery as too fixed and rigid, and quantitative theorists, who see the LNNB as too flexible and criticize the variation in item content within the scales of the test. Despite this, the battery is one of the most used standardized test batteries in neuropsychology and is especially useful for bedside evaluations and evaluations of clients with focal injuries as well as those who have extensive impairments that make other standard tests impractical.

MALE ROLE NORMS INVENTORY

Ronald F. Levant and colleagues developed the Male Role Norms Inventory (MRNI), which measures seven theoretically derived norms of traditional masculinity ideology: Avoidance of Femininity, Fear and Hatred of Homosexuals, Self-Reliance, Aggression, Achievement/Status, Non-Relational Attitudes Toward Sex, and Restrictive Emotionality. It also includes a Non-Traditional Attitudes subscale.

The MRNI consists of 57 normative statements to which subjects indicate their degree of agreement/disagreement on 7-point Likert-type scales. Examples of MRNI items: “A man should do whatever it takes to be admired and respected.” “A boy should be allowed to quit a game if he is losing.”

Scores are obtained by adding up the raw scores on individual items for each subscale and then dividing by the number of items for that subscale. For each traditional subscale, the range is 1–7, with higher scores indicating greater endorsement of traditional masculinity ideology. To obtain the Total Traditional score, add up raw scores on the six traditional subscales (i.e., excluding the Non-Traditional Attitudes subscale) and divide by 45. For the Non-Traditional Attitudes subscale, the range is also 1–7, but higher

scores indicate greater endorsement of nontraditional masculinity ideology.

The Cronbach alpha coefficients of the subscales of the original MRNI and the newly developed MRNI-R are, respectively, Avoidance of Femininity (.77, .85); Fear and Hatred of Homosexuals (.54, .91); Self-Reliance (.54, .78); Aggression (.52, .80); Achievement/Status (.67, .84.); Non-Relational Attitudes Toward Sex (.69, .79); Restrictive Emotionality (.75, .86); Non-Traditional Attitudes Toward Masculinity (.57, not used in MRNI-R); and Total Traditional scale (.84, .96).

The test-retest reliability of the MRNI (Total Traditional scale) over a 3-month time period for men was .65, and for women, .72.

Discriminant construct validity was assessed by examining the correlation of the MRNI Total Traditional scale with a theoretically distinct measure of gender—the short form of the Personal Attributes Scale (PAQ). We hypothesized that the MRNI would not be significantly correlated with PAQ and found that the MRNI Total Traditional scale was not related to the PAQ in a college student sample (for men, $r = .06$ with M, or the Masculinity scale; for females, $r = .08$ with F, or the Femininity scale). Convergent construct validity was assessed by examining the correlation of the MRNI Total Traditional scale with two

theoretically related measures of gender. We hypothesized that the MRNI would be correlated with each of these two measures and did find significant moderate correlations between the MRNI Total Traditional scale and both the Gender Role Conflict Scale-I ($r = .52$, $p < .001$) and the Masculine Gender Role Stress Scale ($r = .52$, $p < .001$).

MALTHUS, THOMAS (1766–1834)

Malthus could be described as England's first academic economist. He became famous for his 1798 pamphlet "An Essay on the Principle of Population as It Affects the Future Improvement on Society, With Remarks on the Speculation of Mr. Godwin, M. Condorcet and Other Writers." His claim, sensational at the time, was that any growing population would eventually be unable to sustain itself.

Malthus was born in Dorking, Surrey, on February 13, 1766. He was the second son in a prosperous family of eight (two boys, six girls). Educated at home, he went up to Jesus College, Cambridge, in 1784, becoming a college fellow in 1793. He was ordained a minister of the Church of England in 1788, and in 1796, he became curate of Okewood Chapel near Albury in Surrey. For the next 8 years, he divided his time between Surrey (living with his parents) and Cambridge. When at home, he and his father had long debates on the

nation's economy, and they are what led to his famous pamphlet.

Publication of the pamphlet, which was expanded in subsequent editions by the inclusion of population data that confirmed his reasoning, turned Malthus into an intellectual celebrity. In the 1803 edition of his work, Malthus suggested that one way of reducing population would be to give to the poor those rights possessed by the middle class, such as universal suffrage, state-run education, the elimination of the Poor Laws, and the establishment of a national labor market. In effect, he was arguing that an increase in income would lead to a decrease in family size. These were controversial views, unpopular with many, yet acknowledged by others as having merit.

In 1804, Malthus gave up his fellowship and got married. The following year, he was appointed Professor of Modern History and Political Economy at the East India College in Haileybury (now Haileybury College), a position he held for the rest of his life. Malthus remained prominent in economic discussions for the rest of his life. In 1814 he published *Observations on the Effects of the Corn Laws, and of a Rise or Fall in the Price of Corn on the Agriculture and General Wealth of the Country*, which presented both sides of the argument for these laws. By the following year, however, it was clear that he personally was in favor of restrictions on the importation of foreign corn.

In 1820, he published *Principles of Political Economy*, in which he disagreed with the "classical approach" proposed by David Ricardo, a good friend.

Malthus died in Bath on December 29, 1834, following a Christmas visit to his in-laws.

MANN-WHITNEY U TEST (WILCOXON RANK-SUM TEST)

The Wilcoxon Rank-Sum Test was developed by Wilcoxon in 1945, and it is useful when comparing the location of two independent samples. A slightly different version of the test was later introduced by Mann and Whitney in 1947. Therefore, it is sometimes referred to as the Wilcoxon Mann-Whitney test.

The underlying assumptions of the Wilcoxon Rank-Sum Test are that the scores are independent and come from a continuous probability distribution. The null hypothesis is $H_0: f_i(x) = g_i(x)$, or the two samples come from identical distributions. The alternative hypotheses are $H_a: f_i(x) \neq g_i(x)$ (two-tail), $H_a: f_i(x) < g_i(x)$ (lower-tail), or $H_a: f_i(x) > g_i(x)$ (upper-tail).

The null hypothesis suggests that the Wilcoxon Rank-Sum is a test of general differences. Even though the Wilcoxon procedure is a test of stochastic ordering, it is particularly powerful in detecting differences between group means. As a rank-based procedure, it is not useful in testing for differences in scale (variance).

The Wilcoxon test is nonparametric. This means that it preserves the Type I error rate (i.e., false positive rate) to nominal alpha regardless of the population shape. This is a fundamental advantage over its parametric counterpart, the Student's t test, which relies on the normality distribution assumption.

When sampling from nonnormal distributions, the Wilcoxon Rank-Sum Test is often more powerful than the t test when the hypothesis being tested is a shift in location parameter. This was suggested by the large sample property known as the asymptotic relative efficiency (ARE). The ARE of the Wilcoxon (Mann-Whitney) relative to the t test under population normality is 0.955. However, under population non-normality, the ARE of the Wilcoxon Rank-Sum Test can be as high as ∞ .

Small-sample Monte Carlo studies confirmed the comparative statistical power advantage of the Wilcoxon Rank-Sum Test over the t test for departures from nonnormality. It is often three to four times more

powerful for sample sizes and treatment effect sizes common in education and psychology.

Because of the relationship between statistical power and sample size, research studies may be designed with considerably fewer participants when using the Wilcoxon Rank-Sum Test instead of the t test. It provides a considerable efficiency advantage in terms of cost, time, and effort in conducting an experiment.

In order to compute the Wilcoxon Rank-Sum Test, combine the two samples, order the scores from lowest to highest, and keep track of the score's group membership. The ordered scores are assigned ranks. If there are tied values, the average of the ranks is assigned to each of the tied scores. The Wilcoxon formula is

$$S_n = \sum_{i=1}^n R_i, \quad (1)$$

where R_i are the ranks and S_n is the sum of the ranks for a sample of size n .

The rank-sum statistic can be converted to a Mann-Whitney U in order to use commonly available tabled critical values for the U statistic. The formula for the conversion is

$$U_n = S_n - \frac{1}{2}n(n+1). \quad (2)$$

If a table of critical values is not available, the Wilcoxon Rank-Sum Test can be evaluated with a large-sample approximation using the following formula:

$$z = \frac{S_n - \frac{n(n+m+1)}{2}}{\sqrt{\frac{mn(m+n+1)}{12}}}, \quad (3)$$

where m and n are the sample sizes of the two groups and S_n is the rank sum for sample n . The large-sample approximation for the critical value to test the obtained Mann-Whitney U statistic is

$$z = \frac{U + \frac{1}{2} - \frac{1}{2}mn}{\sqrt{\frac{mn(m+n+1)}{12}}}. \quad (4)$$

The large-sample approximation maintains the Type I error rate at nominal α when each sample size is greater than 14 for $\alpha = .05$, and greater than 29 for $\alpha = .01$, unless the data are heavily tied. In this case, each sample should be at least $n = 17$ ($\alpha = .05$) and $n = 44$ ($\alpha = .01$).

If there are few ties, they can be handled using average ranks. However, for heavily tied data, it is advisable to use a tie correction formula. The following expression is used to replace the denominator in the large sample approximation formula, either Equation 3 or Equation 4, as appropriate:

$$\sqrt{\frac{mn}{12N(N-1)} \left[N(N^2-1) - \left(\sum \tau_i^3 - \sum \tau_i \right) \right]} \quad (5)$$

where τ_i is the number of ties at the i th tied score.

Example

Twenty students are randomly assigned into Group 1 (treatment group) or Group 2 (comparison group). Group 1 receives a new curriculum, whereas Group 2 receives the traditional curriculum. Their test scores are displayed in Table 1. The ranked scores are presented in Table 2. For ease of computation, Group 1 is referred to as A and Group 2 is referred to as B in this table.

The sum of the ranks for Group 1 is 133, and the sum of the ranks for Group 2 is 77. For convenience, the smaller of the rank sums is taken as the obtained value and compared with the critical value. Because tabulated critical values are not often available, this value is converted to a z score based on Equation 3.

74	A	17	10	
75	A	18	10	
76	A	19	10	
77	A	20	10	

The result is $z = -2.12$. The p value associated with this z is 0.034. Therefore, we can conclude that the new curriculum produced statistically significant higher scores than the traditional curriculum at the $\alpha = .05$ level. In comparison, Student's t test for these data yields $t = 1.87$. With $df = 18$, $p = .078$. Thus, had the parametric t test been conducted, we would have concluded incorrectly that the new curriculum was no more effective than the traditional curriculum.

Mann-Whitney U Test

The Mann-Whitney U statistic is calculated as follows. For each score in Group 1, count the number of Bs that precede it, or count the number of As that precede each Group 2 score.

$$U_1 = 3 + 4 + 7 + 8 + 8 + 8 + 10 + 10 + 10 + 10 = 77.$$

$$U_2 = 0 + 0 + 0 + 1 + 2 + 2 + 2 + 3 + 6 + 6 = 22.$$

The U test is significant if the larger U_1 (77) is *greater* than the critical value or if the smaller U_2 (22) is *less* than the critical value. Tables of critical values are commonly available. They are constructed for convenience based on whichever value (U_1 or U_2) is smaller, which in this case is $U_2 = 22$. The critical value for a one-sided test with $n_1 = n_2 = 10$ and $\alpha = .05$ is 27. Because the obtained value 22 is *less* than the critical value of 27, the null hypothesis is rejected.

SPSS

To compute the Wilcoxon Rank-Sum Mann-Whitney U test via SPSS, enter the data into a column. In the next column, indicate if the score's membership is Group 1 or Group 2. Then, choose Analyze | Nonparametric Tests | 2 Independent Tests.

Highlight the scores variable and click on the arrow to move it to the Test Variable List. Highlight the grouping variable and click on the arrow to move it to the Grouping Variable. Click on Define Groups to identify Groups 1 and 2. Finally, click on OK. The output appears as Figure 1.

MARKOV, ANDREI ANDREEVICH (1856–1922)

Much of what is known regarding Andrei Andreevich Markov comes from two sources. The first is a short biography provided by Ahiezer and Volkobyskii, which was written in Russian 25 years after Markov's death. The second resource is an obituary written by Vladimir A. Stekloff (or Steklov, 1864–1927) and Ya. V. Uspenskii.

Markov was born in Ryazan, Russia. He had two sons from two different marriages, both of whom were mathematicians, but especially noted was the first son, Andrei, Jr. (1903–1979). Markov completed his undergraduate work in 1878 and his master's degree in 1880 as a student of A. N. Korokin (d. 1908) and Egor Ivanovich Zolotarev (1847–1878). That same year, Markov accepted a lecturer's position in mathematics at St. Petersburg University. Four years later, he

defended his doctoral dissertation, “On Certain Applications of Algebraic Continuous Functions,” under the tutelage of Pafnuty Lvovich Chebyshev (or Tchebichef, 1821–1894).

Markov rose through the professorial ranks from Adjunct (1886), to Extraordinary (1890), and to Ordinary Academician (1896) of the Imperial Academy of Science of St. Petersburg, which was later renamed the Russian Academy of Sciences after the revolution of 1917. Two of his most well-known students were Georgy F. Voronoy (or Voronoi, 1868–1908) and Stanislaw Zaremba (1863–1942). In 1905, Markov retired from the university with the title of Distinguished Professor, but continued lecturing until his death.

Markov worked on analysis, approximation theory, converging series, continuous fractions, integrals, interpolation, number theory, limits, and probability theory. Building on the work of Chebyshev, Markov made major advances in the methods of moments in probability theory. Two of his primary pedagogical works were “Calculus of Finite Differences” and “Calculus of Probabilities.”

Markov is best known for his work on extensions from the law of large numbers that led to the development of *Markov chains*. It is a set of finite or discrete states (e.g., on vs. off) and an associated matrix that determines the probability of moving from one state to another. The primary feature, called the *Markov property*, is that the future state is determined by a random process based on the present state, but independent from all previous states, meaning that it has no memory.

A *Markov process* may be discrete or continuous, such as displacement over continuous time. A Markov process of the n th order means that both the memory and future probability state of the process are fully articulated by n elements. A *Markov field* pertains to multidimensional space.

A simple example of a Markov chain is a random walk, such as Brownian motion. The Markov chain is the progenitor and special case of stochastic processes, and led to the application of Liouville’s theorem (Joseph Liouville, 1809–1882) to the ergodic hypothesis.

MARKOV CHAIN MONTE CARLO METHODS

Markov chain Monte Carlo (MCMC) is a modification of the Monte Carlo simulation method. In a typical Monte Carlo simulation, we are trying to compute the expectation of some random variable, which we do by sampling and using the law of large numbers. However, often, it is either impossible or intractable to obtain enough independent samples from the desired distribution. The basic modification in MCMC from Monte Carlo is that in MCMC we use dependent samples, which are generated by a Markov chain. Under suitable and very general conditions, averages computed from the trajectory of a Markov chain will also converge to the desired expectation.

Because MCMC was motivated by Monte Carlo simulation methods, we start with a short discussion of Monte Carlo methods.

Monte Carlo Simulation

The basic problem in Monte Carlo simulations is to estimate a target density π on some (usually very complicated and large) state space. This estimation is done by drawing independent and identically distributed samples from π and using the empirical distribution as an approximation to the true distribution.

Clearly, the central concern in a Monte Carlo simulation is drawing a random sample from the target distribution π . Because of this, many sampling methods have been devised.

Rejection Sampling

Many MCMC algorithms are strongly related to rejection sampling, and this is the main reason for our discussion of rejection sampling.

A simple example best illustrates the idea behind rejection sampling. Let π is a distribution on $[0,1]$ with density $p(x)$. Now, suppose that there is another distribution with density $q(x)$ on $[0,1]$ such that $p(x) < Mq(x)$ for all x and such that we can sample from q . To get one sample X from π , let Y be a sample from q and U be a sample from $U[0,1]$. If $U < p(Y)/(Mq(Y)) = p(Y)/M$, then we accept Y as a sample from q and set $X = Y$, else we reject and try again (see Figure 1 for an illustration of this).

We see that the infinitesimal probability that $X = x$ is returned is

$$\begin{aligned} Pr(X = x)dx &= \frac{Pr(Y = x \text{ and } x \text{ is returned})}{Pr(\text{something is returned})} dx \\ &= \frac{q(x)dx \frac{p(x)}{Mq(x)}}{\int_x q(x) \frac{p(x)}{Mq(x)} dx} = p(x)dx, \end{aligned}$$

so this gives a perfect sample from $p(x)$. Notice, however, that the efficiency is $1/M$, because only one out of every M samples will be accepted.

Figure 1 Rejection Sampling

In general, any distribution q with $p(x) \leq Mq(x)$ will do (not just uniform), and the efficiency will again be $1/M$.

Generalities on MCMC

For Monte Carlo simulation, we require samples from the distribution π . This is very often either impossible or highly impractical to do. Even if it is possible to generate one perfect sample, we need many independent samples for a Monte Carlo simulation. MCMC eases this problem by giving up the requirement for independent samples from π and generating instead many correlated approximate samples from π , with the approximation improving as the simulation continues.

The ergodic theorem gives some very general conditions under which MCMC will work. A Markov chain with state space Ω is *irreducible* if it is possible for the chain to get from any state in Ω to any other state in Ω , and it is *positively recurrent* if the expected time for transition from state i to state j is finite for every $i, j \in \Omega$. Clearly if Ω is finite and the chain is irreducible, then it is also positively recurrent.

Ergodic Theorem for Markov Chains

Let $\{X_n\}$ be an irreducible positively recurrent Markov chain on the state space Ω with stationary distribution π . If $f: \Omega \rightarrow \mathbb{R}$ is π -summable (in the sense that $\sum_{\omega \in \Omega} |f(\omega)| \pi(\omega) < \infty$), then

$$\frac{1}{N} \sum_{i=1}^N f(X_i) \rightarrow \sum_{\omega \in \Omega} f(\omega)\pi(\omega) = E_{\pi}(f).$$

Notice that the ergodic theorem also yields $P(X_n = \omega) \rightarrow \pi(\omega)$ by considering f to be the characteristic function of $\{\omega\}$.

Of course, in practice, the rate of convergence is a critical issue.

Detail Balance

Let π be a distribution on Ω . A very important way of finding a Markov chain on Ω with transition matrix

P , which has invariant distribution π , is to ensure that the *detail balance* condition

$$\pi(x)P(y | x) = \pi(y)P(x | y), \quad \text{for all } x, y \in \Omega,$$

holds. It is easy to see that this condition is sufficient; simply sum both sides over all possible $x \in \Omega$ to get

$$\sum_x P(y | x)\pi(x) = \pi(y).$$

Markov chains that satisfy the detail balance condition are called *reversible* chains.

Metropolis Sampler

In 1953, Metropolis, Rosenbluth, Rosenbluth, Teller, and Teller published the paper “Equations of State Calculations by Fast Computing Machines,” thereby introducing to the world the incredibly useful Metropolis simulation algorithm. This algorithm has been cited as among the top 10 algorithms having the greatest influence on the development of science and engineering.

The basic idea, like many great ideas, is rather simple. Given a desired distribution π on Ω , we split the chain into a *proposal* phase and an *acceptance* phase (like rejection sampling). For the proposal phase, the Metropolis algorithm uses a symmetric irreducible Markov chain Q (so $Q(x | y) = Q(y | x)$). Given the current state x , we use Q to generate a new state y and accept y with probability

$$A(y | x) = \min \left\{ 1, \frac{\pi(y)}{\pi(x)} \right\}.$$

Thus, the transition matrix P for the Metropolis algorithm is a product of the form $P(y | x) = Q(y | x)A(y | x)$ for $y \neq x$ (the diagonal terms of P are forced by the fact that P is a transition matrix). From this, we see that (without loss of generality, $\pi(y) \leq \pi(x)$),

$$\begin{aligned} \pi(x)P(y | x) &= \pi(x)Q(y | x)\frac{\pi(y)}{\pi(x)} = \pi(y)Q(y | x) \\ &= \pi(y)Q(x | y) = \pi(y)P(x | y), \end{aligned}$$

so the Metropolis chain satisfies detail balance and has π as invariant distribution.

The Metropolis algorithm will produce many repeated states in the chain X_n . In computing expectations using this chain, it is important to keep these repeats because this is one way the algorithm corrects the bias from the proposal process, thus allowing it to converge to π .

The separation of the proposal and acceptance phases makes designing a chain much simpler, because the proposal process can be virtually any process. The choice of proposal process is often guided by the structure of the state space. The condition that Q be irreducible and symmetric is rarely much of a problem in practice. For Ω finite, the proposal process is often defined by first giving a local (symmetric) neighborhood structure and then choosing y uniformly from the neighbors of the current x , and the resulting Q is irreducible as long as the given neighborhood system is reasonable. We are free to let the structure of the problem guide the neighborhood system (or proposal process) and use the acceptance phase to correct the proposal process in such a way as to ensure the desired stationary distribution.

Another very important feature of the Metropolis algorithm is that one need know π only up to a multiplicative factor, because only ratios are used in computing the acceptance probability. This can be very important in situations where we want specific relative probabilities but the state space is too large or complicated to allow us to compute a normalizing constant. Optimization by simulated annealing is often such a situation.

Simulated Annealing for Global Optimization

Given an energy function E on the state space Ω and a temperature $T > 0$, the *Boltzmann distribution* is the probability distribution

$$\pi(x) = \frac{e^{-E(x)/T}}{Z_T},$$

where Z_T is a normalizing constant called the partition function. Clearly, this distribution peaks at the states with the lowest temperature, and this peaking becomes more pronounced as $T \rightarrow 0$. Given this fact, one way to find the minima of the energy E might be to try to lower the temperature in a controlled way (clearly, setting $T = 0$ won't work). This is the basic idea of simulated annealing.

Simulated annealing typically uses the Metropolis sampler, with corresponding acceptance

$$A(y | x) = \min\{1, e^{(E(y)-E(x))/T}\},$$

where we notice that the partition function has canceled out. This is a clear advantage to using the Metropolis algorithm, because the partition function is almost always impossible to compute.

The interpretation of the Metropolis acceptance in this context is that if the energy of the proposed state is smaller than the energy of the current state, we always accept the transition, whereas if the energy of the proposed state is greater than the energy of the current state, we accept the transition only with some probability that decreases to zero as T decreases to zero. Care must be taken in lowering the temperature that it is not lowered too quickly, or the process will “freeze.” Conceptually, one fixes the temperature at some level, allows the Markov chain to approach the Boltzmann distribution for that temperature, and then lowers the temperature. At lower temperatures, it takes longer for the Markov chain to converge to the Boltzmann distribution (for that temperature). In practice, one usually lowers the temperature on each iteration of the chain (so that the chain is a nonhomogeneous Markov chain with transition matrix depending on time), but following a very slow cooling schedule. Theoretical results indicate that a cooling schedule of the form

$$T = \frac{c}{\log(\text{iteration count})}$$

is sufficiently slow to guarantee convergence to the minimum energy states. Because this cooling schedule is incredibly slow, most actual simulated annealing algorithms use a faster cooling schedule.

Metropolis-Hastings

W. K. Hastings's 1970 paper generalized the work of Metropolis et al. and introduced the Metropolis-Hastings algorithm. This algorithm is the most frequently used algorithm in MCMC, and most of the other algorithms are instances or modifications of it.

The Metropolis-Hastings algorithm also splits the chain into a proposal and acceptance phase. However, the proposal process Q is not assumed to be symmetric, but it does have to satisfy $Q(x | y) > 0$ whenever $Q(y | x) > 0$ and be irreducible. This time, the acceptance probability is

$$A(y | x) = \frac{S(y | x)}{1 + \frac{\pi(x)Q(y|x)}{\pi(y)Q(x|y)}} = \frac{S(y | x)}{1 + T(y | x)},$$

where $S(y | x) = S(x | y)$ is any symmetric Markov kernel. Using these definitions it is easy to see that $P(y | x) = Q(y | x)A(y | x)$ satisfies detail balance for π . The advantages of the Metropolis-Hastings algorithm over the Metropolis algorithm are that Q need not be symmetric and the flexibility in choosing S .

Because $A(y | x) \in [0, 1]$, we must have that $S(y | x) \leq 1 + \min\{T(y | x), T(x | y)\}$. The Metropolis algorithm corresponds to the case of equality in this inequality. In fact, over the class of all possible Metropolis-Hastings transition matrices, the Metropolis algorithm has the maximum chance of accepting a move (so it minimizes the diagonal elements). A theorem of P. Peskun then implies that the asymptotic variance of the Metropolis algorithm is optimal (in the sense of being smallest) among the class of all Metropolis-Hastings chains with a fixed proposal process. Thus, even though the general Metropolis-Hastings algorithm gives more flexibility in the design of the chain, the Metropolis algorithm is, in some ways, optimal when it is feasible.

Another special case of the Metropolis-Hastings sampler is Barker's algorithm, where we choose $S(y | x) = 1$ and get the nice acceptance probability

$$A(y | x) = \frac{\pi(y)Q(y | x)}{\pi(x)Q(x | y) + \pi(y)Q(y | x)}.$$

Another useful modification to the generic Metropolis-Hastings sampler is the Langevin Metropolis-Hastings algorithm. The generic Metropolis-Hastings sampler uses the acceptance phase to correct the bias from the proposal process. This often results in many rejections and a slow convergence to π . Partly, this is due to the fact that the proposal process can be independent of π . The Langevin Metropolis-Hastings is motivated by a stochastic differential equation and introduces a bias into the proposal process that is influenced by the derivative of the density of π , which often speeds up the convergence.

Gibbs Sampler

The Gibbs sampler is especially designed for situations where X_n is multivariate and we can easily (or more easily) sample from the marginal distributions than from the full distribution. This is best explained by the following example.

Take a 10×10 grid with each site being in the state 0 or in the state 1 (see Figure 2 where we shade all 1 states). For each site, we consider the four adjacent sites (with wraparound for the edges) and count the number of neighbors in state 0. We want to have the marginal distributions given in Table 1. The problem is to sample a “random” 10×10 grid that has these local marginal distributions.

Figure 2 Simple Grid for Gibbs Sampler Example

Table 1 Marginal Distributions for Gibbs Sampler Example

# 0 neighbors	Prob. of being 0
0	.1
1	.3
2	.5
3	.7
4	.9

The Gibbs sampler solves this problem by the following steps in cycles. First, we randomly initialize the states in the grid, and then for each cycle do the following:

- Choose a (random) ordering of the grid points.
- For each grid point in turn in the order chosen, sample the value of the current grid point according to the distribution given by its four neighbors.

Sometimes, we keep a copy of the “old” grid around for the marginal draws and update the entire grid only at the end of the sample. It is also possible to simplify the algorithm by eliminating the cycles and randomly choosing a site to update at each iteration. These different choices shouldn’t affect the limiting distribution but might influence the speed of convergence. The grid in Figure 2 was generated using this model.

The Gibbs sampler can also incorporate a Metropolis or Metropolis-Hastings proposal/acceptance scheme.

Other Methods and Discussion

There are many variations on these basic samplers and other general Monte Carlo and MCMC algorithms. Among these, we mention the EM algorithm (an algorithm for ML and MAP point estimates), the Slice sampler (a generalized Gibbs sampler), Reversible Jump MCMC, and Sequential Monte Carlo.

A useful property of MCMC is the ability to combine several samplers. If P_1 and P_2 are transition kernels that both have π as an invariant distribution, then so do $\lambda P_1 + (1 - \lambda)P_2$ (for $0 \leq \lambda \leq 1$) and $P_1 P_2$. The

Gibbs sampler can be thought of as an example of the second kind of combination, where each factor changes only one component of X at a time.

Obtaining good estimates of the convergence rate is usually difficult but extremely useful. One major problem in running an MCMC simulation is the problem of how long is long enough. There is a large (and growing) literature on bounding the mixing rate of a Markov chain, and these estimates can give useful guidelines on the required length of a run. In simple cases, the running time is shown to be polynomial in the dimension of the state space.

A recent and very exciting development in MCMC is the existence of algorithms for perfect sampling. These completely answer the question of how long you need to run the MCMC chain. Two such algorithms are Coupling From the Past and Fill's Algorithm. Although they are limited to certain types of Markov chains, the class of possible chains is steadily growing, and in these instances, these algorithms guarantee a perfect draw from π . Essentially, these two algorithms provide a computable stopping criterion.

MATRIX ANALOGIES TEST

The Matrix Analogies Test (published by Harcourt Assessment) consists of two forms: the Matrix Analogies Test–Expanded Form (MAT-EF) and the Matrix Analogies Test–Short Form (MAT-SF). Stimulus items on both tests employ abstract designs of the standard progressive matrix type. The matrix design of the stimulus items of both the MAT-EF and the MAT-SF require minimal verbal comprehension and no verbal response on the part of the examinee.

The MAT-EF is an individually administered test of nonverbal reasoning ability designed for children and adolescents 5 to 17 years old. The MAT-EF is reported to be appropriate for assessing the abilities of children with learning disabilities, mental retardation, hearing or language impairments, physical disabilities, those who may speak more than one language, and those with the ability to perform at the gifted level. It may be used as a stand-alone measure or as part of a comprehensive battery of tests.

The MAT-EF is organized into four specific item groups (Pattern Completion, Reasoning by Analogy, Serial Reasoning, and Spatial Visualization). The author claimed that these item groups were developed based on the results of item factor analysis. The MAT-EF was designed in such a way as to reduce the effects of impaired color vision. The colors (blue, yellow, black, and white) were used in the stimulus materials to reduce the influence of impaired color vision.

When administering the MAT-EF, a maximum of 12 minutes is allowed for each item group. The MAT-EF yields an overall standard score ($M = 100$, $SD = 15$) and item-group standard scores ($M = 10$, $SD = 3$). The MAT-EF is reported to yield similar scores for boys and girls, whites and African Americans, and Hispanics and non-Hispanics. Additionally, research has shown that similar scores are obtained across samples from different countries.

The MAT-SF is a group-administered version of the MAT-EF that is also used to obtain a measure of nonverbal reasoning ability. The MAT-SF consists of 34 items. It yields stanines and percentile scores for the total test score. As with the MAT-EF, the MAT-SF requires minimal motor involvement and a minimal level of verbal comprehension. The MAT-SF is appropriate for use with the same age group as the MAT-EF. The primary use of the MAT-SF is as a quick screening device to help identify students who may be at risk and students who may be gifted and are performing above age expectations. The MAT-SF uses self-scoring answer sheets that eliminate the need for scoring keys and provide immediate results.

$$A = \begin{bmatrix} 0 & \frac{-3}{2} & 5 \\ 1 & -7 & 2 \end{bmatrix}, M = \begin{bmatrix} 3 & 2 \\ -\pi & 0 \\ 1 & 1 \end{bmatrix}, S = \begin{bmatrix} 2 & -1 & 3 & 0 \\ 0 & 2 & -1 & 3 \\ 3 & 0 & 2 & -1 \\ -1 & 3 & 0 & 2 \end{bmatrix}$$

Given an m by n matrix A , for each $i = 1, \dots, m$, and $j = 1, \dots, n$, the symbol a_{ij} denotes the entry of A in row i , column j .

For m by n matrices A and B , their sum, $A + B$, is the m by n matrix such that for all $i = 1, \dots, m$, $j = 1, \dots, n$, the entry in row i , column j is given by $a_{ij} + b_{ij}$. The sum of two matrices is defined only when both the number of rows and the number of columns of the summands agree. For example,

$$\begin{bmatrix} 0 & \frac{-3}{2} & 5 \\ 1 & -7 & 2 \end{bmatrix} + \begin{bmatrix} \frac{1}{2} & 1 & -3 \\ -2 & 6 & 0 \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & \frac{-1}{2} & 2 \\ -1 & -1 & 2 \end{bmatrix}.$$

For any m by n matrix A and any scalar x , the scalar multiple xA is the m by n matrix such that for all $i = 1, \dots, m$, $j = 1, \dots, n$, the entry in row i , column j is given by xa_{ij} . For example, if

$$A = \begin{bmatrix} 0 & \frac{-3}{2} & 5 \\ 1 & -7 & 2 \end{bmatrix}, \text{ then } -4A = \begin{bmatrix} 0 & 6 & -20 \\ -4 & 28 & -8 \end{bmatrix}.$$

MATRIX OPERATIONS

A matrix is a rectangular array of numbers, and is called m by n when it has m rows and n columns. Examples include the matrices A (which is 2 by 3), M (3 by 2), and S (4 by 4) below:

Addition and scalar multiplication can be combined for two m by n matrices A and B , so that the matrix $xA + yB$ has the entries $xa_{ij} + yb_{ij}$ for all $i = 1, \dots, m, j = 1, \dots, n$. Thus, if

$$A = \begin{bmatrix} 0 & \frac{-3}{2} & 5 \\ 1 & -7 & 2 \end{bmatrix} \text{ and } B = \begin{bmatrix} \frac{1}{2} & 1 & -3 \\ -2 & 6 & 0 \end{bmatrix}, \text{ then } 3A - 2B = \begin{bmatrix} -1 & \frac{-13}{2} & 21 \\ 7 & -33 & 6 \end{bmatrix}.$$

For an m by n matrix U and an n by k matrix V , the matrix product UV is the m by k matrix such that for each $i = 1, \dots, m, j = 1, \dots, k$, the entry in row i , column j of UV is given by $\sum_{p=1}^n u_{ip}v_{pj}$. The matrix product UV is defined only when the number of columns of U agrees with the number of rows of V . For example, if

$$U = \begin{bmatrix} 1 & -1 & 2 \\ 3 & 0 & 1 \end{bmatrix}, V = \begin{bmatrix} 2 & -1 \\ -3 & 4 \\ 0 & -2 \end{bmatrix}, \text{ then } UV = \begin{bmatrix} 5 & -9 \\ 6 & -5 \end{bmatrix} \text{ whereas } VU = \begin{bmatrix} -1 & -2 & 3 \\ 9 & 3 & -2 \\ -6 & 0 & -2 \end{bmatrix}.$$

If a matrix S has an equal number of rows and columns, we say that S is square. Given a square matrix S , for each natural number k , the k th power of S , denoted S^k , is the k -fold product of S with itself. For example, if

$$S = \begin{bmatrix} 0 & 1 & 0 \\ -1 & 1 & 1 \\ -1 & 0 & 2 \end{bmatrix}, \text{ then } S^2 = \begin{bmatrix} -1 & 1 & 1 \\ -2 & 0 & 3 \\ -2 & -1 & 4 \end{bmatrix}, \text{ and } S^3 = \begin{bmatrix} -2 & 0 & 3 \\ -3 & -2 & 6 \\ -3 & -3 & 7 \end{bmatrix}.$$

For each natural number n , the identity matrix of order n , denoted by I_n , is the n by n matrix with diagonal entries equal to 1 and all other entries equal to 0. For example,

$$I_3 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

For any m by n matrix A and any n by k matrix B , we have $AI_n = A$ and $I_n B = B$. Given an n by n matrix S , we say that S is invertible if there is an n by n matrix T such that $ST = I_n$ and $TS = I_n$. If such a T exists, it is the inverse of S and is denoted by S^{-1} . For any natural number k , the k -fold product of S^{-1} with itself is denoted S^{-k} . For each natural number k , we have $(S^k)^{-1} = S^{-k}$. For example if

$$S = \begin{bmatrix} 0 & 1 & 0 \\ -1 & 1 & 1 \\ -1 & 0 & 2 \end{bmatrix}, \text{ then } S^{-1} = \begin{bmatrix} 2 & -2 & 1 \\ 1 & 0 & 0 \\ 1 & -1 & 1 \end{bmatrix} \text{ and } S^{-2} = \begin{bmatrix} 3 & -5 & 3 \\ 2 & -2 & 1 \\ 2 & -3 & 2 \end{bmatrix}.$$

Because of their computational utility and well-developed theory, matrices arise throughout the mathematical sciences and have numerous applications in science and engineering.

MAXIMUM LIKELIHOOD METHOD

The maximum likelihood method is applicable to any scientific problem in which it is desired that unknown or unobservable quantities, called *parameters*, be estimated based on observed data. Thus, maximum

likelihood is a method of solving the statistical problem of *estimation*.

Under the maximum likelihood principle, a parameter is estimated by the value that maximizes the likelihood of the observed data. In other words, the maximum likelihood estimate (MLE) of a parameter is the value that gives the observed data the highest probability possible. Depending on the complexity of the underlying model, MLEs may be solvable by elementary calculus, or they may require sophisticated computational methods. The former instance is illustrated in the following example.

In a survey of 6,000 randomly selected U.S. high school students, 2,166 knew that Geoffrey Chaucer wrote *The Canterbury Tales*. What is the MLE for the percentages of *all* U.S. high school students who know this fact?

Let n denote the number of subjects surveyed, and X the number who knew the correct answer. Let p denote the proportion of all U.S. high school students who know the answer. The sample size n and population percentage p are fixed quantities, or parameters, the former known and the latter unknown. The observed quantity X is a random variable—it can assume any integer value between 0 and n , depending on the result of the random sample—and follows the binomial distribution. For any realizable value x , the probability is given by

$$\Pr(X = x) = \frac{n!}{x!(n - x)!} p^x (1 - p)^{n-x}, \quad (1)$$

where $k! = k(k - 1) \dots 2 \cdot 1$ for any integer k .

The MLE of p , denoted by \hat{p} , is the number between 0 and 1 that maximizes the value of Equation 1. In Equation 1, the quantity p is held fixed, and a probability is evaluated for any possible value of x from 0 to n . The method of maximum likelihood involves fixing x at the observed value and considering Equation 1 a function of the unknown success probability p . Consider the Chaucer question. Based on the results of the survey, the values $p = 0$ and $p = 1$ can be eliminated, but any number between 0 and 1 remains a possibility. Here, $n = 6,000$ and $x = 2,166$; the probability of the observed result is given as follows for selected values of p .

p	$\Pr(X = 2166)$ where $X \sim \text{Binomial}(6000, p)$
.35	.00219
.36	.01058
.37	.00377

This probability is maximized at $p = .361$. More generally, elementary calculus will show that the MLE is given by $\hat{p} = x/n$; hence, the MLE of the population percentage is just the sample percentage. Thus, by the maximum likelihood method, it is estimated that 36.1% of students know that Chaucer wrote *The Canterbury Tales*.

Of course, few problems admit such straightforward solutions. Indeed, the development of efficient algorithms for finding MLEs is an active area of research.

MCNEMAR TEST FOR SIGNIFICANCE OF CHANGES

It is often of interest to examine changes in the dichotomous categorical responses taken from subjects before and then after some treatment condition is imposed (i.e., evaluating repeated measurements of the same subjects using them as their own controls). In 1947, the psychologist Quinn McNemar developed a simple and valuable technique for comparing differences between the proportions in the responses before and after. McNemar’s procedure is the categorical

data counterpart of the *t* test for the mean difference in matched, paired, or related samples.

McNemar’s procedure has enjoyed widespread usage in both behavioral and medical research and some attention in business, particularly with applications in advertising or marketing research, wherein it may be desirable to evaluate the significance of changes in attitudes and opinions.

Development

The dichotomous responses from a sample of *n*’ individuals over two periods of time may be tallied into a 2 × 2 table of cross-classifications as follows:

With respect to the population from which the aforementioned sample was taken, let *p*_{*ij*} be the probability of responses to the *i*th category before the treatment condition was imposed and the *j*th category after. The pairs of marginal probabilities before and after treatment sum to unity; that is, *p*_{1·} + *p*_{2·} = 1 and *p*_{·1} + *p*_{·2} = 1.

Table 1 2 × 2 Table of Cross-Classifications for a Sample of *n*’ Subjects

		+	–	<i>Totals</i>
<i>I</i>		<i>x</i> ₁₁	<i>x</i> ₁₂	<i>x</i> ₁
		<i>x</i> ₂₁	<i>x</i> ₂₂	<i>x</i> ₂
	<i>Totals</i>	<i>x</i> _{·1}	<i>x</i> _{·2}	<i>n</i> ’

where

- I = Time period I (before treatment) in a repeated measurements experiment
- II = Time period II (after treatment) in a repeated measurements experiment
- + = positive classification
- = negative classification
- x*₁₁ = number of subjects with a positive response both before and after treatment
- x*₁₂ = number of subjects with a positive response before treatment and a negative response after treatment
- x*₂₁ = number of subjects with a negative response before treatment and a positive response after treatment
- x*₂₂ = number of subjects with a negative response both before and after treatment
- n*’ = sample size

Testing for Significance of Changes in Related Proportions

In order to investigate changes in repeated dichotomous measurements, the null hypothesis is that of symmetry:

$$H_0: p_{ij} = p_{ji} \text{ for } i \neq j.$$

That is, the null hypothesis tested is conditioned on those *n* = *x*₁₂ + *x*₂₁ individuals whose responses change, where the probability (*p*₂₁) of a switch to a more favorable position is equal to the probability (*p*₁₂) of a switch to a less favorable position, and that this probability is 0.5.

Under the null hypothesis the random variable *x*₁₂ is binomially distributed with parameters *n* and 0.5, as is the random variable *x*₂₁. The expected value of each of these binomial distributions is 0.5*n*, and the variance for each is 0.25*n*. McNemar’s procedure enables an exact test of the null hypothesis using the binomial probability distribution with parameters *n* and *p* = 0.5.

The McNemar test statistic *M*, written as Min[*x*₁₂, *x*₂₁], is defined as the minimum of the response tallies *x*₁₂ or *x*₂₁ in the cross-classification table.

For a two-tailed test, the null hypothesis can be rejected at the α level of significance if

$$P(M \leq \text{Min}[x_{12}, x_{21}] | n \text{ and } p_{12} = p_{21} = 0.5) = \sum_{M=0}^{\text{Min}[x_{12}, x_{21}]} \frac{n!}{M!(n - M)!} (0.5)^n \leq \alpha/2.$$

For a one-tailed test, the null hypothesis may be rejected if

$$P(M \leq \text{Min}[x_{12}, x_{21}] | n \text{ and } p_{12} = p_{21} = 0.5) = \sum_{M=0}^{\text{Min}[x_{12}, x_{21}]} \frac{n!}{M!(n - M)!} (0.5)^n \leq \alpha.$$

Using Microsoft Excel’s BINOMDIST function, exact *p* values of the McNemar test are obtained for all *n* ≤ 1,000.

For studies where $n > 1,000$ a simple normal approximation formula for the test statistic M is given by

$$Z = \frac{M - 0.5n}{0.5\sqrt{n}},$$

where $Z = N(0,1)$, the standardized normal distribution. The decision rule for testing the null hypothesis ($H_0: p_{ij} = p_{ji}$ for $i \neq j$) depends on whether the test is two-tailed or one-tailed. Based on its definition, M cannot exceed $0.5n$, so the test statistic Z can be rejected only in the left tail of a standardized normal distribution. For a two-tailed test against the alternative $H_1: p_{ij} \neq p_{ji}$, the decision rule is to reject H_0 if $Z \leq Z_{\alpha/2}$. For a one-tailed test, the decision rule is to reject H_0 if $Z \leq Z_{\alpha}$.

Applying the McNemar Procedure

The following hypothetical example is presented: Suppose a consumer panel of $n' = 500$ participants is selected, and the panel members are initially asked to state their preferences for two competing Internet service providers, say, AOL versus EarthLink. Suppose 290 panelists initially say they prefer AOL. After exposing the entire panel to a newly designed advertisement as part of some intensive marketing campaign strategy for EarthLink, the same 500 panelists are again asked to state their preferences. Suppose that of the 290 panelists who previously preferred AOL, 260 maintain their brand loyalty but 30 switch to EarthLink. Moreover, suppose that of the 210 panelists who initially preferred EarthLink, 200 remain

Table 2 Hypothetical Results of a Marketing Campaign

<i>Before \ After</i>	<i>EarthLink</i>	<i>AOL</i>	<i>Totals</i>
<i>EarthLink</i>	$x_{11} = 200$	$x_{12} = 10$	$x_{1.} = 210$
<i>AOL</i>	$x_{21} = 30$	$x_{22} = 260$	$x_{2.} = 290$
<i>Totals</i>	$x_{.1} = 230$	$x_{.2} = 270$	$n' = 500$

brand loyal but 10 switch to AOL. The results are displayed in Table 2.

To test the null hypothesis of symmetry

$$H_0: p_{ij} = p_{ji} \text{ for } i \neq j$$

(that is, the marketing campaign strategy has no effect—Internet users are just as likely to shift their preference from AOL to EarthLink as they are to switch from EarthLink to AOL), it may be tested against the two-tailed alternative

$$H_1: p_{ij} \neq p_{ji}$$

(that is, exposure to the advertisement does influence one’s disposition to switch from one Internet service provider to the other).

For these data, the McNemar procedure enables an exact test of the null hypothesis using the binomial probability distribution with parameters $n = x_{12} + x_{21} = 40$ and $p = 0.5$ and with a stated level of significance $\alpha/2$ in each tail. For a two-tailed test, the McNemar test statistic M —defined here as 10, or the minimum of the response tallies x_{12} and x_{21} from the cross-classification table—can be rejected at the $\alpha = 0.05$ level of significance if

$$P(M \leq 10 | n = 40 \text{ and } p_{12} = p_{21} = 0.5) \leq 0.025.$$

Using Microsoft Excel’s BINOMDIST,

$$\begin{aligned} P(M \leq 10 | n = 40 \text{ and } p_{12} = p_{21} = 0.5) \\ &= \sum_{M=0}^{10} \frac{40!}{M!(40 - M)!} (0.5)^{40} = 0.00111 < \alpha/2 \\ &= 0.025. \end{aligned}$$

Thus, the null hypothesis is rejected. The p value is 0.00222. The advertisement significantly increased EarthLink’s market share at the expense of its arch rival AOL.

Had Microsoft Excel not been readily available, the normal approximation formula could have been employed. For these data,

$$Z = \frac{M - 0.5n}{0.5\sqrt{n}} = \frac{10 - 20}{0.5\sqrt{40}} = -3.16.$$

For a two-tailed test at the α level of significance, H_0 is rejected if $Z \leq Z_{\frac{\alpha}{2}}$. Using the traditional .05 level of significance, because $Z = -3.16 < Z_{0.025} = -1.96$, H_0 is rejected, and it is concluded that the advertisement significantly influenced Internet provider preference. A significantly greater number of users switched to EarthLink from AOL than switched from EarthLink to AOL. The p value, or size of this test, is approximated to be 0.00158, a highly significant result, but more liberal than the exact p value obtained from the binomial distribution, 0.00222.

Discussion

Testing for Matched or Paired Differences in Proportions

The McNemar test may also be used to compare differences in the dichotomous categorical responses from a set of matched or paired subjects when one member of each pair is exposed to a particular treatment condition and the other member to a different treatment condition. The null hypothesis of equality of marginal probability distributions

$$H_0: p_i = p_{.i} \text{ for } i = 1, 2$$

is equivalent to testing the hypothesis of symmetry in the 2×2 table of cross-classifications. If $p_{11} = p_{21}$, then $p_{11} + p_{12} = p_{11} + p_{21}$ so that $p_{12} = p_{21}$ (i.e., symmetry).

Using Directional or Nondirectional Tests

Aside from justification through ethical arguments, biostatistician Joseph Fleiss proposed that a two-tailed test be used in lieu of a one-tailed test "in the vast majority of research undertakings . . . to guard against the unexpected." In the hypothetical application presented here, if the advertisement copy is seen by the user as effective, EarthLink would be expected to gain market share at the expense of AOL. However, if the advertisement is deemed unrealistic, the strategy may backfire and EarthLink could lose market share to AOL.

Forming McNemar's Confidence Interval Estimate

A $(1 - \alpha)\%$ confidence interval estimate of the differences in related population proportions ($p_{.1} - p_{1.}$) was given by Marascuilo and McSweeney as

$$(\hat{p}_{.1} - \hat{p}_{1.}) \pm Z_{1-\frac{\alpha}{2}} \sqrt{\frac{\hat{p}_{.1}\hat{p}_{.2}}{n'} + \frac{\hat{p}_{1.}\hat{p}_{2.}}{n'} - \frac{2(\hat{p}_{11} - \hat{p}_{1.}\hat{p}_{1.})}{n'}}$$

where $\hat{p}_{.1}$, $\hat{p}_{1.}$, $\hat{p}_{.2}$, $\hat{p}_{2.}$ are the estimators of the respective parameters, $p_{.1}$, $p_{1.}$, $p_{.2}$, $p_{2.}$.

To form a 95% confidence interval estimate of the differences in related population proportions ($p_{.1} - p_{1.}$), representing increase in support for EarthLink over AOL following an intense marketing campaign, the estimates from the hypothetical data in Table 2 are summarized as follows:

<i>Before Marketing Campaign</i>	<i>After Marketing Campaign</i>
EarthLink: $\hat{p}_{.1} = \frac{210}{500} = 0.42$	$\hat{p}_{1.} = \frac{230}{500} = 0.46$
AOL: $\hat{p}_{.2} = \frac{290}{500} = 0.58$	$\hat{p}_{2.} = \frac{270}{500} = 0.54$

For these data

$$(0.46 - 0.42)$$

$$\pm 1.96 \sqrt{\frac{(0.46)(0.54)}{500} + \frac{(0.42)(0.58)}{500} - \frac{2[(0.40) - (0.46)(0.42)]}{500}}$$

and

$$0.016 \leq (p_{.1} - p_{1.}) \leq .065$$

It can be concluded with 95% confidence that the gain in support for EarthLink at the expense of AOL as a result of the marketing campaign is between 1.6% and 6.5%.

Comments

It is essential to a good data analysis that the appropriate statistical procedure be applied to a specific situation. When comparing differences in two proportions based on related samples, the McNemar test

should always be used. Failure to do so will often lead to erroneous conclusions. A researcher unaware of the magnitude of the correlated proportions that are accounted for in the standard error term shown in the McNemar confidence interval formula may erroneously treat the paired responses as independent and thus inflate the standard error, causing a loss of precision in the confidence interval estimate or a loss in statistical power when testing inappropriately for differences in the two proportions.

The pedagogical advantage to the confidence interval approach to McNemar's procedure over the significance testing approach derives from the fact that the former makes use of all 500 repeated responses, whereas the corresponding hypothesis test statistic is conditioned on the reduced set that contains only the brand-switching panelists off the main diagonal of the cross-classifications table; the fact that the test statistic discards the brand-loyal panelists unaffected by the advertisement is not palatable to some researchers. On the other hand, the major advantage of the hypothesis test procedure over the confidence interval is its inherent simplicity, be it using the binomial probability distribution for an exact test result or the quick and easy normal approximation formula for an approximate test result.

Conclusions

The McNemar procedure is quick and easy to perform. The only assumption is that the outcome of each response is categorized into a dichotomy. For studies involving multichotomous categorical responses, an extension developed by the statistician Albert Bowker may be employed if the objective is to evaluate patterns of symmetry in the changes in response.

When evaluating the worth of a statistical procedure, famed statistician John Tukey defined "practical power" as the product of statistical power and the utility of the statistical technique. Based on this, the McNemar test enjoys a high level of practical power.

MEAN

Of all the measures of central tendency, the mean is the most often used and can be defined in a variety of ways. It can be defined as the sum of all the scores in a data set divided by the number of observations, and can also be defined as the point about which the sum of the deviations is equal to zero.

The formula for the computation of the mean is as follows:

$$\bar{X} = \frac{\sum X}{n},$$

where

\bar{X} (also called "X bar") is the mean value of the group of scores or the mean;

Σ (sigma) is the summation sign, which directs you to add together what follows it;

X is each individual score in the group of scores;

n is the size of the sample from which you are computing the mean.

Table 1 Sample Data for Computation of the Mean

For example, the data set in Table 1 consists of 25 cases with two variables, Test Score 1 and Test Score 2.

To compute the mean, follow these steps:

1. List the entire set of values in one or more columns such as you see in the table. These are all the *X*s.
2. Compute the sum or total of all the values.
3. Divide the total or sum by the number of values.

Applying the above formula to the sample data results in the following two means:

$$X_{Test1} = \frac{162}{25} = 6.48$$

$$X_{Test2} = \frac{589}{25} = 23.56$$

The mean is sometimes represented by the letter *M* and is also called the typical, average, or most central score.

More About the Mean

In the formula, a small *n* represents the sample size for which the mean is being computed. A large *N* represents the population size.

- The sample mean is the measure of central tendency that most accurately reflects the population mean.
- The mean is like the fulcrum on a seesaw. It's the centermost point where all the values on one side of the mean are equal in weight to all the values on the other side of the mean.
- The mean is very sensitive to extreme scores. An extreme score can pull the mean in one direction or another and make it less representative of the set of scores and less useful as a measure of central tendency.

MEASUREMENT

It seems reasonable to expect that within the context of the *Encyclopedia of Measurement and Statistics*, one of the first questions that a reader might ask himself or herself would be, “What is the relationship between measurement and statistics?” Are these two terms synonymous, or is a distinction implied? Because the title of this encyclopedia uses both terms, perhaps we should attempt to understand the distinction between these two concepts. And perhaps it is for this reason that you have found yourself looking up the definition of measurement within this very volume.

Historical Perspectives on Measurement

For some, measurement is simply a tool of statistics, a necessary predecessor. We cannot perform statistical analyses if we have not measured anything. Consequently, some would say that measurement is simply the handmaiden of statistics. They might be inclined to take the point of view of S. S. Stevens, who defined measurement as “the assignment of numerals to objects or events according to a rule.” Stevens went on to propose four scales of measurement: nominal, ordinal, interval, and ratio.

Nominal scales are made up of variables with levels that are qualitatively different from one another. For example, consider the variable “ethnic background.” This variable could consist of any number of levels, but for the purposes of this example, let us consider just a few possibilities. A participant might report being Asian, African American, Latino, or Native American. Each of these different levels of the ethnic background variable represents a qualitatively different category. More specifically, each category is mutually exclusive of the others.

A second scale of measurement is an ordinal scale. Within the context of ordinal scales, the researcher is typically interested in knowing something about the rank order of the levels of the variable; however, there is no implication that these levels differ by any fixed

amount. Perhaps the classic example of ordinal-level measurement is found in the Olympic Games, where athletes receiving medals are ranked from 1st to 3rd place. It does not matter whether the gold medalist beat the silver medalist to the finish line by a fraction of a second or by 10 minutes. What matters is the order in which the athletes reached the finish line. The first one to cross the finish line receives a ranking of 1, and the second one across receives a ranking of 2. The assumption within an ordinal scale of measurement is that the fundamental quantity of interest is the relative placement and not the absolute difference between points on the scale. Another practical example of an ordinal scale of measurement would be the percentile ranking a student receives on an examination.

A third scale of measurement proposed by Stevens is the interval scale. Interval scales of measurement have several useful properties. For example, the difference between any two points on the scale is always the same. This is not always true within the context of an ordinal scale (e.g., percentile rankings). It is important to note, however, that interval scales do not have a true zero point—that is, a zero does not necessarily imply the complete absence of the construct of interest. Consider, for example, the measurement of intelligence. A person may receive a score of zero on a particular intelligence test if he or she answered all items incorrectly. Even if a person were to answer incorrectly every item on the test and receive a score of zero, this does not imply that the person has absolutely no intelligence. His or her intelligence was simply not captured by the items on that particular test (e.g., consider a Western intelligence test that is administered to participants from a very different culture).

By contrast, consider an example from the fourth scale of measurement, the ratio scale. Height is on a ratio scale, which is to say, there is a true zero point. Nothing exists that has a height of zero. A height of zero implies a total lack of the construct (i.e., absolutely no height). Other examples of ratio scales include temperature and weight. Besides retaining the desirable properties of the interval-level scale in which the difference between any points on the scale

is the same regardless of the placement on the continuum, the ratio-level scale has the desirable property of having a meaningful zero point. Most inferential statistical techniques assume that variables are measured at least on an interval-level scale, with the ideal being a ratio scale.

Modern Perspectives on Measurement

Although Stevens's definition of measurement and the corresponding four scales of measurement he set out continue to enjoy the limelight in the field of psychology as the popular conception of measurement, these ideas do not reign supreme. Modern theorists have suggested that measurement is not simply an operation that is performed on data in order to prepare them for statistical analysis. Rather, measurement and statistics themselves are fundamentally different concepts with different assumptions and different implications, as well as different rules about how best to approach analysis and interpretation.

Within such an alternative framework, the fundamental distinction between measurement and statistics is that in measurement, the researcher starts out with a predefined theoretical model of how the world looks. The researcher then collects some data and performs statistical tests to see whether the data fit the theoretical expectations of the theoretical model. If the data do not fit the model, then there are two options: (a) the data are bad, or (b) the theoretical model needs to be revised. By contrast, within the context of statistics, the researcher starts by gathering data related to a construct of interest and then attempts to use statistics to build a model that fits, or best explains, the patterns observed in the data.

Notice that these are radically different approaches to data analysis. Within the context of measurement, the theoretical models are falsifiable, which is a highly desirable property. Within the context of statistics, data analytic tools are used to help develop a theory about why the world (and the data) is (or are) a certain way. Michell outlines many of the limitations of psychological measurement in general when one

takes this latter atheoretical perspective. He argues that it is often assumed without evaluation that the measures used to develop and validate theories have quantitative structure. The implication is that when the measurement properties of the scores are unknown, the appropriateness of the conclusions is also unknown.

Unfortunately, the covert nature of the constructs in educational and psychological research means that it is very unlikely that a situation would exist where quantitative measurement can be assessed directly. In its stead, Michell advocates the work of Luce and Tukey on additive conjoint measurement as a means of assessing quantity indirectly. Conjoint measurement is concerned with the way the *ordering* of a dependent variable varies with the joint effect of two or more independent variables. For example, assume that C (complexity) represents the ordering of differences in task complexity, and that I (intelligence) represents the ordering of differences in intelligence (note that only ordering is assumed here). The dependent variable, P (performance), represents performance on an appropriate measure along which the effect of C and I is assessed. Therefore, the ordering of C and I is necessarily dependent upon the order of P. That is, their orders are relative to their effect on P, and if appropriate conditions hold, the variables C and I are quantified relative to their effects on P. Michell outlines the sufficient experimental conditions that satisfy conjoint measurement and therefore presents one approach for testing the presence of interval measurement.

The strongest advocates of the additivity concept of measurement within contemporary psychometrics are associated with the field of Rasch measurement. Wright, and Bond and Fox, have argued that there are at least two properties of the Rasch model central to fundamental measurement. The first is that the Rasch model tests the core assumption of conjoint additivity. The second property of the Rasch model essential to pure measurement is specific objectivity. Specific objectivity occurs when (a) estimates of the person's trait level (e.g., ability) are freed from the effects of the actual items

attempted, and (b) estimates of item difficulty are freed from the effects of the particular sample of people who answered the items. Sample-free estimates of test characteristics are important if one wants to generalize interpretations of measurements beyond the sample on which the test was developed. Specific objectivity is a function of the unique mathematical characteristics of the Rasch measurement model and is not present in other item response theory models.

In summary, Michell argues that fundamental measurement requires the presence of an additive structure in the data. Raw scores (i.e., numbers that are assigned to objects according to rules) may or may not represent interval (additive) levels of measurement, and the assumption that they do must be tested. Bond and Fox argue that most often, by simply following the assignment of numbers to objects according to rules—the dominant but naïve view of measurement inculcated by Stevens—the researcher is left with a score that is at best measured at the ordinal level. Unfortunately, researchers almost invariably then treat this score as if it represented interval-level measurement (a typical requirement for subsequent statistical analyses) without recognizing that there is a way to empirically test the assumption of additivity via the Rasch measurement model (or using the procedures advocated by Michell). Assuming that variables are measured at an interval level and summing them to create a composite score will potentially lead to invalid and misleading results. That is, interpretation of the statistics applied to the analysis of test scores, no matter how carefully constructed the test is, will be qualified to the extent that the scores deviate from an interval scale measure. Rather than simply assuming additivity, we are obliged to test the limits of this assumption before applying our statistics.

Conclusion

Measurement and statistics represent fundamentally different approaches to analysis. Measurement is concerned with examining the extent to which data fit a model, and statistics is concerned with building a

model to fit the data. But the concepts of measurement and statistics do have a symbiotic relationship. At best, when fundamental measurement is achieved, the researcher is able to develop a set of variables that meets the strict assumptions of her or his preferred theoretical model. When this kind of pure measurement is achieved, the researcher is then in a position to use various statistical techniques to analyze the data and will be in a strong position to contribute valid, replicable findings to the research community.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Essex, C., & Smythe, W. E. (1999). Between numbers and notions: A critique of psychological measurement. *Theory & Psychology, 9*(6), 739–767.

When certain mathematical machinery is applied to ideas from psychology or education, that machinery imposes certain requirements in the relationship between numbers and notions. The result can be a theory-neutral approach to research, where commitments in response to the options are made unknowingly, thus becoming instead a theory-by-default endeavor. This paper catalogs some of these mathematical choices to help make theoretical commitments more explicit.

MEASUREMENT ERROR

Measurement error can be described as the variability in measurements of the same quantity on the same item. These errors occur for a variety of reasons, including inadequate survey design, sampling variability, inherent biological variation, and laboratory error analysis. Measurement error is often classified into two broad categories: random error and systematic error.

Random error refers to any random influence on the measurement of a variable. Consider, for example, a person whose weight is taken at a hospital. If two different nurses see the patient, they may not record the same weight, or if the same nurse takes two measurements only minutes apart, different eye positions may cause different scale readings. There is no discernible pattern, so the measurement may be higher or lower than the true value. Therefore, the sum of all random error in a series of measurements on the same variable should, in theory, equal zero. Thus, random error does not strongly influence the average value of the measurement. This type of error is sometimes referred to as noise.

Systematic error causes measurements to be consistently higher or lower. For example, suppose that the scale used to weigh patients consistently

shows readings that are five pounds heavier than the true value. This suggests that the scale should be recalibrated. Systematic errors can be minimized or completely eliminated by the use of careful planning in an experiment. This type of error is commonly referred to as bias.

The statistical models and methods for analyzing data measured with error are called measurement error models. A typical problem in statistics is to determine the linear relationship between two quantitative variables, say, X and Y , in order to use X to explain or predict Y . In this case, we assume that X cannot be observed, and a substitute variable W is used. Often, we write $W = X + U$, where U is the measurement error. One problem of interest is how the linear relationship between W and Y differs from the relationship between X and Y . It can be shown that the best-fitting line that relates W to Y is biased toward zero. Thus, using W as a substitute restricts one's ability to accurately assess the true linear relationship between X and Y . Various techniques have been developed to correct for such problems.

It is difficult to completely avoid measurement error; however, one can take several steps to reduce it. First, make sure that any instruments used are tested initially, monitored over time, and recalibrated as needed. Second, if possible, use only one instrument or set of instruments to do all of the measuring in an experiment. Third, use statistical methods that account for the presence of measurement error when analyzing data. Finally, take repeated measurements on the same variable.

MEASURES OF CENTRAL TENDENCY

Measures of central tendency are measures of the location of the center or middle of a distribution. However, the definition of “center” or “middle” is deliberately left broad, such that the term *central tendency* can refer to a wide variety of measures. The three most common measures of central tendency are the mode, the mean, and the median.

Mode

The mode for a collection of data values is the data value that occurs most frequently (if there is one). Suppose the average number of colds in a family of six in a calendar year is as presented in Table 1.

Then, the mode is 1 because more family members (i.e., $n = 2$) caught one cold than any other number of colds. Thus, 1 is the most frequently occurring value. If two values occur the same number of times and more often than the others, then the data set is said to be bimodal. The data set is multimodal if there are more than two values that occur with the same greatest frequency. The mode is applicable to qualitative as well as quantitative data.

With continuous data, such as the time patients spend waiting at a particular doctor’s office, which can be measured to many decimals, the frequency of each value is most commonly 1 because no two scores will be identical. Consequently, for continuous data, the mode typically is computed from a grouped frequency distribution. The grouped frequency distribution in Table 2 shows a grouped frequency distribution for the waiting times of 20 patients. Because the

interval with the highest frequency is 30 – <40 minutes, the mode is the middle of that interval (i.e., 35 minutes).

Mean

Arithmetic Mean

The *arithmetic mean*, or average, is the most common measure of central tendency. Given a collection of data values, the mean of these data is simply the arithmetic average of these data values. That is, the mean is the sum of observations divided by the number of observations. If we use the following notation:

- x is the variable for which we have data (e.g, test scores),
- n is the number of sample observations (sample size),
- x_1 is the first sample observation (first test score),
- x_2 is the second sample observation (second test score),
- x_n is the n th (last) sample observation (last test score),

then the sample mean of a sample x_1, x_2, \dots, x_n is denoted by

$$\bar{x} = \frac{x_1 + x_2 + \dots + x_n}{n} = \frac{\sum x}{n}.$$

To find the average number of colds in the family presented earlier, we compute

$$\bar{x} = \frac{5 + 4 + 1 + 2 + 1 + 3}{6} = \frac{16}{6} = 2.67.$$

The arithmetic mean is not the only “mean” available. Indeed, there is another kind of mean that is called the geometric mean, which is explained below. However, the arithmetic mean is by far the most commonly used. Consequently, when the term *mean* is used, one can assume that it is the arithmetic mean.

Weighted Mean

The weighted mean of a set of measurements x_1, x_2, \dots, x_n with relative weights w_1, w_2, \dots, w_n is given by

$$\bar{x} = \frac{\sum xw}{\sum w}$$

The weighted mean has many applications. In effect, it is used to approximate the mean of data grouped in a frequency distribution. In order to approximate the mean waiting time of the 20 patients presented above, the class mark is used to represent the waiting time of each person falling within that class. A weighted mean is then calculated, where the x s are the class marks and the weights are the corresponding class frequencies, as in Table 3.

$$\begin{aligned} \bar{x} &= \frac{\sum xw}{\sum w} \\ &= \frac{670}{20} = 33.5 \end{aligned}$$

Thus, the weighted mean is 33.5 minutes. The mean has two important properties. First, the sum of the deviations of all scores in the distribution from the mean is zero. Second, the sum of squares of deviations about the mean is smaller than the sum of

squares of deviations about any other value. Consequently, the mean is the measure of central tendency in the *least squares* sense inasmuch as the sum of the squared deviations is a minimum.

Trimean

The trimean is another measure of central tendency. It is computed by adding the 25th percentile plus twice the 50th percentile plus the 75th percentile, and then dividing by four. The 25th, 50th, and 75th percentile of the cold data set is 1, 2.5, and 4.25, respectively. Therefore, the trimean is computed as

$$\frac{1 + (2 \times 2.5) + 4.25}{4} = 2.56.$$

The trimean value of 2.56 is close to the arithmetic mean value of 2.67. The trimean has logical appeal as a measure of central tendency. However, it is rarely used.

Trimmed Mean

The trimmed mean is computed by discarding a certain percentage of the lowest and the highest scores in a ranked (i.e., ordered) set of data and then computing the mean of the remaining scores. For example, a mean trimmed 50% is computed by discarding the highest and lowest 25% of the scores and taking the mean of the remaining scores. The mean trimmed 0% provides the arithmetic mean. Trimmed means are used in certain sporting events (e.g., ice skating, gymnastics) to judge competitors’ levels of performance and to prevent the effects of extreme ratings possibly caused by biased judges. Before scores are discarded, the analyst must first rank the data. For the cold data, the mean trimmed 33% would result in the highest value (i.e., 5) and lowest value (i.e., 1) being discarded, resulting in the following trimmed mean:

$$\bar{x} = \frac{1 + 2 + 3 + 4}{4} = \frac{10}{4} = 2.5.$$

Geometric Mean

The geometric mean of n numbers is obtained by multiplying all of them together, and then taking the

Table 3 Computation of Weighted Mean

0 – <10	5	2	10

60 – <70	65	1	65

n th root of them. In other words, the geometric mean is the n th root of the product of the n scores in the dataset. Thus, the geometric mean of the cold data—5, 4, 1, 2, 1, and 3—is the sixth root of $5 \times 4 \times 1 \times 2 \times 1 \times 3$, which is the sixth root of 120 (because there are six numbers), which equals 2.22. The formula can be written as

$$\text{Geometric mean} = (\Pi X)^{1/n},$$

where ΠX means to take the product of all the values of X , and the superscript value (i.e., $1/n$) indicates the n th root. The geometric mean can also be computed by

1. computing the logarithm of each number,
2. computing the arithmetic mean of the logarithms,
3. raising the base used to take the logarithms to the arithmetic mean.

Thus, if the natural logarithm (i.e., Ln) is used, then raising this base would necessitate use of the exponent. For the cold data, the computation would be as in Table 4.

The base of natural logarithms is 2.718. The expression $\text{EXP}[0.7979]$ means that 2.718 is raised to the 0.7979th power. $\text{Ln}(X)$ is the natural log of X .

An identical result can be obtained by using logs base 10 as shown in Table 5.

If any one of the scores is zero, then the geometric mean is zero. If any scores are negative, then the geometric mean is meaningless. The geometric mean

is an appropriate measure to use for averaging rates. However, it is one of the least used measures of central tendency.

Harmonic Mean

The harmonic mean is the mean of n numbers expressed as the reciprocal of the arithmetic mean of the reciprocals of the numbers. The harmonic mean typically is used to take the mean of sample sizes. For the cold data, the harmonic mean is defined as

$$\bar{x}_h = \frac{i}{\frac{1}{n_1} + \frac{1}{n_2} + \dots + \frac{1}{n_i}},$$

where i is the number of scores from which the harmonic mean is computed. For the cold data, the harmonic mean is

$$\bar{x}_h = \frac{6}{\frac{1}{5} + \frac{1}{4} + \frac{1}{1} + \frac{1}{2} + \frac{1}{1} + \frac{1}{3}} = 1.83.$$

This is less than the arithmetic mean of 2.67, the trimean of 2.56, and the geometric mean of 2.22.

Median

The median is the midpoint of a distribution such that the same number of scores is above the median as below it. In other words, the median is the 50th percentile. More specifically, the median for a collection of data values is the number that is exactly

in the middle position of the list when the data are ranked (i.e., arranged in increasing order of magnitude). The formula for the median (Md) is

$$Md = L + \left(\frac{N(0.50) - cfb}{fw} \right) (i)$$

where

L is the lower limit of the interval within which the median lies,

N is the number of cases in the distribution,

cfb is the cumulative frequency in all intervals below the interval containing the median,

fw is the frequency of cases within the interval containing the median,

i is the interval size.

In order to compute the median for the cold data, the first step is to rank the data:

1, 1, 2, 3, 4, 5.

Because there are six numbers (i.e., an even number of data points), there are two middle numbers, namely, 2 and 3. Therefore, $L = 1.5$ (i.e., the lowest of the two middle numbers $- 0.5$). Also, $N = 6$ (number of observations), and $cfb = 2$ (i.e., the number of observations that lie below the lower limit of 1.5). Also, $fw = 2$ (i.e., the number of observations that are equal to the middle numbers) because the two middle numbers (i.e., 2 and 3) do not appear anywhere else in the data set. Finally, $i = 2$ (i.e., the highest middle number $-$ the lowest middle number $+ 1 = 3 - 2 + 1 = 2$). (Please note that $i = 1$ if the middle numbers are all the same.) Thus, the median is

$$Md = 1.5 + \left(\frac{6(0.50) - 2}{2} \right) (2) = 2.5.$$

Thus, the median cold is 2.5. When the number of observations is relatively small and the data are not grouped in class intervals—as is the case with the cold data—the median can be computed using the following steps:

1. Order the n observations from smallest to largest, including any repeated observations, so that every observation appears in the list.
2. Determine the location of the sample median, which is given by $(n + 1)/2$. Thus, for example, for a sample size of 5 (i.e., $n = 5$), $(n + 1)/2 = 3$, and the median is represented by the third number in the series. For a sample size of 6, $(n + 1)/2 = 3.5$, and the median can be located somewhere between the third and fourth number in the series.
3. If the number of scores is odd, the median is the middle score. Consider the following ranked distribution of scores: 1, 3, 3, 5, 6, 7, 8, 8, 9. Because there are nine scores (i.e., $N = 9$), the median is 6.
4. If the number of scores is even, the median is the average of the two middle values. Thus, because the cold data have an even number of scores, the two middle numbers are 2 and 3, and the median is the average of 2 and 3 (i.e., the average of the third and fourth observations), which is 2.5.

It can be seen that the simpler method of calculating the median yielded exactly the same number as did using the more general formula. However, for relatively large sample sizes, the simpler formula can distort the true value of the median represented by the more general formula.

Computer Applications

When using SPSS, there are a few ways to compute measures of central tendency. The Frequencies command can be used to compute the mean, median, and mode. The Descriptives command can be used to compute the mean. The Explore command can be used to compute the median, mean, and trimmed mean. The Means command can be used to compute the median, mean, harmonic mean, and geometric mean. Finally, the Reports command can be used to compute the mean and median.

The SPSS output for the Frequencies command pertaining to the cold data set is presented in Figure 1.

The SPSS output for the Descriptives command pertaining to the cold data set is in Figure 2.

The SPSS output for the Explore command pertaining to the cold data set is in Figure 3.

Comparisons of Measures of Central Tendency

To some extent, selection of the most appropriate measure of central tendency is dependent on the scale of measurement of the variable. Specifically, if the

data are nominal, then only the mode is appropriate. If the data are ordinal, either the mode or the median may be appropriate. If the data are interval or ratio, the mode, median, or mean may be appropriate.

For distributions that are symmetrical and unimodal, the three major measures of central tendency (i.e., mean, median, mode) are all the same. When the distribution is symmetrical and bimodal, the mean and the median coincide, but two modes are present. The less symmetrical the distribution, the greater the differential between the mean, the median, and the mode. For skewed distributions, they can differ markedly. Specifically, in positively skewed distributions, the mean is higher than the median, whereas in negatively skewed distributions, the mean is lower than the median. Thus, comparing the mean and median can provide useful information about the level of skewness inherent in the distribution.

Of the eight measures of central tendency discussed, the mean is by far the most widely used because it takes every score into account, is the most efficient measure of central tendency for approximately symmetric (normal) distributions, and uses a simple formula. Also, because the mean requires that the differences between the various levels of the categories on any part of the distribution represent equal differences in the characteristic or trait measured (i.e., equal unit or interval/ratio scale), it can be manipulated mathematically in ways not appropriate to the median and mode. Thus, the mean is mathematically appealing, making it possible for

researchers to develop statistical procedures for drawing inferences about means. However, the mean does have several disadvantages. In particular, the mean is sensitive to skewed data. It is also sensitive to outliers. Thus, the mean often is misleading in highly skewed distributions and is less efficient than other measures of central tendency when extreme scores are possible.

The trimean is almost as resistant to extreme scores as is the median, and it is less subject to sampling fluctuations than the arithmetic mean in extremely skewed distributions. However, it is less efficient than the mean for normal distributions. The trimmed mean, which generally falls between the *mean* and the *median*, is less susceptible to the effects of extreme scores than the arithmetic mean and, in turn, is less susceptible to sampling fluctuation than the mean for extremely skewed distributions. However, like the trimean, the trimmed mean is less efficient than the mean for normal distributions. The geometric mean is less affected by extreme values than the arithmetic mean and is useful as a measure of central tendency for some positively skewed distributions. However, the geometric mean is rarely used because (a) it equals zero if any one of the scores is zero, regardless of how large the remaining scores are; (b) it is meaningless if any scores are negative; and (c) it is more difficult to compute than the arithmetic mean. The weighted mean does not use any of the actual scores in the distribution.

The median is useful because of its ease of interpretation and because it is more efficient than the mean in highly skewed distributions. That is, the median is not sensitive to skewed data. However, it does not take into account every score, relying only on the middle value(s) in an ordered set of data. Also, the median

generally is less efficient than the mean, the trimean, and the trimmed mean. The mode can be informative, is easy to interpret, and is the only measure of central tendency that can be used with nominal data; however, it should almost never be used as the only measure of central tendency because it depends only on the most frequent observation and is

highly susceptible to sampling fluctuations. Another disadvantage of the mode is that many distributions have more than one mode, thereby complicating interpretation. Also, the mode does not always exist.

MEDIAN

The median is a measure of central tendency and is the point in a group of values with an equal number of values above and below that point.

The computation of the median is as follows.

- For an odd number of values, the position of the median is given by $(N + 1)/2$. If we have 15 cases, the median is the 8th case.
- For an even number of cases $(N + 1)/2$ does not give a whole number. In this case, the median is the (arithmetic) mean of the two values immediately above and below.

For example, the data set in Table 1 consists of 11 test scores.

First of all, the values need to be sorted from smallest to largest value: 4, 5, 6, 6, 6, 7, 7, 7, 8, 8, 9. Then, the midpoint needs to be found that splits the sample into two halves. In this example we have an odd number of participants, so we will have a midpoint that represents the point on which an equal number of values on each side is present. To the left of the midpoint, the values 4, 5, 6, 6, and 6 are present, and to the right, the values 7, 7, 8, 8, and 9. In this example, the midpoint of the row of numbers has a value of 7, so the median is 7.

Consider also a sample of an even number of participants who have achieved the test scores 4, 5, 6, 6, 6, 6, 7, 7, 7, 8, 8, and 9. The midpoint has to be computed by finding the two values in the middle—here, 6 and 7—and the mean of the two will be the median, so the median is 6.5.

More About the Median

- In a group with an odd number of values, the median is a specific value (an identifiable individual) in the group. It is not computed by directly taking the other values of the group into account. In a group with an even number of values, the mean of the two middle values is taken. Other than these two, no other values enter the equation.

Figure 1 SPSS Output

- The median is a midpoint that splits a group into two halves equal in their number of values but not equal in their actual values.
- The median is not sensitive to extreme scores. The magnitude of the other values in the group and their relative magnitude in comparison to the median are not taken into account. In a group with the values 1, 2, and 99, 2 is the median. An extreme score can pull the mean in one or another direction and make it less representative of the set of scores and less useful as a measure of central tendency.
- The median can be a more useful descriptor in a skewed distribution than the mean.

MEDIAN TEST

Many statistical procedures test for differences in location parameter, where the measure of location pertains to the median (θ), or the 50th percentile. Hypotheses can be tested about a single or multiple medians.

k = 1 Median

Testing hypotheses about a single sample median presents two problems. First, and perhaps more debilitating, the sample median is not the best unbiased estimate of the population median. (Therefore, the question arises as to the efficacy of testing this hypothesis.)

The Harrell-Davis (θ_{HD}) is one statistic, among many, that is a better estimate of the population median than the sample median. The θ_{HD} is computed by drawing N ordered deviates from the beta distribution. Sort the original scores (x_i), and multiply the first score by the first beta deviate (b_1), the second score by the second beta deviate, and so forth. The Harrell-Davis estimator of the population median is

$$\theta_{HD} = \sum_{i=1}^N b_i x_i. \tag{1}$$

The second problem is that the sampling distribution is intractable. Thus, it is only possible to estimate the standard error of θ . One suitable estimate of the standard error is the Maritz-Jarrett, s , which in turn may be based on the Harrell-Davis estimator of the median.

Thus, for $k = 1$, the null hypothesis is $H_0: \theta = \theta_0$, where θ is the sample median and θ_0 is some hypothesized population value. This is tested against the alternative $H_1: \theta \neq \theta_0$. The test is

$$Z = \frac{\theta - \theta_0}{s}, \tag{2}$$

where s is the Maritz-Jarrett estimate. Wilcox provided algorithms and computer code to automate computing the Maritz-Jarrett estimate. The significance of Z for a specified α level is determined by a table of the standard normal distribution.

k > 1 Medians

A classical test for a difference in two or more ($k \geq 2$) independent medians is due to Mood. The two-sample case is analogous to Fisher's exact test and the $k > 2$ is based on the chi-square, and they share the assumptions of the analogous tests.

Consider the case of $k = 3$. The null hypothesis $H_0: \theta_A = \theta_B = \theta_C$, which is tested against the alternative hypothesis H_a : at least one θ is different from the rest. The grand median is computed. The number of scores above and below the median is tabulated. The expected value for each group is half the sample size for that group. The chi-square test is computed, and significance is determined by comparing the obtained chi-square statistic with the critical value based on $df = k - 1$.

Example

Three groups of test scores are presented in Table 1. The grand median is 65.5 (Fay has provided advice concerning values tied with the grand median).

Count the number of scores greater than 65.5 and the number of scores less than or equal to 65.5 for each group. The frequencies are displayed in Table 1.

>65.5	16	12	11
<65.5	10	14	15

The expected value for each cell is 13. This was found by dividing the sample size for each group ($n_1 = n_2 = n_3 = 26$). The values for each of the six cells are calculated based on

$$\chi^2 = \sum_{i=1}^2 \sum_{j=1}^k \frac{(O_{ij} - E_{ij})^2}{E_{ij}}, \quad (3)$$

where O is the observed value, E is the expected value, i is the row, j is the column, and k is the number of groups. The 16 participants in Group 1 had a score above 65.5. Thus,

$$\frac{(16 - 13)^2}{13} = \frac{(3)^2}{13} = \frac{9}{13} = 0.692.$$

χ^2 = the sum for the six cells, as indicated in Table 3.

χ^2 is 2.154, and $df = (k - 1) = 3 - 1 = 2$. The critical value for χ^2 is 5.991. Because $2.154 < 5.991$, the decision is to fail to reject the null hypothesis that there is no difference in the medians of the three groups.

Calculation Using SPSS

The data must be entered into one variable—in this case, “scores”—using a grouping variable. Table 4 shows how to use the grouping variable for the first few data points.

To conduct Mood’s test (called the median test in SPSS), select the following: Analyze | Nonparametric

META-ANALYSIS

Meta-analysis is a method of analysis that allows for the statistical aggregation of data from individual empirical findings. This is conducted by transforming results from a pool of studies into one common metric, the effect size (ES). The earliest form of research synthesis was performed as early as 1904 by biometrician Karl Pearson in order to review the empirical basis for the routine use of the typhoid vaccine in the British army for soldiers at risk for the disease. Pearson estimated inoculation effectiveness by averaging correlations reported in five studies about the relationship between inoculation status and typhoid immunity as well as those reported in six studies about the relationship between inoculation status and mortality among those who suffered from the condition. The modern usage of this statistical procedure and the coining of the term *meta-analysis* began with the work of Gene Glass in 1976. Applications of the method by individuals such as Mary L. Smith and Gene Glass to psychotherapy, John E. Hunter and Frank L. Schmidt to validity of employment tests, and Robert Rosenthal and Donald B. Rubin to interpersonal expectancy effects highlighted the utility of the meta-analysis in the social sciences. In 1985, Larry V. Hedges and Ingram Olkin, with the publication of *Statistical Methods for*

Meta-Analysis, helped to introduce the method as a statistical specialty.

Stages of Research Synthesis in a Meta-Analysis

Conducting a systematic review involves the aggregation and comparison of findings across empirical research studies presenting quantitative data. Although this continues to be an important issue of debate in the field of meta-analysis, many experts agree that a useful research synthesis should be based on findings from high-quality studies with methodological rigor. Relaxed inclusion standards for studies in a meta-analysis may lead to a problem that Hans J. Eysenck in 1978 labeled as “garbage in, garbage out.” Several technical objections have been noted by critics of meta-analysis such as John S. Searles: (a) The meta-analysis approach mixes apples and oranges in combining the findings of studies with varying methodological quality; (b) the meta-analysis approach aggregates the findings of poor studies, thus setting low standards of judgment for quality of outcome study; (c) the meta-analysis approach is problematic in light of shortcomings and flaws in the published literature (e.g., selective reporting, bias, insufficient reporting of primary data); (d) the meta-analysis approach has used “lumpy,” nonindependent data (i.e., multiple uses of the same data in several studies); and (e) the meta-analysis approach has given equal weighting to all studies regardless of methodological rigor.

According to Harris Cooper and Larry V. Hedges, a methodologically robust meta-analysis needs to be completed in five organized stages. The first stage of research synthesis in meta-analysis is to formulate an appropriate research hypothesis. For instance, one may question whether a specific independent variable causes systematic changes in specific dependent or outcome variables. Other issues of interest may be the generalizability or the external validity of findings from specific populations, settings, and procedures to a larger set of studies. Answers to such research questions can then advance the theoretical understanding of a specific phenomenon in a meaningful manner.

The second stage of research synthesis focuses on identification of studies and subsequent data collection from these primary sources. Clear eligibility guidelines in terms of inclusion and exclusion criteria will be helpful in identifying appropriate studies. Several methods may be used to locate and retrieve empirical reports. One strategy is to perform keyword searches of selected computerized bibliographic databases such as *Psychological Abstracts* (PsycINFO or PsychLit), *Sociological Abstracts*, ERIC (Educational Resources Information Center), SSCI (Social Science Citation Index), or MEDLINE. Computer searches, however, have been criticized for their unreliability and inaccuracy in locating relevant studies in meta-analyses. Additional methods may be employed for retrieval of appropriate studies: (a) manual search of journals that routinely publish research relevant to the topic selected; and (b) usage of the ancestry approach (i.e., “footnote chasing”) where the reference sections of relevant literature are reviewed for eligible studies. In order to effectively minimize publication bias or the “file drawer” effect (i.e., low publication probability for nonsignificant research findings), a comprehensive search of fugitive literature may also be conducted. For instance, one may search for master’s theses and dissertations by using the Dissertation Abstracts International (ProQuest Digital Dissertations) database. Obvious advantages in using this method are the availability of theses and dissertations as well as their detailed description of methodology and results.

Data collection, through the process of coding, is one of the most demanding tasks involved in the conduct of a meta-analysis. In order to extract information from each eligible study, a coding manual may be developed by the meta-analyst(s). A coding protocol is conceptualized as consisting of two major parts, with the first part designed to collect data about the factors that may potentially influence the nature and value of the overall effect size (i.e., study descriptors) and the second part designed to collect information about specific study findings (i.e., effect size values for dependent variables). Because each study is expected to report varying numbers and forms of effect size statistics,

the coding form may be constructed in such a way as to offer the coder the flexibility of recording statistical information in a number of different formats. Reliability checks of the coding can then be performed during the continuous training of study coders. In cases of meta-analyses performed by a single analyst, Mark W. Lipsey and David B. Wilson recommend that coder reliability could be verified by selecting a subsample of coded studies and coding them again after sufficient time has passed since the first coding. Coder reliability (i.e., agreement rate) can then be obtained by dividing the number of observations agreed upon by the total number of observations, as suggested by Robert G. Orwin.

The third stage of research synthesis involves a careful evaluation of the data collected. A comprehensive review of these evaluation strategies is beyond the purpose of this entry, and the reader should refer to the reading list provided. The fourth stage is analysis and interpretation (see section below on statistical methods of effect size estimation). The fifth stage is the public presentation of the findings.

Statistical Methods of Effect Size Estimation

Two types of effect sizes have been described by Robert Rosenthal: the r family and the d family. The r family consists of the Pearson product moment correlation, whereas the d family includes Hedges’s g , Glass’s Δ , and Cohen’s d . An effect size for each study is calculated, and the mean effect size is then obtained from averaging all effect sizes calculated for each study. A widely used convention of evaluating the magnitude of an effect size is based on Jacob Cohen’s d estimates of small, moderate, and large effect sizes as 0.20, 0.50, and 0.80, respectively. Once effect sizes are calculated from a number of different studies, then particular attention is given to detecting any variability across these findings. In cases of observed variability, specific moderators that might have had an impact on effect sizes are consequently examined.

Brief Example of Effect Size Estimation

Effect sizes may be calculated based on the standardized mean difference index (ES_{sm}) or Cohen's d , which is used to synthesize data from studies that contrast two independent groups on measures that have a continuous distribution. A formula for ES_{sm} is the difference between the posttreatment group means divided by the posttreatment pooled standard deviation,

$$ES_{sm} = \frac{\bar{X}_{G1} - \bar{X}_{G2}}{S_{pooled}}, \quad (1)$$

where \bar{X}_{G1} is the posttreatment Group 1 mean, \bar{X}_{G2} is the posttreatment Group 2 mean, and S_{pooled} is the posttreatment pooled standard deviation, which is estimated by Equation 2 presented below:

$$S_{pooled} = \sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}}, \quad (2)$$

where n_1 and n_2 are posttreatment sample sizes (i.e., completers) for Group 1 and Group 2, respectively; standard deviations for Groups 1 and 2 are represented by s_1 and s_2 .

Cohen's d is a biased estimate of the population d effect size and needs to be corrected. In particular, for this effect size index, the upward bias may become non-negligible when sample sizes are less than about 20. Larry V. Hedges's and Ingram Olkin's d , which is an unbiased estimate, may be calculated by the investigator for correcting this bias.

Methods of Identifying and Correcting Publication Bias

Publication bias can have rather deleterious effects on the validity of a meta-analysis and consequent inferences drawn from its results. According to Colin Begg, publication bias occurs when a study is selected to be published because it has estimated the largest effect size. This, however, provides an overly optimistic estimate of the "true (mean) effect," whose magnitude is a function of the sample size of the study as well as the number of studies from which the effect size is estimated. Robert Rosenthal describes this

failure of journal editors to publish or the failure of original investigators to report their nonsignificant findings as a censorship of effect size estimates. Unpublished nonsignificant results are placed in the "file drawers" of the researchers.

A possible strategy to detect potential publication bias is to obtain a "funnel plot." A funnel plot is a scatterplot of sample size versus estimated effect size for all included studies in a meta-analysis. If the plot obtained does not resemble the shape of a funnel, then the possibility of a publication bias is considered highly likely. Some meta-analysts comment that funnel plots may be difficult to interpret. Another method of detecting publication bias involves an examination of the correlation between sample size and effect size. A Fail-Safe-N (FSN) may also be calculated. According to Robert Rosenthal, this approach calculates the number of studies with an effect size of zero needed to reduce the mean obtained effect size to the point of nonsignificance.

Ruling Out Other Explanations for Significant Effect Sizes

Joseph A. Durlak has recommended that prior to making interpretations about effect sizes, other explanations that may have accounted for positive effects should be analyzed. Four areas of investigation have been outlined: (a) sampling error, (b) study artifacts, (c) methodological features, and (d) confounded study features.

Tests of homogeneity are often carried out in order to determine whether effect sizes are actually attributable to treatment effects or sampling error. In other words, in meta-analysis, it is necessary to find whether the various combined effect sizes all estimate the same population effect size. A homogeneous distribution suggests that a given effect size differs from the population effect size only by sampling error. In cases where a significant heterogeneity is obtained for the effect sizes, an analysis of preselected moderating variables is conducted in order to account for the observed variability in effect sizes.

Although corrections for study "artifacts" (imperfections) may be carried out, some meta-analytic

experts have argued that study imperfections should not be corrected in order to estimate what would have been found in a perfect study because these procedures are at odds with the true purpose of a meta-analysis, which is to reflect study findings accurately in a given field of research.

METRIC MULTIDIMENSIONAL SCALING

Metric multidimensional scaling (MDS) transforms a distance matrix into a set of coordinates such that the (Euclidean) distances derived from these coordinates approximate as well as possible the original distances. The basic idea of MDS is to transform the distance matrix into a cross-product matrix and then to find its eigendecomposition, which gives a principal component analysis (PCA). Like PCA, MDS can be used with supplementary or illustrative elements that are projected onto the dimensions after they have been computed.

An Example

The example is derived from O'Toole, Jiang, Abdi, and Haxby, who used a combination of principal component analysis and neural networks to analyze brain imaging data. In this study, 6 subjects were scanned using fMRI when they were watching pictures from 8 categories (faces, houses, cats, chairs, shoes, scissors, bottles, and scrambled images). The authors computed for each subject a distance matrix corresponding to how well they could predict the type of pictures that the subject was watching from his or her brain scans. The distance used was d' , which expresses the discriminability between categories.

O'Toole et al. give two distance matrices. The first one is the average distance matrix computed from the brain scans of all 6 subjects. The authors also give a distance matrix derived directly from the pictures watched by the subjects. The authors computed this distance matrix with the same algorithm that they used for the brain scans; they just substituted images for brain scans.

We will use these two matrices to review the basics of multidimensional scaling: namely, how to transform a distance matrix into a cross-product matrix and how to project a set of supplementary observations onto the space obtained by the original analysis.

Multidimensional Scaling: Eigenanalysis of a Distance Matrix

PCA is obtained by performing the eigendecomposition of a matrix. This matrix can be a correlation matrix (i.e., the variables to be analyzed are centered and normalized), a covariance matrix (i.e., the variables are centered but not normalized), or a cross-product matrix (i.e., the variables are neither centered nor normalized). A distance matrix cannot be analyzed directly using the eigendecomposition (because distance matrices are not positive semi-definite matrices), but it can be transformed into an equivalent cross-product matrix, which can then be analyzed.

Transforming a Distance Matrix Into a Cross-Product Matrix

In order to transform a distance matrix into a cross-product matrix, we start from the observation that the scalar product between two vectors can be transformed easily into a distance (the scalar product between vectors corresponds to a cross-product matrix). Let us start with some definitions. Suppose that \mathbf{a} and \mathbf{b} are two vectors with I elements. The Euclidean distance between these two vectors is computed as

$$d^2(\mathbf{a}, \mathbf{b}) = (\mathbf{a} - \mathbf{b})^T(\mathbf{a} - \mathbf{b}). \tag{1}$$

This distance can be rewritten to isolate the scalar product between vectors \mathbf{a} and \mathbf{b} :

$$d^2(\mathbf{a}, \mathbf{b}) = (\mathbf{a} - \mathbf{b})^T(\mathbf{a} - \mathbf{b}) = \mathbf{a}^T\mathbf{a} + \mathbf{b}^T\mathbf{b} - 2 \times (\mathbf{a}^T\mathbf{b}), \tag{2}$$

where $\mathbf{a}^T\mathbf{b}$ is the scalar product between \mathbf{a} and \mathbf{b} .

If the data are stored into an $I \times J$ data matrix denoted \mathbf{X} (where I observations are described by J variables), the between-observations cross-product matrix is then obtained as

$$\mathbf{S} = \mathbf{X} \mathbf{X}^T. \tag{3}$$

A distance matrix can be computed directly from the cross-product matrix as

$$\mathbf{D} = \mathbf{s}\mathbf{1}^T + \mathbf{1}\mathbf{s}^T - 2\mathbf{S}. \tag{4}$$

(Note that the elements of \mathbf{D} gives the *squared* Euclidean distance between rows of \mathbf{S} .)

This equation shows that an Euclidean distance matrix can be computed from a cross-product matrix. In order to perform MDS on a set of data, the main idea is to “revert” Equation 4 in order to obtain a cross-product matrix from a distance matrix. There is one problem when implementing this idea, namely, that *different* cross-product matrices can give the *same* distance. This can happen because distances are invariant for any change of origin. Therefore, in order to revert the equation, we need to impose an origin for

the computation of the distance. An obvious choice is to choose the origin of the distance as the center of gravity of the dimensions. With this constraint, the cross-product matrix is obtained as follows.

First define a mass vector denoted \mathbf{m} whose I elements give the mass of the I rows of matrix \mathbf{D} . These elements are all positive, and their sum is equal to 1:

$$\mathbf{m}^T \mathbf{1} = 1. \tag{5}$$

When all the rows have equal importance, each element is equal to $\frac{1}{I}$.

Second, define an $I \times I$ centering matrix denoted $\mathbf{\Xi}$ (read “big Xi”) equal to

$$\mathbf{\Xi} = \mathbf{I} - \mathbf{1} \mathbf{m}^T. \tag{6}$$

Finally, the cross-product matrix is obtained from matrix \mathbf{D} as

$$\mathbf{S} = -\frac{1}{2} \mathbf{\Xi} \mathbf{D} \mathbf{\Xi}^T. \tag{7}$$

The eigendecomposition of this matrix gives

$$\mathbf{S} = \mathbf{U} \mathbf{\Lambda} \mathbf{U}^T \tag{8}$$

with

$$\mathbf{U}^T \mathbf{U} = \mathbf{I} \text{ and } \mathbf{\Lambda} \text{ diagonal matrix of eigenvalues.} \tag{9}$$

See the “Appendix: Proof” section toward the end of this entry for a proof.

The scores (i.e., the projection of the rows on the principal components of the analysis of \mathbf{S}) are obtained as

$$\mathbf{F} = \mathbf{M}^{-\frac{1}{2}} \mathbf{U} \mathbf{\Lambda}^{-\frac{1}{2}} (\text{with } \mathbf{M} = \text{diag}\{\mathbf{m}\}). \tag{10}$$

The scores have the properties that their variance is equal to the eigenvalues

$$\mathbf{F}^T \mathbf{M} \mathbf{F} = \mathbf{\Lambda}. \tag{11}$$

Example

To illustrate the transformation of the distance matrix, we will use the distance matrix derived from the brain scans given in Table 1:

$$\mathbf{D} = \begin{bmatrix} 0.00 & 3.47 & 1.79 & 3.00 & 2.67 & 2.58 & 2.22 & 3.08 \\ 3.47 & 0.00 & 3.39 & 2.18 & 2.86 & 2.69 & 2.89 & 2.62 \\ 1.79 & 3.39 & 0.00 & 2.18 & 2.34 & 2.09 & 2.31 & 2.88 \\ 3.00 & 2.18 & 2.18 & 0.00 & 1.73 & 1.55 & 1.23 & 2.07 \\ 2.67 & 2.86 & 2.34 & 1.73 & 0.00 & 1.44 & 1.29 & 2.38 \\ 2.58 & 2.69 & 2.09 & 1.55 & 1.44 & 0.00 & 1.19 & 2.15 \\ 2.22 & 2.89 & 2.31 & 1.23 & 1.29 & 1.19 & 0.00 & 2.07 \\ 3.08 & 2.62 & 2.88 & 2.07 & 2.38 & 2.15 & 2.07 & 0.00 \end{bmatrix}. \quad (12)$$

The elements of the mass vector \mathbf{m} are all equal to $1/8$:

$$\mathbf{m}^T = [.125 \ .125 \ .125 \ .125 \ .125 \ .125 \ .125 \ .125]. \quad (13)$$

The centering matrix is equal to

$$\mathbf{E}_{8 \times 8} = \begin{bmatrix} .875 & -.125 & -.125 & -.125 & -.125 & -.125 & -.125 & -.125 \\ -.125 & .875 & -.125 & -.125 & -.125 & -.125 & -.125 & -.125 \\ -.125 & -.125 & .875 & -.125 & -.125 & -.125 & -.125 & -.125 \\ -.125 & -.125 & -.125 & .875 & -.125 & -.125 & -.125 & -.125 \\ -.125 & -.125 & -.125 & -.125 & .875 & -.125 & -.125 & -.125 \\ -.125 & -.125 & -.125 & -.125 & -.125 & .875 & -.125 & -.125 \\ -.125 & -.125 & -.125 & -.125 & -.125 & -.125 & .875 & -.125 \\ -.125 & -.125 & -.125 & -.125 & -.125 & -.125 & -.125 & .875 \end{bmatrix}.$$

The cross-product matrix is then equal to

$$\mathbf{S} = \begin{bmatrix} 1.34 & -0.31 & 0.34 & -0.46 & -0.25 & -0.26 & -0.12 & -0.29 \\ -0.31 & 1.51 & -0.38 & 0.03 & -0.26 & -0.24 & -0.37 & 0.02 \\ 0.34 & -0.38 & 1.12 & -0.16 & -0.19 & -0.14 & -0.27 & -0.31 \\ -0.46 & 0.03 & -0.16 & 0.74 & -0.08 & -0.05 & 0.07 & -0.09 \\ -0.25 & -0.26 & -0.19 & -0.08 & 0.83 & 0.05 & 0.09 & -0.20 \\ -0.26 & -0.24 & -0.14 & -0.05 & 0.05 & 0.71 & 0.08 & -0.15 \\ -0.12 & -0.37 & -0.27 & 0.07 & 0.09 & 0.08 & 0.65 & -0.13 \\ -0.29 & 0.02 & -0.31 & -0.09 & -0.20 & -0.15 & -0.13 & 1.15 \end{bmatrix}.$$

The eigendecomposition of \mathbf{S} gives

$$\mathbf{U} = \begin{bmatrix} 0.60 & -0.36 & -0.10 & 0.48 & -0.23 & 0.02 & 0.30 \\ -0.52 & -0.64 & 0.36 & 0.14 & 0.10 & -0.06 & -0.18 \\ 0.48 & -0.17 & 0.10 & -0.67 & 0.24 & 0.04 & -0.30 \\ -0.23 & 0.16 & 0.20 & -0.38 & -0.54 & 0.29 & 0.49 \\ -0.02 & 0.39 & 0.19 & 0.28 & 0.61 & 0.47 & 0.14 \\ -0.03 & 0.32 & 0.11 & -0.00 & 0.14 & -0.83 & 0.23 \\ 0.00 & 0.38 & 0.02 & 0.25 & -0.43 & 0.04 & -0.69 \\ -0.28 & -0.08 & -0.87 & -0.09 & 0.11 & 0.04 & 0.02 \end{bmatrix}. \quad (14)$$

and

$$\Lambda = \begin{bmatrix} 2.22 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1.72 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1.23 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1.00 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.79 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.69 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0.39 \end{bmatrix}. \quad (15)$$

As in PCA, the eigenvalues are often transformed into percentage of explained variance (or inertia) in order to make their interpretation easier. Here, for example, we find that the first dimension “explains” 28% of the variance of the distances (i.e., $\frac{2.22}{2.22+\dots+0.39} = .28$).

We obtain the following matrix of scores:

$$\mathbf{F} = \begin{bmatrix} 2.53 & -1.35 & -0.30 & 1.36 & -0.58 & 0.04 & 0.53 \\ -2.19 & -2.37 & 1.13 & 0.39 & 0.24 & -0.15 & -0.32 \\ 2.04 & -0.63 & 0.32 & -1.90 & 0.61 & 0.10 & -0.52 \\ -0.97 & 0.61 & 0.62 & -1.09 & -1.35 & 0.68 & 0.86 \\ -0.10 & 1.44 & 0.59 & 0.81 & 1.53 & 1.10 & 0.25 \\ -0.13 & 1.18 & 0.33 & -0.00 & 0.35 & -1.96 & 0.40 \\ 0.02 & 1.41 & 0.05 & 0.70 & -1.09 & 0.09 & -1.22 \\ -1.20 & -0.29 & -2.74 & -0.27 & 0.28 & 0.10 & 0.03 \end{bmatrix}.$$

Figure 1a displays the projection of the categories on the first two dimensions. The first dimension explains 28% of the variance of the distance, it can be interpreted as the opposition of the face and cat categories to the house category (these categories are the ones most easily discriminated in the scans). The second dimension, which explains 21% of the variance, separates the small objects from the other categories.

Multidimensional Scaling: Supplementary Elements

After we have computed the MDS solution, it is possible to project supplementary or illustrative elements onto this solution. To illustrate this procedure, we will project the distance matrix obtained from the pictures (see Table 2) onto the space defined by the analysis of the brain scans.

The number of supplementary elements is denoted by I_{sup} . For each supplementary element, we need the values of its distances to all the I active elements. We

can store these distances in an $I \times I_{sup}$ supplementary distance matrix denoted \mathbf{D}_{sup} . So, for our example, we have

$$\mathbf{D}_{sup} = \begin{bmatrix} 0.00 & 4.52 & 4.08 & 4.08 & 4.52 & 3.97 & 3.87 & 3.73 \\ 4.52 & 0.00 & 2.85 & 4.52 & 4.52 & 4.52 & 4.08 & 4.52 \\ 4.08 & 2.85 & 0.00 & 1.61 & 2.92 & 2.81 & 1.96 & 3.17 \\ 4.08 & 4.52 & 1.61 & 0.00 & 2.82 & 2.89 & 2.91 & 3.97 \\ 4.52 & 4.52 & 2.92 & 2.82 & 0.00 & 3.55 & 3.26 & 4.52 \\ 3.97 & 4.52 & 2.81 & 2.89 & 3.55 & 0.00 & 2.09 & 3.26 \\ 3.87 & 4.08 & 1.96 & 2.91 & 3.26 & 2.09 & 0.00 & 1.50 \\ 3.73 & 4.52 & 3.17 & 3.97 & 4.52 & 3.26 & 1.50 & 0.00 \end{bmatrix}. \tag{16}$$

The first step is to transform \mathbf{D}_{sup} into a cross-product matrix denoted \mathbf{S}_{sup} . This is done by centering the rows with the same centering matrix that was used previously to transform the distance of the active

elements. Specifically, the cross-product matrix is obtained as

$$\mathbf{S}_{\text{sup}} = -\frac{1}{2} \mathbf{E} \mathbf{D}_{\text{sup}} \mathbf{E} \tag{17}$$

For our example, this gives

$$\mathbf{S}_{\text{sup}} = \begin{bmatrix} 1.80 & -0.41 & -0.83 & -0.62 & -0.63 & -0.54 & -0.71 & -0.32 \\ -0.46 & 1.85 & -0.21 & -0.84 & -0.63 & -0.82 & -0.81 & -0.72 \\ -0.24 & 0.42 & 1.21 & 0.62 & 0.17 & 0.04 & 0.25 & -0.04 \\ -0.24 & -0.41 & 0.41 & 1.42 & 0.22 & 0.00 & -0.22 & -0.44 \\ -0.46 & -0.41 & -0.25 & 0.01 & 1.63 & -0.33 & -0.40 & -0.72 \\ -0.18 & -0.41 & -0.19 & -0.02 & -0.14 & 1.44 & 0.18 & -0.09 \\ -0.14 & -0.20 & 0.23 & -0.03 & 0.00 & 0.40 & 1.23 & 0.79 \\ -0.07 & -0.41 & -0.37 & -0.56 & -0.63 & -0.19 & 0.48 & 1.54 \end{bmatrix} \tag{18}$$

The next step is to project the matrix \mathbf{S}_{sup} onto the space defined by the analysis of the active distance matrix. We denote by \mathbf{F}_{sup} the matrix of projection of the supplementary elements. Its computational formula is obtained by first combining Equations 10 and 8 in order to get

and then substituting \mathbf{S}_{sup} for \mathbf{S} and simplifying gives

$$\mathbf{F}_{\text{sup}} = \mathbf{S}_{\text{sup}}^T \mathbf{M}^{-\frac{1}{2}} \mathbf{U} \mathbf{A}^{-\frac{1}{2}} = \mathbf{S}_{\text{sup}}^T \mathbf{F} \mathbf{A}^{-1} \tag{20}$$

$$\mathbf{F} = \mathbf{S}^T \mathbf{M}^{-\frac{1}{2}} \mathbf{U} \mathbf{A}^{-\frac{1}{2}}, \tag{19}$$

For our example, this equation gives the following values:

$$\mathbf{F}_{\text{sup}} = \begin{bmatrix} 2.45 & -1.38 & -1.18 & 2.53 & -2.05 & -0.30 & 2.56 \\ -1.46 & -3.24 & 2.30 & -0.55 & 1.04 & -0.34 & -3.68 \\ 0.43 & 0.55 & 1.19 & -3.89 & -0.23 & 0.69 & -2.81 \\ 0.37 & 1.98 & 1.50 & -3.74 & -1.90 & 1.61 & 2.21 \\ 0.25 & 2.74 & 1.87 & -0.19 & 2.90 & 3.24 & 0.79 \\ 0.26 & 2.61 & 0.06 & -1.07 & -0.44 & -4.43 & -0.11 \\ 0.08 & 2.22 & -1.79 & -1.10 & -1.37 & -0.99 & -5.05 \\ -0.30 & 0.83 & -4.59 & -0.59 & -1.24 & -0.87 & -3.72 \end{bmatrix} \tag{21}$$

Figure 1b displays the projection of the supplementary categories on the first two dimensions. Comparing plots *a* and *b* shows that an analysis of the pictures reveals a general map very similar to the analysis of the brain scans with only one major difference: The cat category for the images moves to the center of the space. This suggests that the cat category

is interpreted by the subjects as being facelike (i.e., “cats have faces”).

Analyzing Nonmetric Data

Metric MDS is adequate only when dealing with distances. In order to accommodate weaker measurements

(called dissimilarities), nonmetric MDS is adequate. It derives a Euclidean distance approximation using only the ordinal information from the data.

Appendix: Proof

We start with an $I \times I$ distance matrix \mathbf{D} and an $I \times 1$ vector of mass (whose elements are all positive or zero and whose sum is equal to 1) denoted \mathbf{m} and such that

$$\mathbf{m}^T \mathbf{1} = 1. \quad (22)$$

The centering matrix is equal to

$$\mathbf{E} = \mathbf{I} - \mathbf{1}\mathbf{m}^T. \quad (23)$$

We want to show that the following cross-product matrix,

$$\mathbf{S} = -\frac{1}{2} \mathbf{E} \mathbf{D} \mathbf{E}^T, \quad (24)$$

will give back the original distance matrix when the distance matrix is computed as

$$\mathbf{D} = \mathbf{s}\mathbf{1}^T + \mathbf{1}\mathbf{s}^T - 2\mathbf{S}. \quad (25)$$

In order to do so, we need to choose an origin for the coordinates (because several coordinates systems will give the same distance matrix). A natural choice is to assume that the data are centered (i.e., the mean of each original variable is equal to zero). There, we assume that the mean vector, denoted \mathbf{c} , is computed as

$$\mathbf{c} = \mathbf{X}^T \mathbf{m} \quad (26)$$

(for some data matrix \mathbf{X}). Because the origin of the space is located at the center of gravity, its coordinates are equal to $\mathbf{c} = \mathbf{0}$. The cross-product matrix can therefore be computed as

$$\begin{aligned} \mathbf{S} &= \begin{pmatrix} \mathbf{X} & -\mathbf{1}\mathbf{c}^T \\ \mathbf{X} & -\mathbf{1}\mathbf{c}^T \end{pmatrix} \begin{pmatrix} \mathbf{X} & -\mathbf{1}\mathbf{c}^T \\ \mathbf{X} & -\mathbf{1}\mathbf{c}^T \end{pmatrix}^T \\ &= \begin{pmatrix} \mathbf{X} & -\mathbf{1}\mathbf{c}^T \\ \mathbf{X} & -\mathbf{1}\mathbf{c}^T \end{pmatrix} \begin{pmatrix} \mathbf{X}^T & -\mathbf{c}\mathbf{1}^T \\ \mathbf{X}^T & -\mathbf{c}\mathbf{1}^T \end{pmatrix} \end{aligned} \quad (27)$$

First, we assume that there exists a matrix denoted \mathbf{S} such that Equation 25 is satisfied. Then we plug Equation 25 into Equation 24, develop, and simplify in order to get

$$-\frac{1}{2} \mathbf{E} \mathbf{D} \mathbf{E}^T = -\frac{1}{2} \mathbf{E} \mathbf{s}\mathbf{1}^T \mathbf{E}^T - \frac{1}{2} \mathbf{E} \mathbf{1}\mathbf{s}^T \mathbf{E}^T + \mathbf{E} \mathbf{S} \mathbf{E}^T. \quad (28)$$

Then, we show that the terms $\mathbf{E}(\mathbf{s}\mathbf{1}^T)\mathbf{E}^T$ and $\mathbf{E}(\mathbf{1}\mathbf{s}^T)\mathbf{E}^T$ are null because

$$\begin{aligned} (\mathbf{s}\mathbf{1}^T)\mathbf{E}^T &= \mathbf{s}\mathbf{1}^T(\mathbf{I} - \mathbf{1}\mathbf{m}^T)^T \\ &= \mathbf{s}\mathbf{1}^T(\mathbf{I} - \mathbf{m}\mathbf{1}^T) \\ &= \mathbf{s}\mathbf{1}^T - \mathbf{s}\mathbf{1}^T\mathbf{m}\mathbf{1}^T \text{ (but from Equation 22: } \mathbf{1}^T\mathbf{m} = 1) \\ &= \mathbf{s}\mathbf{1}^T - \mathbf{s}\mathbf{1}^T \\ &= \mathbf{0}. \end{aligned} \quad (29)$$

The last thing to show now is that the term $\mathbf{E} \mathbf{S} \mathbf{E}^T$ is equal to \mathbf{S} . This is shown by developing

$$\begin{aligned} \mathbf{E} \mathbf{S} \mathbf{E}^T &= (\mathbf{I} - \mathbf{1}\mathbf{m}^T)\mathbf{S}(\mathbf{I} - \mathbf{m}\mathbf{1}^T) \\ &= \mathbf{S} - \mathbf{S}\mathbf{m}\mathbf{1}^T - \mathbf{1}\mathbf{m}^T\mathbf{S} + \mathbf{1}\mathbf{m}^T\mathbf{S}\mathbf{m}\mathbf{1}^T. \end{aligned} \quad (30)$$

Because

$$\begin{aligned} (\mathbf{X}^T - \mathbf{c}\mathbf{1}^T)\mathbf{m} &= \mathbf{X}^T\mathbf{m} - \mathbf{c}\mathbf{1}^T\mathbf{m} \text{ (cf. Equations 26 and 22)} \\ &= \mathbf{c} - \mathbf{c} \\ &= \mathbf{0}, \end{aligned} \quad (31)$$

we get (cf. Equation 27):

$$\mathbf{S}\mathbf{m} = (\mathbf{X} - \mathbf{1}\mathbf{c}^T)(\mathbf{X}^T - \mathbf{c}\mathbf{1}^T)\mathbf{m} = \mathbf{0}. \quad (32)$$

Therefore, Equation 33 becomes

$$\mathbf{E} \mathbf{S} \mathbf{E}^T = \mathbf{S}, \quad (33)$$

which leads to

$$-\frac{1}{2} \mathbf{E} \mathbf{D} \mathbf{E}^T = \mathbf{S}, \quad (34)$$

which completes the proof.

MILLON BEHAVIORAL MEDICINE DIAGNOSTIC

The Millon Behavioral Medicine Diagnostic (MBMD), published by NCS Assessments in 2001, is a revision of the 1974 Millon Behavioral Health Inventory (MBHI). Both are designed to evaluate psychosocial factors that influence the course of medical disease and to assist health care providers in planning successful treatment regimens. The MBMD eliminated underperforming scales of the MBHI, widened the base of medical disorders, and added new scales to assist case management, including scales responsive to *DSM-IV* revisions concerning psychological factors affecting medical conditions. Recent Stress and Chronic Tension subscales were eliminated from the revision even though both factors play major roles in primary, secondary, and tertiary prevention.

The MBMD contains 165 true/false self-report items that contribute to 39 scales that inform about Response Patterns (Disclosure, Desirability, Debasement); Negative Health Habits (Alcohol, Drugs, Eating, Caffeine, Inactivity, Smoking); Psychiatric Indicators (Anxiety-Tension, Depression, Cognitive Dysfunction, Emotional Lability, Guardedness); Coping Styles (Introversive, Inhibited, Dejected, Cooperative, Sociable, Confident, Nonconforming, Forceful, Respectful, Oppositional, Denigrating); Stress Moderators (Spiritual Absence, Illness Apprehension, Functional Deficits, Pain Sensitivity, Social Isolation, Future Pessimism); Prognostic Indicators (Interventional Fragility, Medication

Abuse, Information Discomfort, Utilization Excess, Problematic Compliance); Management Guides (Adjustment Difficulties, Psychiatric-Psychosocial Referral); and a Validity Indicator.

The MBMD is administered within 20 to 25 minutes for medical patients between 18 and 85 years old. Interpretation of the MBMD is based on prevalence scores rather than traditional scaling methods. This approach is intended to increase certainty about patient evaluation. Prevalence score norms are generic, although there is no reason to believe that prevalence scores are the same across medical disorders. Test-retest reliability was assessed at 7- and 30-day intervals and resulted in moderate to strong coefficients (.71 to .92). Most scales obtained a sound Cronbach's alpha coefficient (.74 to .89). However, on approximately half of the Coping Styles scales, lower coefficients were obtained (.54 to .67). Redundancy of items across 39 subscales is problematic; that is, 165 items are scored 492 times.

The MBMD manual presents concurrent validity through comparison of the individual scales against other measures with well-established validity, such as the State-Trait Anxiety Inventory, Profile of Mood States, and Beck Depression Inventory. Moderate to high (.50 to .87) convergent correlations between the MBMD and other standard measures were found, excluding the Problematic Compliance (.38) and Utilization Excess (.39 to .52) scales. Predictive validity studies have shown scores on various scales to be valid for predicting disease adjustment and adaptations, probability of seeking treatment, and the course of medical illness. The extreme revision of the MBMD questions the applicability of research that accrued with the MBHI. Rather, a new empirical base, presently small but growing, will help guide practitioners in the application of test results.

The MBMD is a novel tool for assessing the complexity of identifying the treatment needs of medical patients. This tool lends hope for the further integration of the biopsychosocial model into traditional medical systems, providing a better understand of the prognostics, treatment, rehabilitation, and management of disease.

MILLON CLINICAL MULTIAXIAL INVENTORY-III

The Millon Clinical Multiaxial Inventory-III (MCMI-III) is a 170-item objective measure of personality developed by Theodore Millon. It is somewhat unique among self-report inventories in that it focuses on personality disorders and their symptoms rather than standard clinical disorders such as depression and anxiety, and/or normal variations in personality. In fact, the focus is exclusively on clinical populations, and it should not be used with normal populations. First published in 1977, the MCMI has undergone two revisions (currently MCMI-III) and currently reflects a combination of Millon's own theory of personality disorders and the *DSM-IV* criteria for diagnosis of those disorders. It is ranked second only to the Minnesota Multiphasic Personality Inventory (MMPI-2) in frequency of use in clinical settings for personality assessment.

There are essentially three broad categories of scores generated on the MCMI: 4 Validity scales, 14 Personality Disorder scales (3 of which are labeled Severe), and 10 Clinical Syndrome scales (3 of which are labeled Severe). The Validity scales can help to determine the degree to which an individual is minimizing or exaggerating symptoms. The Personality scales cover the 10 personality disorders listed in the *DSM-IV* and four others, two of which are listed in the *DSM-IV* for further study and two that are derived

from Millon's theory of personality. The Clinical Syndrome scales are composed of three that assess disorders of mood, two that focus on anxiety, two that deal with disorders of belief and thought, one each for drug and alcohol problems, and one somatoform scale. All of these scales use a base rate scoring system that adjusts scores based on how frequently the symptoms measured will occur in a clinical population. In this way, disorders whose symptoms are somewhat common in a clinical population will require a higher level of symptom reporting than do disorders whose symptoms are more rare in order to be considered elevated. Two cut-score points are established (75BR suggesting the presence of symptoms, and 85BR suggesting the presence of the disorder). Regardless of the level of elevation, it is important that the clinician using the test incorporates additional information into any diagnostic decision, and should never base a diagnosis on the test results in isolation.

Millon has also developed inventories for use with other populations. The Millon Behavioral Medicine Diagnostic (MBMD) is an updated revision of the earlier Millon Behavioral Health Inventory (MBHI) and is designed for use with adults in primary care or other medical settings. The Millon Adolescent Clinical Inventory (MACI) is essentially a version of the MCMI for use with 13- to 19-year-olds, whereas the Millon Pre-Adolescent Clinical Inventory (M-PACI) extends coverage to 9- to 12-year-olds. The Millon Adolescent Personality Inventory (MAPI) combines assessment of normal personality factors with the MACI, and finally, the Millon Inventory of Personality Styles-Revised (MIPS-Revised) is an assessment of normal personality traits in adults. Hand scoring, mail-in scoring, and on-site scoring software is available for all forms, as are both scoring and interpretive reports. Clinicians are charged a per-use fee, with the exception of hand scoring. However, because hand scoring is complicated, time-consuming, and error prone, it is not recommended.

MINNESOTA CLERICAL TEST

The Minnesota Clerical Test (published by The Psychological Corporation) measures perceptual abilities that are commonly used in the performance of various clerical activities. Most often, the MCT is used by employers to select employees who can work with information quickly and accurately, for clerical positions such as clerks, cashiers, tellers, and typists.

Composed of two parts—Number Comparison and Name Comparison—the test assesses the accuracy and speed with which test takers are able to distinguish between pairs of numbers or names that are similar and those that are identical. For example, an item including two numbers that are similar (e.g., 12343 and 13243) would be correctly identified as being different, whereas two numbers that are identical (e.g., 12232 and 12232) would be correctly identified as being the same. An item including two similar names (e.g., Davenport Inc. and Davinport Inc.) would be correctly identified as different, whereas two identical names (e.g., Smith & Co. and Smith & Co.) would be correctly identified as the same.

After receiving the test materials, as well as completing identification information and sample items, the test taker is given 15 minutes to complete both parts. Each consisting of 200 items, the two parts are scored by subtracting the number of incorrect responses from the number of correct responses.

The MCT was constructed in 1931 by psychologists at the University of Minnesota and first published in 1933. Initially known as the Minnesota Vocational Test for Clerical Workers, the test was given its current name in 1946. Remarkably, the

content of the test's items have not been altered since the original publication, although the manual has been revised five times with particular regard to psychometric and normative information. The most recent manual presents normative data, which enables a comparison of raw scores with larger groups, for trainees and employees working at utility companies, banks, financial institutions, universities, and temp agencies, as well as male, female, Caucasian, African American, and Hispanic individuals.

Overall, the MCT has been found to have good psychometric properties. In particular, test scores predicted future levels of job performance in clerical occupations and were related to typing speed, General Clerical Test scores, and Wechsler Adult Intelligence Scale scores. Also, the relationships found between the number and name comparison parts suggest that the two parts are measuring similar but distinct abilities. Although the MCT is used primarily in vocational settings, the test also is used by counselors to aid those considering clerical occupations, and by researchers in areas such as cognitive and vocational psychology.

MINNESOTA MULTIPHASIC PERSONALITY INVENTORY

The Minnesota Multiphasic Personality Inventory (MMPI) is the most widely used psychological test of

all time. It is routinely administered to patients in psychiatric hospitals and mental health clinics, students in college counseling centers, individuals involved in the criminal justice system, and applicants for certain areas of employment (and some graduate school programs). It is suitable for use with adults aged 18 and older, and there is an adolescent version (MMPI-A) for ages 14 to 18.

The MMPI was first published in 1943 by Starke Hathaway and J. C. McKinley of the University of Minnesota and revised in 1989 to become the MMPI-2. It is currently published by the University of Minnesota Press and marketed through Pearson Assessments. The MMPI-2 consists of 567 declarative statements that the examinee indicates as either true or false about herself or himself and takes approximately 60 to 90 minutes to complete. The test was originally designed as an objective measure for obtaining clinical-diagnostic information in psychiatric and general medical settings. Although the original clinical scales no longer match our current understanding of psychopathology, the vast amount of research on the MMPI and the MMPI-2 can lead to an enhanced understanding of how the individual is functioning (i.e., people with particular patterns to their scores tend to display particular characteristics). A skilled clinician can garner information about symptoms, personality, relationship style, response to stress, level of distress, self-perception, and many other aspects of functioning, and then can facilitate treatment planning and/or differential diagnosis.

The MMPI-2 generates a variety of scores, including the 10 original clinical scales, 9 restructured clinical scales, 8 validity scales, 15 content scales, subscales for many of these scales, and a host of supplementary scales. These scales cover areas ranging from depression and anxiety to self-esteem and openness to treatment to gender identity and level of distress. The sheer volume of information is often confusing and overwhelming to the novice. In response to this, there are a number of computerized interpretive programs on the market, some targeted toward a particular setting (e.g., forensic, personnel). The use of these reports has dramatically increased in recent years, but remains somewhat controversial among the psychological community because they cannot take into consideration the

individual's history and current circumstances. Such reports typically have a warning stating that the content should serve as hypotheses that a trained clinician would use as a starting point.

MISSING DATA METHOD

In 1959, Robert E. Dear proposed a missing data method that used the first extracted principle component. This unique method appeared in a technical report produced by the now-defunct Systems Development Corporation (SDC) in Santa Monica, California. For the next two decades, the Dear missing data method was a subject of much discussion and research. This report is no longer in print and its availability is scarce. It is, however, an important method that was documented in Neil Timm's doctoral dissertation and subsequent *Psychometrika* article in 1970. Terry Gleason and Richard Staelin also discussed it in their 1975 *Psychometrika* article. These publications document the efficiency and statistical properties of the Dear method. They also compare it to other available methods such as the ones proposed by Buck and Wilks. Both Timm and Gleason and Staelin found the Dear method to be among the best methods in terms of computational ease and accuracy.

Dr. Dear created this method because of the problems that researchers at SDC encountered using multiple regression with missing data values. A typical illustration of the missing data problem involves the prediction of a certain health variable for a sample of patients given a set of fixed, independent variables that should have been recorded for each patient in the study. The set of independent variables might include case history items. These would include the patient's age when she or he may have acquired a given disease, the age at death of each parent, the number of siblings who may have acquired a given disease that has a hereditary basis, and so forth. The set of independent variables may also include clinical measurements such as the patient's blood type, height, and rate of basal metabolism. In carrying out analyses of the dependence of some health variable on a set of case history and clinical measurement variables, it is not uncommon to find that not all of the variables are recorded for each of the patients. For some of the patients in the study, some of the case history items may not have been obtainable or were not recorded, and some of the clinical measurements may not have been made or were not recorded. In such cases, if these patients' data are to be included in the study, some method must be used for estimating the missing items.

Dr. Dear studied psychometrics and statistics with Professor Paul Horst at the University of Washington. One of the foundational cornerstones of the Dear method is from Horst's earlier work on estimation when data values were missing. Both Timm and Gleason and Staelin have documented the performance of the Dear method in estimating missing data values. These studies compared it to other methods of handling missing data in terms of efficiency and bias. It has fared well enough that researchers who want to estimate missing data values should consider it. The method is not difficult from a conceptual and computational point of view.

Although Dear's paper was concerned with the "estimation" of values to use for missing independent variables in multiple regression models, the method could be applied to nonregression types of problems where individual data points need to be estimated.

Dear's method, however, handles missing data values for independent variables that are considered as fixed numbers or nonrandom variables.

In multiple regression, the real statistical estimation problem is the estimation of regression coefficients for the regression of a dependent variable on a set of independent variables. However, Dear points out that there are occasions when missing values among the independent variables necessitate methods for constructing or estimating entries for these missing data before the main regression analysis can be carried out.

The Regression Model

The multiple regression model is written as

$$Y_i = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_m X_m + \varepsilon_i$$

or

$$Y_i = \sum_j^n \beta_j X_{ij} + \varepsilon_i, \text{ where } i = 1, 2, \dots, m.$$

In this model, the Y s are the observable dependent variable values (Y is assumed to be the random variable). The X s are the fixed, observable independent variables. The coefficients, β s, are the regression parameters to be estimated, and the random variables, ε s, are the errors or differences between observed and predicted Y values.

The only assumptions that are made about the random variables of this model are (a) the expected value of the errors is zero, (b) the expected value of covariance between error terms is zero, and (c) the expected value of each error value squared is some fixed value σ^2 across all values of i .

If $X_{ij}^{(k)}$ represents the values where X is known and $X_{ij}^{(u)}$ represents the values where X is unknown, the regression model equation can be written as

$$Y_i = \sum_j^n \beta_j X_{ij}^{(k)} + \sum_j^n \beta_j X_{ij}^{(u)} + \varepsilon_i.$$

Using matrices, the equation becomes

$$\mathbf{Y} = \mathbf{X}^{(k)}\mathbf{B} + \mathbf{X}^{(u)}\mathbf{B} + \mathbf{E}.$$

The description of the missing-data model explicitly requires the rewriting of the \mathbf{X} matrix in an expanded form and the definition of several auxiliary weighting matrices.

The regression model can now be written in terms of the newly defined matrices as

$$\mathbf{Y} = (\mathbf{I} - \mathbf{C})' \mathbf{X}^* \mathbf{B} + \mathbf{C}' \mathbf{X}^* \mathbf{B} + \mathbf{E},$$

where \mathbf{I} is the identity matrix with dimensions $(mn \times m)$ and \mathbf{C} is the matrix of indicator variables with dimensions $(mn \times m)$. The missing values will be accounted for by elements of the \mathbf{C} matrix. The indicator variables, c_{ij} are specified, where

- c_{ij} is 0 if the value for X_{ij} is known,
- c_{ij} is 1 if the value for X_{ij} is unknown (missing).

We can rewrite some terms that will assist in setting up the missing data method:

$$\mathbf{X}^{(k)} = (\mathbf{I}^* - \mathbf{C})' \mathbf{X}^* \text{ and } \mathbf{X}^{(u)} = \mathbf{C}' \mathbf{X}^*.$$

A Principal-Component Missing-Data Method

This method involves developing a certain kind of average for each person or element in the total sample of observations using the available independent variables. A prediction coefficient will also be developed for each of the independent variables to reflect differences among these variables in scale values. The missing elements in the independent variable matrix will be represented as products of these average scores for persons and the prediction coefficients for the available independent variables.

Let the mathematical model for this missing-data method be

$$\mathbf{X}^{(k)} = \mathbf{A} \mathbf{P}' + \mathbf{G}.$$

$\mathbf{X}^{(k)}$ is an $(m \times n)$ matrix. The \mathbf{A} matrix is $(m \times 1)$, the \mathbf{P} matrix is $(n \times 1)$, and the \mathbf{G} matrix is $(m \times n)$.

The \mathbf{A} matrix consists of a special kind of average constructed from the available independent variables

for each sample element. The \mathbf{P} matrix consists of the prediction coefficients for each of the independent variables, and the \mathbf{G} matrix consists of errors or discrepancies between the matrix of observed values of independent variables, $\mathbf{X}^{(k)}$, and the matrix of predicted values, $\mathbf{A} \mathbf{P}'$.

To find the roots and the subsequent estimates for the missing values, we first form the $\mathbf{X}^{(k)'} \mathbf{X}^{(k)}$ symmetric matrix. We then find the eigenvalues (characteristic roots) for this matrix. A number of different versions of computer programs are available to solve for this characteristic root. In the example given in this write-up, the MATRIX function within SPSS is used. The vector associated with the largest characteristic root is chosen for the vector labeled $\tilde{\mathbf{P}}$. The values of $\tilde{\mathbf{P}}$ are used to obtain the other set of least-squares estimates, $\tilde{\mathbf{A}}$.

Least-squares matrices of estimates, $\tilde{\mathbf{A}}$, are determined using the following formula:

$$\tilde{\mathbf{A}} = \frac{1}{\tilde{\mathbf{P}}' \tilde{\mathbf{P}}} \mathbf{X}^{(k)} \tilde{\mathbf{P}}.$$

The values within vectors $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{P}}$ are then used to set up two matrices, \mathbf{A}_u and \mathbf{P}_u , whose structures are

$$\mathbf{A}_u = \begin{bmatrix} \tilde{a}_1 & 0 & \cdots & 0 \\ \tilde{a}_2 & 0 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ \tilde{a}_m & 0 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & \tilde{a}_1 \\ 0 & 0 & \cdots & \tilde{a}_2 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & \tilde{a}_m \end{bmatrix}$$

$$\mathbf{P}_u = \begin{bmatrix} \tilde{p}_1 & 0 & \cdots & 0 \\ 0 & \tilde{p}_2 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & \tilde{p}_n \end{bmatrix}.$$

$$\mathbf{A}_u = \begin{bmatrix} 3.946 & 0 & \dots & 0 \\ 3.501 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 4.508 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & 3.946 \\ 0 & 0 & \dots & 3.501 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & 4.508 \end{bmatrix}$$

$$\mathbf{P}_u = \begin{bmatrix} .5884 & 0 & 0 \\ 0 & .6921 & 0 \\ 0 & 0 & .4179 \end{bmatrix}$$

MIXED MODELS

A mixed-effects model, or just mixed model, is a statistical model in which the set of predictor variables includes both fixed and random effects. A common application of mixed models is to longitudinal, or repeated measures, data in which the data consist of multiple observations on each subject. Here, observations on different subjects can be treated as independent, but observations on the same subject cannot. The inclusion of random effects in the model induces

a correlation among repeated measures on a given subject. More generally, mixed-effects models are potentially useful any time a practitioner is faced with grouped data, in which observations are correlated within groups but independent across groups.

Whether a predictor term is to be treated as a fixed or random effect depends on the desired scope of inference, as well as the mechanism by which factor levels were chosen for inclusion in the study. If the investigator is concerned only with the factor levels included in the data set, then that factor should be treated as a fixed effect. If the investigator wishes to draw inference about the population from which the observed levels were drawn, the factor should be modeled as a random effect. Alternatively, the analyst can ask, If the experiment were to be repeated, would the observed levels of this factor be the same or possibly different? If the same, then the factor is a fixed effect; otherwise, it should be treated as a random effect.

The mixed model most commonly encountered in applications is the linear mixed-effects (LME) model with normally distributed random effects. A mathematical formulation of the model is given here. Let y_i denote the m_i -dimensional vector of responses for the i th subject in the study, for i going from 1 to M , the total number of subjects. Under the LME model, we have

$$y_i = X_i\beta + Z_i b_i + e_i,$$

where X_i and Z_i are known matrices of dimension m_i by p and m_i by q respectively, β is the p -dimensional vector of unknown fixed effects, b_i is the q -dimensional vector of random effects associated with the i th subject, and e_i is a random error term. The random vectors b_i and e_i , for i going from 1 to M , are assumed to be mutually independent and multivariate normally distributed with a mean of zero. The unknown parameters in this model consist of the vector of coefficients β and whatever parameters determine the covariance matrices of the random vectors b_i and e_i . The usual statistical inference consists of the estimation of unknown parameters and prediction of the unobserved random effects.

Following are two examples of the general LME model. Both data sets are included in the “nlme” library within the free statistical software package R.

Example 1: An Ergometric Experiment

This experiment involved nine human subjects and four types of stools. Each subject was asked to arise from each of the stools, and the effort exerted (Borg scale) was recorded. The data are available with the R package, as the object “ergoStool” in the “nlme” library.

Let y_{ij} denote the effort exerted by the i th subject in arising from the j th stool—that will be the response variable. The model should include two categorical predictors: subject (9 levels) and stool type (4 levels). Are they fixed or random effects? The four stool types were selected by the experimenters; thus, stool type is a fixed effect. As for the subjects, there is no particular interest in these nine individuals; rather, the goal is to study the person-to-person variability in effort required by all persons. The nine subjects are just a random sample from some human population, so subject is a random effect. Another way to reach the same conclusion is to note that if the experiment were repeated, the same four stool types would be used because they are part of the experimental design. But another random sample would yield a different set of nine individuals. Thus, stool type is a fixed effect and subject is a random effect.

A reasonable LME model for this experiment is given by

$$y_{ij} = \beta_j + b_i + e_{ij},$$

where the subject random effects b_1, \dots, b_9 are independent and identically distributed (i.i.d.) as normal with mean 0 and variance σ_b^2 , and the random error terms e_{ij} are i.i.d. as normal with mean 0 and variance σ_e^2 . The model parameters are the four stool means $\beta_1, \beta_2, \beta_3,$ and β_4 , and the variance components σ_b^2 and σ_e^2 .

One of the reasons mixed-effects models are so widely applicable is that they naturally and elegantly induce correlation among repeated measures on the same subject. For the model given here, it can be

shown that this correlation is given by $\sigma_b^2/(\sigma_b^2 + \sigma_e^2)$, which, depending on the values of σ_b^2 and σ_e^2 , can be anything between 0 and 1. Of course, the correlation between measurements on different subjects is 0, as the subjects are assumed to be independent.

In Example 1, we assume an additive effect (i.e., no interaction) between subject and stool type. This may be an unreasonable assumption, but it is necessary for these data because there is only one observation at each subject-stool type combination. The experiment in Example 1 is said to be unreplicated. For replicated experiments, an interaction term can be included in the model. Of course, the interaction between a fixed effect and a random effect is a random effect, as the following example illustrates.

Example 2: An Industrial Experiment

Six workers in a plant were randomly selected, and each worker was tested on each of three different machine types. The data are summarized in an interaction plot (see Figure 1). Each point in the graph represents the average score for a particular worker-machine combination—18 such points total. The position on the horizontal axis indicates the machine, and the six lines correspond to the six workers. That the

Figure 1 Interaction Plot for Example 2, Suggests Machine by Worker Interaction Effect

lines are not parallel indicates the presence of an interaction effect in predicting the response score from the predictor variables machine and worker.

Employing the same logic as in Example 1, we conclude that machine is a fixed effect and worker a random effect—the three machine types were precisely those the experimenter wished to compare, whereas the six workers were drawn at random from a population of plant workers. What about the interaction term? Is that a fixed or a random effect? There are 18 levels of worker-machine combination, and they are only a random sample of those that might have been observed. A different random sample of workers would have yielded different observed levels of worker-machine combination, and thus the interaction term is random. This result is true in general: The interaction between a fixed main effect and a random main effect is a random effect.

Let y_{ijk} denote the score for worker i on machine j in trial k , where i runs from 1 to 6 and j and k go from 1 to 3. A common model for this experiment is given by

$$y_{ijk} = \beta_j + b_i + c_{ij} + e_{ijk},$$

where the random worker effects b_i , the random interaction effects c_{ij} , and the random error terms e_{ijk} are mutually independent, normally distributed with mean 0 and variances σ_b^2 , σ_c^2 , and σ_e^2 , respectively.

According to this model, the scores of a particular worker are positively correlated, with a higher correlation between two tests on the same machine than between tests on different machines. More precisely, it can be shown that the correlation between two tests of the same worker on the same machine is equal to $(\sigma_b^2 + \sigma_c^2)/(\sigma_b^2 + \sigma_c^2 + \sigma_e^2)$, and the correlation between two tests of the same worker but on different machines is equal to $\sigma_b^2/(\sigma_b^2 + \sigma_c^2 + \sigma_e^2)$. Of course, the scores of two different workers are uncorrelated because the workers were tested independently in the experiment.

Estimation

In fitting mixed-effects models to data, we distinguish between the estimation of unknown parameters and

the prediction of unobserved random effects. The parameters in an LME model include the fixed-effects coefficients (the β_j in the examples) and the variance-covariance parameters (the σ^2 terms in the examples). These are unknown but fixed quantities, and they can be estimated from the data using one of the methods discussed below. The unobserved random effects are likewise unknown, and the investigators may wish to make an intelligent guess of their value. Because these are random quantities, this is a problem not of estimation but of prediction.

The two most common approaches to estimation are the methods of maximum likelihood (ML) and restricted maximum likelihood (REML). Both methods are available in the R software, in function “lme” (library “nlme”), with REML as the default method. Some authors have noted the tendency for ML to underestimate the variance components, and thus we will focus on REML in the example.

Example 1 Continued: Estimation

The R commands needed to produce REML estimates are given here. First, we must create an “lme object”—we call it “ergoStool.lme.” On the R command line, enter “library(nlme)” to load the “nlme” library, then “ergoStool.lme <- lme (effort~Type-1, data=ergoStool, random=~1|Subject)” to create the object. Entering the name of the object on the command line produces the following output:

```
> ergoStool.lme
Linear mixed-effects model fit by REML
Data: NULL
Log-restricted-likelihood: -60.5654
Fixed: effort ~ Type - 1
TypeT1 TypeT2 TypeT3 TypeT4
8.555556 12.444444 10.777778 9.222222

Random effects:
Formula: ~1 | Subject
(Intercept) Residual
StdDev: 1.332465 1.100295

Number of Observations: 36
Number of Groups: 9
```

Thus, the REML estimates of β_1 , β_2 , β_3 , and β_4 are 8.56, 12.44, 10.78, and 9.22, respectively. The standard deviations σ_b and σ_e are estimated as 1.33 and 1.10, respectively.

Prediction

The usual method of predicting unobserved random effects is based on an empirical Bayes approach. The method produces the Best Linear Unbiased Predictors, or BLUPs. In R, BLUPs can be obtained from the function “lme,” as we now demonstrate.

Example 1 Continued: Prediction

Once an “lme object” is created in R, the command “random.effects” produces BLUPs of the random effects. For the stool data, the BLUPs based on REML estimates are as follows:

```
> random.effects(ergoStool.lme)
(Intercept)
8 -1.708716e+00
5 -1.495127e+00
4 -8.543581e-01
9 -2.135895e-01
6 -1.912893e-15
3 4.271791e-01
7 4.271791e-01
1 1.708716e+00
2 1.708716e+00
```

We see that Subject 8 rose from the stools with the least effort, and Subject 2 required the greatest effort. BLUPs based on the ML estimates are similar.

Other Mixed-Effects Models

We have thus far discussed the inclusion of random effects only in linear statistical models. Generalized linear models (GLMs), such as the logistic regression model, can also have random effects among the predictors. A GLM with fixed and random effects is called a generalized linear mixed model, or GLMM.

An important application of GLMMs is to item-response models, which are widely used in educational and psychological assessment. The best-known

item-response model is the Rasch model, illustrated here. Suppose 30 students are to take the same 10-question quiz, and let p_{ij} denote the probability of a correct answer by the i th student to the j th question. The Rasch model posits that

$$\log\left(\frac{p_{ij}}{1 - p_{ij}}\right) = b_i - \beta_j,$$

where b_i represents the i th student’s ability, a random effect, and β_j represents the difficulty of the j th question, a fixed effect.

Computing for GLMMs is often challenging and requires high-speed computers and sophisticated algorithms. Indeed, the development of such algorithms is currently an active area of research among statisticians.

Other Software

Although we have used the R software in our examples, many other software packages exist. For example, the MIXED procedure in SAS is a popular alternative to the R “lme” package. S-PLUS is a commercially available package similar to R—the R commands given above will work in S-PLUS as well.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Blitstein, J. L., Murray, D. M., Lytle, L. A., Birnbaum, A. S., & Perry, C. L. (2005). Predictors of violent behavior in an early adolescent cohort: Similarities and differences across genders. *Health Education & Behavior, 32*(2), 175–194.

The authors assessed a cohort of 2,335 students from the Minneapolis, Minnesota, area to identify predictors of violent behavior and to determine whether the predictors varied by gender. The sample was 76% White; boys and girls were equally represented. The majority lived with two parents. A measure of violent behavior collected at the end of the eighth-grade year was entered into Poisson regression against baseline data collected at the beginning of the seventh-grade year. The analysis followed a general linear **mixed model** where there are multiple sources of random variation. Predictors of violent behavior influencing both boys and girls included depressive symptoms, perceived invulnerability to negative future events, paternal nonauthoritative behavior, and drinking alcohol. Additional predictors of violent behavior specific to girls included both risk and protective factors.

MIXTURE MODELS

This entry discusses statistical models involving mixture distributions. As well as being useful in identifying and describing subpopulations within a mixed population, mixture models are useful data analytic tools, providing flexible families of distributions to fit to unusually shaped data. Theoretical advances in the past 30 years, as well as advances in computing technology, have led to the wide use of mixture models in applications as varied as ecology, machine learning, genetics, medical research, psychology, reliability, and survival analysis.

Suppose that $\mathcal{F} = \{F_\theta : \theta \in S\}$ is a parametric family of distributions on a sample space X , and let Q denote a probability distribution defined on the parameter space S . The distribution

$$F_Q = \int F_\theta dQ(\theta)$$

is a mixture distribution. An observation X drawn from F_Q can be thought of as being obtained in a two-step procedure: First a random Θ is drawn from the distribution Q and then conditional on $\Theta = \theta$, X is drawn from the distribution F_θ . Suppose we have a random sample X_1, \dots, X_n from F_Q . We can view this as a missing data problem in that the “full data” consist of pairs $(X_1, \Theta_1), \dots, (X_n, \Theta_n)$, with $\Theta_i \sim Q$ and $X_i | \Theta_i = \theta \sim F_\theta$ but then only the first member X_i of each pair is observed; the labels Θ_i are hidden.

If the distribution Q is discrete with a finite number k of mass points $\theta_1, \dots, \theta_k$, then we can write

$$F_Q = \sum_{j=1}^k q_j F_{\theta_j},$$

where $q_j = Q\{\theta_j\}$. The distribution F_Q is called a finite mixture distribution, the distributions F_θ are the component distributions, and the q_j are the component weights.

There are several reasons why mixture distributions, and in particular finite mixture distributions, are of interest. First, there are many applications where the mechanism generating the data is truly of a mixture form; we sample from a population that we know or suspect is made up of several relatively homogeneous subpopulations, in each of which the data of interest have the component distributions. We may wish to draw inferences, based on such a sample, relating to certain characteristics of the component subpopulations (parameters θ_j) or the relative proportions (parameters q_j) of the population in each subpopulation, or both. Even the precise number of subpopulations may be unknown to us. An example is a population of fish, where the subpopulations are the yearly spawnings. Interest may focus on the relative abundances of each spawning, an unusually low

proportion possibly corresponding to unfavorable conditions one year.

Second, even when there is no a priori reason to anticipate a mixture distribution, families of mixture distributions, in particular finite mixtures, provide us with particularly flexible families of probability distributions and densities that can be used to fit to unusually shaped (skewed, long-tailed, multimodal) data that would be difficult to describe otherwise with a more conventional parametric family of densities. Also, such a fit is often comparable in flexibility to a fully nonparametric estimate but structurally simpler, and often requires less subjective input, for example, in terms of choosing smoothing parameters. As another example, it has been shown that the very skewed log-normal density often can be well approximated by a two- or three-component mixture of normals, each with possibly different means and variances.

Formal interest in finite mixtures dates back to at least Karl Pearson’s laborious method-of-moments fitting of a two-component normal mixture to data on physical dimensions of crabs in the late 19th century. The mathematical difficulties inherent in fitting mixtures have been greatly eased with the advent of the Expectation-Minimization (EM) algorithm in the 1970s. This algorithm yields an iterative method for computing maximum likelihood estimates (or very accurate approximations thereof) in a general missing-data situation. As mentioned above, mixtures have a natural missing-data interpretation and so the EM algorithm, together with improved computing technology, has made the task of fitting mixtures models to data much easier, leading to a renewal of interest in them.

Fitting Finite Mixtures Using Maximum Likelihood

The EM algorithm generates a sequence of parameter estimates, each of which is guaranteed to give a larger likelihood than its predecessor. It can be used whenever the original log-likelihood $\log f_X(x; \theta)$ is difficult to maximize over θ for given x , but $f_X(x; \theta)$ can be expressed as the marginal distribution of X in a pair

(X, J) whose corresponding log-likelihood $\log f_{XJ}(x, j; \theta)$ is easier to maximize over θ for a given x and j . Given a “current estimate” θ_0 , the next in the sequence, θ_1 , is defined as the maximizer of the EM-log-likelihood $\ell_{EM}(\theta; x)$, which is defined as the conditional expectation of $\log f_{XJ}(x, J; \theta)$ over the “missing data” J given $X = x$ computed under θ_0 ; that is,

$$\ell_{EM}(\theta; x) = E \log f(x, J; \theta) \text{ where } J \text{ has density } f_{J|X}(j | x; \theta_0) = f_{XJ}(x, j; \theta_0) / f_X(x; \theta_0).$$

It is guaranteed that $\log f_X(x; \theta_1) \geq \log f_X(x; \theta_0)$.

If we wish to fit a finite mixture

$$f(x; Q) = \sum_{j=1}^k q_j f(x; \theta_j)$$

where the number of components k is known, the EM algorithm works in almost the same way for either one or both of the q_j s or θ_j s unknown. We regard the x_i s as the observed first members of random pairs $(X_1, J_1), \dots, (X_n, J_n)$, but the J_i s are unobserved. We can write the full data log-likelihood as

$$\sum_{i=1}^n \sum_{j=1}^k 1\{J_i = j\} \{\log q_j + \log f(x_i; \theta_j)\}$$

(here $q_j = P\{J_i = j\}$). We now outline how to go from an initial set of estimates $q_{01}, \dots, q_{0k}, \theta_{01}, \dots, \theta_{0k}$ to the next in the EM sequence $q_{11}, \dots, q_{1k}, \theta_{11}, \dots, \theta_{1k}$. If some of these values are known, then they of course remain unchanged. The first step is to compute the posterior probabilities

$$\begin{aligned} \pi_{ji} &= P\{J_i = j | X_i = x_i\} \text{ computed under the } q_{0j}\text{s and } \theta_{0j}\text{s} \\ &= \frac{q_{0j} f(x_i; \theta_{0j})}{\sum_{j=1}^k q_{0j} f(x_i; \theta_{0j})}. \end{aligned}$$

The EM-log-likelihood is then obtained by replacing the $1\{J_i = j\}$ s in the full data log-likelihood with the π_{ji} s; note that the EM-log-likelihood thus obtained separates into a term involving the q_j s only and one involving the θ_j s only.

If the q_j s are unknown, we maximize

$$\sum_{j=1}^k \log q_j \left\{ \sum_{i=1}^n \pi_{j|i} \right\}$$

with respect to the q_j s; this is maximized at

$$q_{1j} = n^{-1} \sum_{i=1}^n \pi_{j|i},$$

simply the averages of the posterior probabilities over the data.

If the θ_j s are unknown, we maximize

$$\sum_{j=1}^k \sum_{i=1}^n \pi_{j|i} \log f(x_i; \theta_j)$$

with respect to the θ_j s. Differentiating with respect to each θ_j and setting to zero yields k weighted score equations:

$$\sum_{i=1}^n \pi_{j|i} \frac{\partial \log f(x_i; \theta_j)}{\partial \theta_j} = 0.$$

In many common models, these are easily solved. For example, in one-parameter exponential families of the form $f(x; \theta) = e^{\theta x - K(\theta)} f_0(x)$ (e.g., normal with known variance, Poisson), let $\hat{\theta}(t)$ be that value of θ that solves $K'(\theta) = t$. Then, for each j , one can explicitly find the EM update as

$$\theta_{j1} = \hat{\theta} \left(\frac{\sum_{i=1}^n \pi_{j|i} x_i}{\sum_{i=1}^n \pi_{j|i}} \right),$$

a known function of a $\pi_{j|i}$ -weighted average of the x_i s.

Further Inferences

Once the model has been fitted, further inferences may consist of confidence intervals for or hypothesis tests concerning the component parameters θ_j and/or the mixing proportions q_j . When the model is correctly specified (i.e., there really are k components and all the q_j s are positive), the parameter estimates behave more or less in a standard fashion: They are

asymptotically normal with an estimable covariance matrix, subject to the component densities $f(x; \theta_j)$ being suitably regular. Hence, confidence regions can be computed in a standard fashion, bearing in mind the restrictions on the q_j s: They are nonnegative and add to 1. In addition, one should be aware that when the weights q_j are small or the parameters θ_j for two or more groups are similar, there is a sharp loss of estimating efficiency as well as a good reason to be doubtful of accuracy of asymptotic approximations. This occurs because of the near loss of identifiability of the parameters near the boundaries of the parameter space.

Hypothesis tests are perhaps not so standard, at least not for tests concerning the q_j s. If one wishes to test whether an estimate \hat{q}_j is significantly different from zero, the nonnegativity constraints have a significant impact, at least when it comes to using large-sample χ^2 approximations to the p values. Because such a hypothesis constrains a parameter to be on the boundary of the parameter space, the asymptotic distribution of twice the log-likelihood ratio will be a mixture of χ^2 distributions rather than a pure χ^2 , assuming the model is otherwise suitably regular. In such a case, a parametric bootstrap approach can be used to obtain an approximate p value.

An Unknown Number of Components, or Completely Unknown Q

If the number of components of a putatively finite mixture is unknown, we are essentially on the same footing as knowing absolutely nothing about Q , for reasons we now explain.

For any given data set x_1, \dots, x_n with $d \leq n$ distinct x_j s and any prespecified Q , no matter whether it is discrete or continuous, so long as the likelihoods $f(x; \theta)$ are bounded in θ , we can find a discrete \tilde{Q} with $m \leq d$ support points such that Q and \tilde{Q} provide exactly the same density values at the observed data. That is, for any mixing distribution Q , there is a possibly different \tilde{Q} yielding a finite mixture such that Q and \tilde{Q} cannot be distinguished, at least in terms of the data x_1, \dots, x_n . So it suffices to restrict attention to such \tilde{Q} s.

An implication of this, when the likelihoods are bounded in θ , is that the maximum likelihood estimate of Q over all distributions, which we denote by \hat{Q} , exists and is finite with at most d (the number of distinct x_i s) support points. So we need never leave the realm of finite mixtures in this setting.

This is not to say, however, that an estimate of an unknown k is readily available. The number of components in \hat{Q} may be an overestimate in that some support points (respectively mixing proportions) may be so close together (small) that combining them into a single point (removing them) hardly decreases the likelihood. This and other issues related to trying to infer something about the number of components in a mixture, like hypothesis tests concerning k , are difficult problems. Some problems are still open, and others have solutions that are possibly too complex to be useful.

The Nonparametric Estimate of Q

When the estimate \hat{Q} discussed above exists, it is discrete with at most d support points. Hence, a strategy for computing it is to try to fit a finite mixture with d components using the EM algorithm. In many situations, this yields a sensible result. More sophisticated algorithms exist, however, that are related to the following gradient function characterization.

The gradient function

$$D_Q(\theta) = \sum_{i=1}^n \left[\frac{f(x_i; \theta)}{f(x_i; Q)} - 1 \right]$$

measures the rate of increase in the log-likelihood if we remove a small amount of weight from the mixing distribution Q and put it at the point θ . Hence, for a candidate estimate Q , if for some θ we have $D_Q(\theta) > 0$, we know that we can increase the log-likelihood by putting some weight at θ .

In light of this, the following result is not surprising: If the nonparametric maximum likelihood estimate \hat{Q} exists, then $D_{\hat{Q}}(\theta) \leq 0$ for all θ , and the support points of \hat{Q} are included in the set of values θ where $D_{\hat{Q}}(\theta) = 0$. The fact that $D_{\hat{Q}}(\theta) > 0$ for no θ makes sense; moving mass around from \hat{Q} to any other θ cannot increase the likelihood.

The nonparametric version of the mixture model falls into the class of convex models, a subject with its own independent literature. Often, convex models can be written as mixture models. For example, a distribution function that is concave on the positive half-line can also be written as a nonparametric mixture of the form $\int f(x; \theta) dQ(\theta)$ with component density $f(x; \theta) = 1\{0 < x < \theta\}/\theta$. One can deduce that the nonparametric likelihood estimator is the least concave majorant of the empirical distribution function using the above gradient characterization.

MIXTURES OF EXPERTS

It is often the case that the analysis of the values of a set of random variables becomes simpler if one posits that these variables are related to another set of variables, called latent variables, whose values are unobserved. Consider, for example, the two-dimensional data in Figure 1. This data set is complicated in the sense that it is multimodal and, thus, cannot be summarized by a standard distribution such as those comprising the exponential family. A way of simplifying the analysis is by assuming that the distribution of these data is a combination of two simple distributions, namely, two Gaussian distributions. Each data item was generated as follows. First, a value for a latent variable was sampled from a Bernoulli distribution. Next, if the latent variable was set to 0, then the data item was sampled from the first Gaussian distribution

(e.g., with mean vector $[3 \ 3]^T$); if the latent variable was set to 1, then the data item was sampled from the second Gaussian distribution (with mean vector $[7 \ 7]^T$). Although the value of the latent variable is not observed, it is easy to use Bayes's rule to compute the distribution of the variable given the data item.

This model is a latent variable model known as a mixture model. Mixture models provide a principled way of combining two or more simple distributions (e.g., unimodal distributions such as Gaussian distributions) into a single complicated (e.g., multimodal) distribution. As this example illustrates, mixture models are “piecewise estimators” in the sense that different components are used to summarize different subsets of the data. The subsets do not, however, have hard boundaries; as discussed below, a data item might be a member of multiple subsets simultaneously.

Mixtures-of-experts (ME) models are an extension of mixture models. They differ from conventional mixture models in that their mixture components are conditional probability distributions. Consequently, they are suitable for summarizing data sets in which the distribution of output or response variables depends on the values of input or covariate variables. Such data sets arise in the context of regression or classification tasks, for example.

Figure 1 Two-Dimensional Data to Be Summarized

ME models perform tasks using a “divide and conquer” strategy—complex tasks are decomposed into simpler subtasks. ME models can be characterized as fitting piecewise models to the data. The data are assumed to form a countable set of paired variables $X = \{(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})\}_{t=1}^T$, where \mathbf{x} is a vector of explanatory variables, also referred to as covariates, and \mathbf{y} is a vector of responses. ME models divide the covariate space, meaning the space of all possible values of the explanatory variables, into regions, and then they fit simple surfaces to the data that fall in each region. Unlike many other piecewise approximators, these models use regions that are not disjoint. The regions have “soft” boundaries, meaning that data points may lie simultaneously in multiple regions. In addition, the boundaries between regions are themselves simple parameterized surfaces whose parameter values are estimated from the data.

ME models combine properties of generalized linear models with those of mixture models. Like generalized linear models, they are used to model the relationship between a set of covariate and a set of response variables. Unlike standard generalized linear models, however, they assume that the conditional distribution of the responses (given the covariates) is a finite mixture distribution. Because ME models assume a finite mixture distribution, they provide a motivated alternative to nonparametric models and provide a richer class of distributions than standard generalized linear models.

Mixtures-of-Experts Model

To define the mixtures-of-experts model, suppose that the process generating the data is decomposable into a set of subprocesses defined on possibly overlapping regions of the covariate space. For each data item, a subprocess is selected, conditional on the covariate $\mathbf{x}^{(t)}$, and the selected subprocess maps $\mathbf{x}^{(t)}$ to the response $\mathbf{y}^{(t)}$. Specifically, for each covariate $\mathbf{x}^{(t)}$,

- a label i is selected from a multinomial distribution with probability $P(i | \mathbf{x}^{(t)}, V)$, where $V = [\mathbf{v}_1, \dots, \mathbf{v}_I]$ is the matrix of parameters underlying the multinomial distribution

- a response $\mathbf{y}^{(t)}$ is generated with probability $P(\mathbf{y}^{(t)} | \mathbf{x}^{(t)}, U_i, \Phi_i)$, where U_i is a parameter matrix and Φ_i represents other parameters, for $i = 1, \dots, I$.

To explicitly relate this approach to the generalized linear models framework, it is supposed that the conditional probability distribution $P(\mathbf{y}^{(t)} | \mathbf{x}^{(t)}, U_i, \Phi_i)$ is a member of the exponential family of distributions. The expected conditional value of the response $\mathbf{y}^{(t)}$, denoted $\boldsymbol{\mu}_i^{(t)}$, is defined to be a generalized linear function f of $\mathbf{x}^{(t)}$, as well as the parameter matrix U_i . The quantities $\boldsymbol{\eta}_i = f^{-1}(\boldsymbol{\mu}_i)$ and Φ_i are, respectively, the natural parameter and dispersion parameter of the response's distribution $P(\mathbf{y}^{(t)} | \mathbf{x}^{(t)}, U_i, \Phi_i)$. The total probability of generating the response $\mathbf{y}^{(t)}$ from $\mathbf{x}^{(t)}$ is given by the mixture density

$$P(\mathbf{y}^{(t)} | \mathbf{x}^{(t)}, \Theta) = \sum_i P(i | \mathbf{x}^{(t)}, V) P(\mathbf{y}^{(t)} | \mathbf{x}^{(t)}, U_i, \Phi_i), \quad (1)$$

where $\Theta = [\mathbf{v}_1, \dots, \mathbf{v}_p, U_1, \dots, U_p, \Phi_1, \dots, \Phi_p]^T$ is the matrix of the parameters. Assuming independently distributed responses, the total probability of the data set X is the product of T such densities, with likelihood

$$L(\Theta | X) = \prod_t \sum_i P(i | \mathbf{x}^{(t)}, V) P(\mathbf{y}^{(t)} | \mathbf{x}^{(t)}, U_i, \Phi_i). \quad (2)$$

Figure 2 presents a graphical representation of the mixtures of experts model. The model consists of n modules referred to as *expert networks*. These networks approximate the data within each region of the covariate space: Expert network i maps its input, the covariate vector \mathbf{x} , to an output vector $\boldsymbol{\mu}_i$. It is supposed that different expert networks are appropriate in different regions of the covariate space. Thus, the model requires a module, referred to as a *gating network*, that identifies for any covariate \mathbf{x} the expert or mixture of experts whose output is most likely to approximate the corresponding response vector \mathbf{y} . The gating network outputs are a set of scalar coefficients g_i that appropriately weights the contributions of each expert. For each covariate \mathbf{x} , these coefficients sum to one and are constrained to be

nonnegative. The total output of the mixtures of experts model, given by

$$\boldsymbol{\mu} = \sum_{i=1}^n g_i \boldsymbol{\mu}_i, \quad (3)$$

is a combination of the expert outputs for each \mathbf{x} .

From the point of view of mixture modeling, we identify the gating network with the selection of a particular subprocess. That is, the gating outputs g_i are interpreted as the covariate dependent, multinomial probabilities of selecting subprocess i . Different expert networks are identified with different subprocesses, and each expert models the covariate dependent distributions corresponding to its particular subprocess.

The expert networks map their inputs to their outputs in a two-stage process. During the first stage, each expert multiplies the covariate vector \mathbf{x} by a matrix of parameters. (The vector \mathbf{x} is required to include a fixed component of one to allow for an intercept term.) For expert i , the matrix is denoted as U_i and the resulting vector is denoted as $\boldsymbol{\eta}_i$, where

$$\boldsymbol{\eta}_i = U_i \mathbf{x}. \quad (4)$$

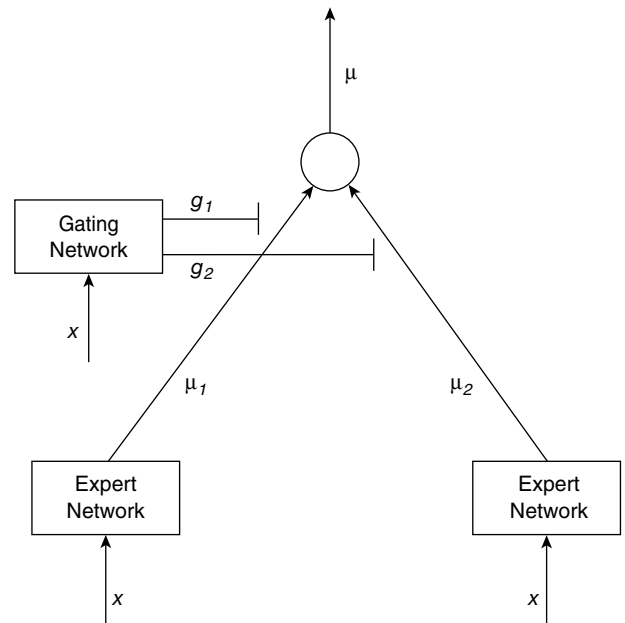

Figure 2 A Mixture-of-Experts Model

During the second stage, η_i is mapped to the expert output μ_i by a monotonic, continuous nonlinear function f .

The selection of the nonlinear function f is based on the nature of the problem. For regression problems, f may be taken as the identity function (i.e., the experts are linear) and the probabilistic component of the model may be Gaussian. In this case, the likelihood is a mixture of Gaussians:

$$L(\Theta | X) = \prod_t \sum_i g_i^{(t)} |\Sigma_i|^{-\frac{1}{2}} e^{-\frac{1}{2}[\mathbf{y}^{(t)} - \mu_i^{(t)}]^T \Sigma_i^{-1} [\mathbf{y}^{(t)} - \mu_i^{(t)}]}. \quad (5)$$

The expert output $\mu_i^{(t)}$ and expert dispersion parameter Σ_i are the mean and covariance matrix of expert i 's Gaussian distribution for response $\mathbf{y}^{(t)}$ given covariate $\mathbf{x}^{(t)}$. The output of the entire model $\mu^{(t)}$ is interpreted as the expected value of $\mathbf{y}^{(t)}$ given $\mathbf{x}^{(t)}$.

For binary classification problems, f may be the logistic function

$$\mu_i = \frac{e^{\eta_i}}{1 + e^{\eta_i}}. \quad (6)$$

In this case, η_i may be interpreted as the log-odds of "success" under a Bernoulli probability model. The probabilistic component of the model is generally assumed to be the Bernoulli distribution. The likelihood is a mixture of Bernoulli densities:

$$L(\Theta | X) = \prod_t \sum_i g_i^{(t)} [\mu_i^{(t)}]^{y^{(t)}} [1 - \mu_i^{(t)}]^{1-y^{(t)}}. \quad (7)$$

The quantity $\mu_i^{(t)}$ is expert i 's conditional probability of classifying the covariate $\mathbf{x}^{(t)}$ as success, and μ is the expected success of $\mathbf{x}^{(t)}$. Other problems (e.g., multiway classification, counting, rate estimation, survival estimation) may require other choices for f . In all cases, the inverse of f is taken to be the canonical link function for the appropriate probability model.

The gating network also forms its outputs in two stages. During the linear stage, it computes the

intermediate variables ξ_i as the inner product of the covariate vector \mathbf{x} and the vector of parameters \mathbf{v}_i :

$$\xi_i = \mathbf{v}_i^T \mathbf{x}. \quad (8)$$

The ξ_i are mapped to the gating outputs g_i during the nonlinear stage. This mapping is performed by using a generalization of the logistic function:

$$g_i = \frac{e^{\xi_i}}{\sum_j e^{\xi_j}}. \quad (9)$$

In the neural network literature, this function is known as the *softmax function*. Note that the inverse of this function is the canonical link for a multinomial response model.

Maximum likelihood estimates of an ME model's parameter values can be obtained using the Expectation-Maximization algorithm. Alternatively, Bayesian inference regarding an ME model's parameters can be performed using Markov chain Monte Carlo methods. Furthermore, the basic ME model can be extended to a hierarchical mixtures-of-experts model that divides tasks into subtasks, and subtasks into sub-subtasks. The recursive nature of this hierarchical extension makes it an efficient and appealing model for many data sets.

MODE

The mode is one characteristic of a distribution. It is the most frequently occurring value in a group of values. The mode can be an informative description when one value occurs noticeably more often than other values. In addition, the mode is the only measure of average, or central tendency, that is appropriate for nominal (categorical) data.

For example, the age distribution in a group of 12 children is 3, 3, 4, 4, 4, 4, 4, 5, 6, 6, 7, and 8. To compute the mode, the frequency of all occurring values has to be calculated.

Value	Frequency
Age 3	2
Age 4	5
Age 5	1
Age 6	2
Age 7	1
Age 8	1

The value that occurs most frequently is a mode of the distribution. In this example, 4 is the modal age of the children. The mode tells us which age occurred more often than others.

In distributions of continuous variables, the mode can be computed as the midpoint of the histogram with the highest peak. It can be useful to revert to modal classes, sometimes called “bins” (e.g., a class of values between 1.1 and 2, 2.1 and 3), which can subsume the individual values 1.23, 1.76, 2.11, or 2.89. Note that this can cause ambiguity, because the choice of class boundaries can have a dramatic effect on the mode.

A distribution that has two peaks is called *bimodal*; when there are more than two peaks, it is called *multimodal*.

For the distribution to be bimodal, the two peaks do not necessarily have to be of equal height.

More About the Mode

- A histogram is an easy method to spot modes.
- If no value occurs more often than another in the group of values, any and every value can be considered a mode of the distribution.
- The mode is independent of the range and the shape of distribution of the represented values. Unlike the mean, it is not affected by extreme values because it does not take other values of the distribution into account. If three people had a score of 3 on a test, the mode is 3 regardless of the fact that other people’s test scores ranged from 1 to 100 (because only one or two people had the same score).

MODERATOR VARIABLE

A moderator variable is an independent or predictor variable (e.g., Z) that interacts with another independent or predictor variable (e.g., X) in predicting scores on and accounting for variance in a dependent or predicted variable (e.g., Y). Note that the terms *independent variable* and *dependent variable* are appropriate only in the case of experimental research. In nonexperimental research, the appropriate, analogous terms are *predictor variable* and *predicted variable*.

Moderator variables (referred to hereinafter as moderators) imply conditional relations. That is, the strength and/or form (e.g., linear, quadratic) of the relation between X and Y varies as a function of the value of the moderator, Z . There are many examples of moderators in both theory and research in such disciplines as psychology, sociology, management, education, political science, biology, epidemiology, and medicine. For instance, in industrial and organizational psychology, extant theory specifies that the relation between ability and performance is moderated by motivation. The greater the level of motivation, the stronger the relation between ability and performance.

By studying moderators, researchers learn about how relations between variables of interest vary across levels of the moderator. Interestingly, it has been argued that the amount of progress in any discipline can be indexed by the degree to which its theory and research have considered the role of moderators.

An Important Distinction

A review of the literature reveals that moderators are often confused with mediator variables (referred to below as mediators). In contrast to the just noted role

Figure 1 Illustration of a Mediating Effect

played by moderators, mediators transmit the effects of independent variables to dependent variables. This is illustrated in the causal chain shown in Figure 1, which depicts M as a mediator of the relation between X and Y . There are many examples of mediation. In psychology, for instance, stress (M) has been shown to mediate the relation between stressors (X) and strain (Y).

Strategies for Detecting Moderators

Over the years, a number of strategies have been proposed for the detection and description of moderators. Unfortunately, many strategies are unsound (e.g., single group validity). In addition, others (e.g., comparing correlation coefficients for artificially created subgroups) have lower levels of statistical power than others (e.g., moderated multiple regression). In the interest of brevity, only three strategies are described here: (a) the analysis of variance based test for an interaction, (b) the multiple regression based test for an interaction, and (c) the test for the homogeneity of correlation coefficients.

The Analysis of Variance Strategy

A commonly used technique for testing interaction effects in *experimental* research is analysis of variance (ANOVA). Assuming a 2×2 experimental design involving independent variables A (a_1, a_2, \dots, a_j) and B (b_1, b_2, \dots, b_k), ANOVA tests for an interaction by determining if the $A \times B$ effect explains variance over and above the additive effects of A and B . The respective population and sample effect models for a two-way ANOVA are as follows:

$$y_{ijk} = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk} + e_{ijk}$$

$$y_{ijk} = y + a_j + b_k + (ab)_{jk} + e_{ijk}$$

In terms of the population model, a main effect of A is implied by the rejection of the null hypothesis of $\alpha_j = 0$, a main effect of B is indicated by the rejection of the null hypothesis of $\beta_j = 0$, and an interaction effect is signaled by the rejection of the null hypothesis of $(\alpha\beta)_{jk} = 0$.

Figure 2 shows a plot of cell means for a 2×2 experimental design in which (a) there are main effects for both A and B , and (b) there is an $A \times B$ (interaction) effect. In terms of moderation, the effect of A on Y is stronger at B_2 than B_1 , as is suggested by the fact that the line at B_2 has a steeper slope than the line at B_1 .

The Moderated Regression Strategy

In nonexperimental research, moderated multiple regression (MMR) is an appropriate and commonly used strategy for testing moderating effects. Note that MMR also may be used for the same purposes when a researcher is dealing with data from an experimental study. It merits adding that when MMR is used for the analysis of data from nonexperimental research, the term *effects* is used in a statistical (model testing) sense, not to imply that causal relations are being tested.

The MMR strategy relies on the test of a linear model having terms for hypothesized main (X , Z) and interactive ($X \times Z$) effects. A sample-based regression

equation for a model involving predictors X and Z (the hypothesized moderator) and a product term that carries information about the interaction (XZ) is as follows:

$$\hat{Y} = b_0 + b_1X + b_2Z + b_3XZ.$$

It is important that X and Z scores be centered (e.g., standardized) prior to the computation of the $X \times Z$ product term. Moderation is signaled by the rejection of the null hypothesis of $\beta_3 = 0$. This hypothesis is tested using the sample based regression coefficient for b_3 in the just noted equation.

The moderator (Z) can be nominal (k groups) or continuous. When nominal, the moderator is represented in the regression equation uses by $k - 1$ dummy variables. For example, if the moderator is sex (e.g., female, male), Z is represented in the regression equation by a single dummy variable. When Z is continuous, it is represented in the regression equation by a single variable.

Information produced by an MMR analysis can be used to show the nature of the moderating effect. Figure 3 illustrates the regression lines for a discrete moderator. As can be seen in the figure, the slope of the regression line is steeper when Z equals 1 than when it equals zero. Figure 4 depicts the regression surface for a continuous moderator. Regression lines are shown for four illustrative levels of Z . Note that the greater the value of Z , the steeper the slope of the Y on X regression.

Figure 2 Interaction Effect for a 2×2 Experimental Study

Figure 3 Moderating Effect for a Discrete Moderator in a Nonexperimental Study

Figure 4 Moderating Effect for a Continuous Moderator in a Nonexperimental Study

The Homogeneity of Correlation Coefficients Strategy

When a moderator is nominally scaled naturally (e.g., fields of psychology, religious sects), moderating effects can be assessed by testing the equality of XY correlation coefficients for k groups. The null hypothesis is as follows:

$$H_0 : \rho_1 = \rho_2 = \rho_3 = \dots = \rho_k.$$

This hypothesis is tested using sample estimates of the k population correlation coefficients. A moderating effect is inferred when the test allows for the rejection of the null hypothesis.

Some Other Considerations

This entry provides a brief summary of some major issues surrounding the detection of moderators and the description of moderating effects. There are a host of other issues surrounding moderators. For example, the ability to detect moderators is a function of such factors as sample size, strength of moderating effect, reliability of measures of the moderator, range restriction on the moderator, and the interaction of several of these factors. Readers are encouraged to learn more

about these issues before doing research that involves moderators.

MONTE CARLO METHODS

The probability of an obverse surfacing was estimated by George Louis Leclerc, Comte de Buffon (1707–1788), by flipping a coin 4,040 times. He obtained 2,048 heads, which produced an estimate of $\frac{2048}{4040} = 50.69\%$. As part of a genetics experiment, Walter

Frank Raphael Weldon (1860–1906) tossed 12 dice at the same time, recorded the results, and repeated the process 26,306 times. (Due to the tediousness and error-prone method of physically counting the results, Karl Pearson (1857–1936) supported the veracity of the outcome with the χ^2 test.) William Sealy Gosset used repeated sampling with slips of stiff paper to find the distribution of the correlation coefficient and to support the development of the t distribution.

These experiments are examples of the Monte Carlo method. It is a resampling approximation technique. The name is derived from the casinos of the principality of Monte Carlo.

The utility and accuracy of the Monte Carlo method was greatly enhanced with the advent of the computer and software. Stanislaw Marcin Ulam (1909–1984) wrote a Monte Carlo computer simulation of the solitaire card game in 1946. In a more important application, along with his boss John (János) von Neumann (1903–1957) and Enrico Fermi (1901–1954), Ulam estimated the eigenvalues for the Schrödinger equation (Erwin Schrödinger, 1887–1961) using Monte Carlo methods. Subsequently, he developed a Monte Carlo computer simulation of random neutron diffusion in fissile material to construct dampers and shields for the atomic bomb as part of the Manhattan Project.

Pseudo Random Number Generators

Initially, the basis of the Monte Carlo method was the use of uniform pseudo random numbers on the interval [0,1]. Today, Monte Carlo methods (plural) apply to the use of any pseudo random number generator, such as variates obtained from the exponential distribution, or repeated sampling from large, real data sets.

Programming Environment

Since its commercial release by the IBM Corporation in 1957, FORTRAN (FORmula TRANslator) remains the fastest high-level programming language for Monte Carlo simulation work. This is because execution time is an essential component for realistic, applied problems. Higher level programming environments,

such as SAS IML, S+, and Lucent Technology’s R (which is available at no cost from <http://www.rproject.org/>), are serviceable for simple Monte Carlo simulations and classroom demonstrations.

Simulating Tossing a Die

A Monte Carlo computer solution easily simulates the tossing of a fair die with a variate drawn from a uniform [0,1] pseudo random number generator and a table of assigned outcomes, such as indicated in Table 1. For example, if the value obtained from the generator is .1770, it simulates the throwing of a fair die and obtaining two spots. Counting the results of repeating this simulation is tremendously faster and more accurate than physically tossing a die.

Estimating the Area of a Regular Figure

Consider the area (A) of a well-defined geometric shape, such as that in the shaded area depicted in Figure 1. The area of interest is bounded by the two equations $f(x) = x$ and $g(x) = x^2$ over the interval $(0, 1)$.

The shaded area can be estimated via the Monte Carlo method by repeatedly drawing pairs $(x$ and $y)$ of pseudo random uniform numbers. If $x > y$, the coordinate pair (x, y) is below the line $f(x) = x$. If $x^2 < y$, then (x, y) is above $g(x) = x^2$. If both conditions are true, the ordered pair (x, y) falls within the shaded region. The number of times the paired coordinate (x, y) falls in the shaded region, divided by the total number of

Figure 1 Estimating Area

Source: Sawilowsky & Fahoome (2003, p. 120).

iterations, multiplied by the total area (which in this case is 1.0), is an estimate of the area of the shaded region.

By inspection, $f(x)$ bisects the unit square, meaning that the area above or below the diagonal line $f(x) = x$ is .5. The Monte Carlo results indicate the area below $g(x) = x^2 \approx .33$, and the shaded area (A) $\approx .17$.

Estimating the Area of an Irregular Figure

The shaded area in the previous example is obtained easily and precisely through elementary calculus. The Monte Carlo method is useful, however, in determining the area of an irregular figure where the calculus either proves difficult or is intractable. For example, consider a unit square with an inscribed arbitrary figure with a curvilinear boundary. The figure need not be contiguous.

Draw a pair (x and y) of pseudo random uniform $[0,1]$ numbers to represent a coordinate pair (x,y) . If it falls within the inscribed figure, increase a counter (N'). Repeat the process N times. The ratio $\frac{N'}{N}$ is the Monte Carlo estimate of the area of the inscribed figure.

Estimating Irrational Numbers

Monte Carlo methods can be used to estimate irrational numbers, such as π . In 1777, Buffon posed a problem pertaining to a surface marked with parallel

lines, with the distance d from each line. If a needle of length $L < d$ is dropped at random on the surface, the probability that it will cross a line is

$$\int_0^\pi \int_0^{L \sin \theta} \frac{1}{d\pi} dA d\theta,$$

where θ is the angle between the needle and the lines. This leads to a Monte Carlo estimate of π as

$$\pi = \frac{2nL}{Md}.$$

Buffon dropped a needle 2,000 times on the above-described surface. Measurements yielded an estimate for $\pi = 3.143$.

An estimate of π may be obtained more simply via Monte Carlo methods on a computer by considering Figure 2. It represents the upper right quadrant of a Cartesian plane where a sector of a circle with the center at $(0, 0)$ has been inscribed in a unit square. Obtain two pseudo random uniform variates on the interval $(0, 1)$, letting the first value represent the x coordinate and the second value represent the y coordinate (x, y) .

The radius of the circle is 1. The length L of the line from the origin to the coordinate pair is determined by

Figure 2 Estimating π

Source: Sawilowsky & Fahoome (2003, p. 123).

the Pythagorean theorem $L = \sqrt{x^2 + y^2}$. If the length is less than the radius of 1, then the point lies within the circle. Otherwise, it is outside the circle but within the square.

The area of a circle, $A = \pi r^2$, reduces to $A = \pi$ when the radius is 1. Because the sector represents 1/4 of a circle, π can be estimated by multiplying this area by 4. As the number of repetitions (e.g., pairs of pseudo random uniform variates) increases, the accuracy of the estimate of π increases.

Monte Carlo Option in Statistics Software Packages

Modern statistical practice has been heavily affected by the availability of high-speed computers that permit hypothesis tests based on permutation methods. However, many statistical problems remain beyond current capabilities. An alternative is to conduct an approximate permutation statistic, which is based on a specific subset of all possible permutations.

Approximate permutation methods require keeping a record of permutations that have been used in the analysis, which can be as burdensome as performing all possible permutations. An estimation procedure that is easily implemented is a Monte Carlo option, where a subset of permutations are randomly selected. Although there may be some overlapping of selected permutations, as the number of repetitions increases, the impact of duplicated permutations becomes trivial.

Many statistical software packages have a Monte Carlo option, such as StatXact, SAS, and SPSS. Subroutines (called macros) can be written for Minitab, and well as for spreadsheet software such as Excel. For example, to compute a stratified 2 × C Wilcoxon Mann Whitney test using the Monte Carlo option in StatXact, select Statistics | 2 × C Tables | Exact using Monte Carlo | OK.

Accuracy of Monte Carlo

Reconsider the problem of estimating the area (A) of an irregular figure. As $N \rightarrow \infty \frac{N'}{N} \rightarrow A$. Because

$$\text{error} \approx \sqrt{\frac{A(1 - A)}{N}},$$

N must increase by a factor of 10^2 to obtain a new significant digit. Sobol recommended the Monte Carlo method where the desired level of accuracy is no less than 5%–10%, because an increase in N by a factor of 10^2 was somewhat daunting in the early years of computing. However, increasing the number of repetitions is trivial with modern computers and software, permitting nearly any desired level of accuracy.

In general, stochastic (and nonstochastic) Monte Carlo studies can be reduced to

$$\bar{\theta} = \frac{1}{n} \sum_{i=1}^n f(U^{[i]}),$$

where the random variable $f(U)$ is the mean, and $U = (U^{[1]}, \dots, U^{[n]})$ is an n dimensional uniform [0,1] variate. The standard error σ_n decreases with the square root of the sample size n :

$$\sigma_n = \frac{\sigma}{\sqrt{n}}.$$

Thus, the utility of Monte Carlo methods becomes evident in considering a family of all numerical methods in m dimensional space that are functions of r point estimations (repetitions). The absolute errors decrease at the rate of only $r^{-1/m}$, whereas the Monte Carlo method's absolute error decreases at the rate of $r^{-1/2}$.

Monte Carlo Study Versus Monte Carlo Simulation

Sawilowsky differentiated between a Monte Carlo study and a Monte Carlo simulation. Determining that the expected value $E[x]$ of a uniform [0,1] continuous variable is $\int_0^1 f(x)dx = .5$ via a Monte Carlo study can be accomplished by drawing N variates from the uniform distribution, summing them, and dividing the total by N . This does not necessarily simulate any real phenomenon. Because the probability $P[x]$ of two spots surfacing on a die is $\frac{1}{6}$, drawing variates from the uniform distribution and assigning spots according to Table 1 is a Monte Carlo simulation of throwing a die.

Four important characteristics of high-quality Monte Carlo study are the following:

1. The pseudo random number generator has desirable characteristics (e.g., a long period before repeating values).
2. The pseudo random number generator produces values that pass tests for randomness.
3. The number of repetitions of the experiment is sufficiently large to ensure accuracy of results.
4. The proper sampling technique is used (e.g., sampling with replacement vs. sampling without replacement).

When Monte Carlo methods are used in *simulation* work, the following two characteristics must be added:

1. The algorithm is valid.
2. The simulation is realistically modeled.

Applications of Monte Carlo Simulation

A Monte Carlo simulation of the probability of surviving a heart attack under various conditions was developed by Sawilowsky and Fahoome. A population of heart attack victims was identified in a certain county of a midwestern state of the United States. Information was collected on their age, where the heart attack occurred, who was present when the heart attack occurred, if the witness to the event was trained in cardiopulmonary resuscitation (CPR), if CPR was administered, if the heart presents a rhythm conducive to electric shock, decrease in survival rate per minute after incident to receiving shock, and the length of time between the attack and when the patient received electric shock treatment by medical personnel.

Probabilities for these conditions were obtained from published sources in the county where the study was undertaken. A software program was coded in Fortran 90 to conduct a Monte Carlo simulation of a heart attack victim's probability of survival based on the conditions surrounding the incident. The simulation provides estimates of survival rates when any of the above mentioned criteria are modified.

The plethora of applications using Monte Carlo simulation is very rich. A small subset of examples

from the applied literature include annealing, consumer behavior of switching brands, controlling dam water, cooling temperature of coffee, customer product ordering behavior, development of ability to perform push-ups, ecology of the Kaibab Plateau on the rim of the Grand Canyon, electromagnetism, estimating migration patterns, expected waiting times, genetic linkage, growth of yeast in a sugar solution, heroin addiction's impact on a community, image processing, inventory control, management planning, mass supply systems, material or time delays, projection of discovery of natural gas reserves, quality and reliability of products, queuing sale and consumption of commodities, systems at a 2-minute car wash, short-term forecasting, and urban growth. The list is growing.

MOSAIC PLOTS

Mosaic plots were introduced by Hartigan and Kleiner as a means of visualizing contingency tables. As the name suggests, mosaic plots are pieced together from smaller rectangular tiles. Each tile corresponds to one cell of a contingency table. Its area is proportional to the size of the cell, and shape and location are determined during the construction process. We will explain the construction process using data from the *Titanic* (see Table 1 for the numbers). In this data set, age, gender, and passenger information is available for all 2,201 persons on board the *MS Titanic* on her fatal maiden voyage. Additionally, survival information is recorded for each person. We start with a single variable: Figure 1 shows a bar chart of Survival. The bars are colored according to the outcome. On the

right, a spineplot is drawn. Spineplots are variations of bar charts, where the width instead of the height of each bar is proportional to the number of cases.

Additionally, the coloring shows survival within class. We can see that survival rates go down from left to right, that is, first class passengers had the highest rate of survival (about 62%), whereas third class passengers and crew members had the lowest survival rate (about 24%). The spineplot of Figure 1 is an example of a one-dimensional mosaic plot. Mosaic plots can show many variables and are limited only by practical issues, such as screen space and interpretability.

To make the mosaic of Figure 1 two-dimensional, we can include the information on age (classified as adult or child) and draw two separate mosaic plots on top of each other, as shown in Figure 2.

The top row in this mosaic plot shows survival rates of children within the classes. It becomes apparent that there were no children in the crew—obviously a structural zero. There also were no deaths in the first two passenger classes. We can now incorporate gender in the mosaic plot by placing the mosaic of Figure 2 for each gender separately side by side, as is shown in Figure 3.

Survival rates by class, age, and gender are shown. Overall, a lot more men were on board than

women. Survival rates for women are significantly higher than for men. The pattern within class also looks different for women than for men. Women have a strong class/survival association: With higher class, survival improves dramatically. This is not true for

Figure 3 Mosaic Plot of Class, Age, and Gender (Sex Variable)

men. Survival rates of men in the second passenger class are curiously low and have led to many speculations.

The construction of mosaic plots is strictly hierarchical, which emphasizes the order of variables. Figure 4 shows the same data as the mosaic in Figure 3 with different order of the variables. The variables of class and gender are exchanged. This enables us to better compare the differences in survival rates between female and male persons on board.

Properties

Mosaic plots have excellent mathematical properties:

- The cells' sizes are visual estimates of the joint distribution of all the variables.
- Various conditional distributions are preserved.
- Links to log linear models have been established.
- Extensions of mosaics include tree maps and trellis displays.

MOVING AVERAGE

A moving average is a simple but powerful technique that can be used on time series data or any data recorded in equal intervals, such as time. The history of moving averages goes back at least to 1924, well before computers or hand calculators were in existence. In its simplest form, it is a progressive and repetitive calculation of simple averages and does not require sophisticated computation power. However,

using a computer to do the simple calculations and to draw related graphs allows the user to focus on the interpretation of the results. The moving average has uses limited only by the imagination of the user.

It has been used as a technique to smooth data to reveal a trend and as a forecasting technique. It is part of the ARMA methodology for forecasting, where the MA stands for moving average. The use in the sophisticated ARMA forecasting process is more of a historical interpretation than an actual implementation.

The theory behind moving averages allows free interpretation and application with few details relating to theory associated with underlying statistical assumptions. It should be viewed as a descriptive statistical technique with many potential theoretical and practical uses. Because it is a very intuitive and practical technique, it is best explained by example.

Moving Average Computation and Use

The software used for illustration purposes is Minitab, a well-known, easy-to-use, and reliable software

package that runs on a PC. To start out, consider the following ordered data that were created to illustrate the calculation of a moving average (Figure 1).

Worksheet 1 ***

18	18	5
19	19	4
20	20	3

Figure 1 Worksheet

The order refers simply to the fact that the data are in order. If the data are time series, then the order variable would be time at equally spaced intervals.

Because moving averages are often used to smooth data in the sense of eliminating nonmeaningful irregularities in the data, the best practice is to first plot the data to see what they look like. The questions that a plot can answer are, Are there any irregularities in the data that are not meaningful? Do the data display some sort of trend that might be meaningful?

Figure 2 Time Series Plot of Data

The plot in Figure 2 was produced in Minitab by simply selecting Graph from the main menu and then Time Series Plot. Notice that the data have a slight upward trend with one valley and a couple of peaks.

To explore a moving average, consider a five-term moving average; the number of terms in the moving average is usually determined by trial and error if no other insight is available.

The hand calculations for the first term of the moving average are to simply average the first five data points:

$$\begin{aligned} MA(1) &= \frac{\text{data}(1)+\text{data}(2)+\text{data}(3)+\text{data}(4)+\text{data}(5)}{5} \\ &= \frac{2+3+5+7+8}{5} = \frac{25}{5} = 5, \end{aligned}$$

where $MA(1)$ is the first smoothed value and $\text{data}(n)$ is the data column value at Period or Order 1.

The second smoothed value is

$$\begin{aligned} MA(2) &= \frac{\text{data}(2)+\text{data}(3)+\text{data}(4)+\text{data}(5)+\text{data}(6)}{5} \\ &= \frac{3+5+7+8+9}{5} = \frac{33}{5} = 6.6. \end{aligned}$$

Thus, the calculations continue by shifting down one step and computing the average of the next five terms—thus the term *moving average*.

When does the calculation stop? When there are no longer five terms to average.

Once the moving average is computed, it needs to be associated at some point with the original data. There are several ways to do this depending on what the purpose of the moving average is.

One practice is to place the new moving average series of numbers one step beyond the period of the average. Thus, in the above example, MA(1) would be positioned at Order 6.

Another practice, which is, in fact, called that, is to center the moving average, so in the case of a five-term moving average, data point MA(1) would be moved to Order 3.

To see what this does in practice to the smoothing characteristics of the moving average, Minitab is used to compute both the five term moving average and the five-term centered moving average. Figure 3 shows the results of those calculations.

Figure 3 Worksheet

Note that the calculated moving averages are the same for the centered and noncentered moving averages. The only difference is with what order the series is associated. A comparison graph (Figure 4) is useful in seeing the implications of the position of the moving average.

Figure 4 Time Series Plot of Data, MA Period 5, Centered MA Period 5

It is clear from the graph that the moving average has indeed smoothed the original data.

If the data represented a cycle—repeating pattern—then this smoothed version might be more representative of the true pattern. If the intent of smoothing the data is to use it to forecast a single future value, then the noncentered moving average would most likely be preferred. A naive forecasting rule, for one period beyond the actual data, is to use the last smoothed value. In this case, the forecast for Period 21, which is a future value with no data, is 5.4, the last smoothed value.

Suppose that the intent of smoothing the data is to draw out the simple upward trend. The question then is, What period of moving average is best? The answer is usually generated by trying various orders or periods (vary the number of data points averaged) of moving averages. Figure 5 shows the results of this investigation.

Figure 5 Moving Average Plot for Data

The first graph shows a two-period moving average with forecasts generated three periods ahead. Note that the moving average is less smooth for two terms

than with five. Also note that the forecasts generated by Minitab for three periods ahead are basically highly related to the last smoothed value. Also note that the three forecasts are identical. Thus, it can be correctly concluded that forecasts beyond one period from the original data might become less accurate. The 95% prediction interval is quite wide and indicates that the forecasts are highly variable.

Next, look at the result of using a very large number of terms in the moving average. A first guess might be that it should be smoother because it averages over many more periods. (See Figure 6.)

As might be expected, the larger period moving average results in a much smoother line, which is reflecting the trend of the data without the peaks and valleys of the original data. The forecasts for three periods ahead are still the same values for all three forecasts; a moving average is not considered useful for more than short term forecasts.

Figure 6 Moving Average Plot for Data

If the goal of using a moving average is to simply smooth the data to pull out the trend, then that has certainly happened with these data. The moving average line is seen to be a very linear trend that is increasing slightly.

To get an overall look at the result of adding more terms to the moving average, Figure 7 is useful.

Figure 7 Time Series Plot of MA 2, MA 10, MA 7, MA Period 5, Centered MA Period

The trend is obviously most apparent when many terms, 10, are averaged. The centered moving average is very good at simply smoothing the existing series and representing the smoothed data consistent with the original data—that is, not shifted. What is correct? Well, there are no incorrect or absolutely correct results. It depends on the use of the moving average. If the goal is to smooth the data to help interpretation or to fit future models, then centering the data is best. If the goal is to produce a general trend in the data, then a higher order number of terms is most likely the best solution.

Applications

Aside from a simple technique to smooth the data or to smooth and produce a simple trend, what are moving averages good for?

There is a classical result that has proved by usage to be very profound for moving averages. The typical application has been in the stock market, where it is desirable to predict changes over time in the upward or downward direction. Although complex statistical models have some use in predicting instantaneous changes (turning points) in stock market performance, few simple techniques can give advice on price movements. Moving averages have been used to give stock performance information with relatively little technical analysis or input.

Consider the following moving average that represents a 50- and 100-period moving average on stock price (Figure 8).

When the stock price falls below the 50- or 100-day moving average, it is recommended that the stock owner sell. Note that if the owner had sold at the point at which the stock went below the moving average, a long period of low prices would have been avoided.

Figure 8 Moving Average Plot for a 50 and 100 Period

Source: <http://www.investopedia.com/university/movingaverage/default.asp>

When the stock goes above the 50- or 100-period moving average, the stock may be purchased with the hope of a long upward trend, as shown on the graph.

How does the individual use this information? The investor can update and plot the moving average, usually over a 49 or longer (days or months as appropriate) period of time. This long period will give a general trend for the data, as seen in the previous example. It is easy to update a long-term moving average one day at a time because one has to remove only the first number and add the last new period to the total and divide by the number averaged. Dedicated investors have used this type of updating along with hand plotting of the averages for many years without calculators or computers. The rule of thumb is that when the stock price drops below the long-term moving average, sell, and when it goes above the long-term moving average, buy. Although this will hardly ever hit the exact turning points in stock prices, over the long term, it has proved to be a very good decision rule that is easy to use. It works especially well with mutual funds, which are a mixture of stocks.

How would these results apply to other ordered data? It might prove very useful in evaluating education systems. Some states require all students in grade school to take end-of-year performance tests. Over a period of time these tests could be recorded and smoothed. The moving average could be used to show trends in the data: A long-term moving average could be used to indicate potential trouble when scores fall below the moving average, or improvement when scores rise above a moving average.

Another example might be in monitoring student weight gain or loss as related to the removal or addition of soft drink dispensing machines in public schools. Suppose student average weight is recorded for several months and years for a particular school. Then suppose at some point in time, soft drink machines were introduced in the school. If the average student weight went above the long-term moving average around the point that the soft drink machines were introduced, that would be an indication that they might be contributing to weight gain among students. If soft drink machines are removed from schools and the average weight goes below the long-term moving

average, that would supply evidence that the program was working.

Conclusions

A moving average is a simple statistical method that can prove very useful in monitoring and predicting data that are recorded in an ordered or time based manner. The basic calculations can be done easily by hand but are also aided by computer calculation. It is a technique that can deal with time or ordered data in an intuitive manner and should be part of the data analysis toolbox of anyone involved in working with data. It has few theoretical restrictions, and its application is limited only by the ingenuity of the user. Several statistical software packages that include spreadsheets can compute moving averages, but if a computer isn't available, they can be computed by hand.

MULTICOLLINEARITY

Multicollinearity is a phenomenon that may occur in multiple regression analysis when one or more of the independent variables are related to each other. The relationship between the independent variables could be expressed as near linear dependencies.

A simple form of multicollinearity could be due to high correlation between some pair(s) of independent variables. Assuming that there are five independent variables, X_1 , X_2 , X_3 , X_4 , and X_5 , that are being used to

develop a model for the dependent variable, Y , suppose that the correlations between X_2 and X_3 , and between X_4 and X_5 , are high (≥ 0.90). In such a case, maybe one of the two variables X_2 or X_3 , and one of the two variables X_4 or X_5 , could be used in the model. The rationale is that there is very little independent contribution of the variable that is left out, in the presence of the one that is retained, in explaining the variation in the dependent variable.

More complex forms of multicollinearity may exist when three or more independent variables are nearly linearly related, even though there might not be a high pair wise correlation among them. This could be represented by the approximate relation $X_1 + 2X_2 - X_3 \simeq 0$.

Effects of Multicollinearity

The impact of multicollinearity on the development of a multiple regression model and drawing inferences from it is multifaceted. First, the variance of the estimated model coefficients is large, which leads to their instability. Small perturbations of the observations and/or omission of an independent variable from a large set of independent variables may cause large fluctuations in the estimated regression coefficients.

Second, the signs associated with the regression coefficients may be somewhat contrary to what is expected, given the setting of the problem. For example, in predicting resource requirements (Y), using production quantity (X_1), direct labor (X_2), and raw material (X_3), it is normally expected that the coefficients associated with X_1 , X_2 , and X_3 will be positive. However, given that X_1 and X_2 are highly correlated, and so are X_1 and X_3 , it is possible for one of the estimated coefficients to turn out negative.

Third, it is possible for the full model to be statistically significant, even though none of the individual coefficients is significant. Thus, all of the independent variables, taken collectively, may provide a good fit to the response variable, leading to a small value of the residual sum of squares. On the contrary, individual coefficients are estimated poorly. In the presence of multicollinearity, a given regression coefficient may not reflect the inherent

effect of the particular regressor. It is influenced by the variables that are in the model.

Detection of Multicollinearity

All of the three possible effects, previously discussed, may be examined closely for the possible presence of multicollinearity. These are as follows: high pairwise correlation among some of the independent variables; wide confidence intervals associated with the regression coefficients; opposite sign of estimated regression coefficients based on theoretical knowledge of the problem; nonsignificant tests on individual coefficients while the model as a whole is significant; and large changes in the estimated coefficients when an observation is slightly changed or deleted, or when an independent variable is added or deleted.

Another method of detecting multicollinearity is through computation of the variance inflation factors (VIFs). A VIF measures the degree to which an independent variable is related to the other independent variables. Consider regressing the independent variable (X_k) to the other independent variables ($X_1, X_2, \dots, X_{k-1}, X_{k+1}, \dots, X_p$). The variance inflation factor for X_k is given by

$$(\text{VIF})_k = \frac{1}{1 - R_k^2}, \quad k = 1, 2, \dots, p,$$

where

p represents the number of independent variables and

R_k^2 is the coefficient of multiple determination when the variable X_k is regressed on the other remaining independent variables.

It is observed that when $R_k^2 = 0$, implying that X_k is not linearly related to the other independent variables, $(\text{VIF})_k$ is equal to 1. As R_k^2 becomes large and closer to 1, $(\text{VIF})_k$ becomes large. In the extreme case when $R_k^2 = 1$ (i.e., X_k is perfectly linearly related to the other independent variables), $(\text{VIF})_k$ is unbounded. The largest $(\text{VIF})_k$, among all the regressors, is frequently used as an indicator of the degree of multicollinearity. As a rule of thumb, a maximum $(\text{VIF})_k$ of 10 or

more is considered an indication of the presence of multicollinearity.

Remedial Measures for Multicollinearity

On examination of the correlation matrix of the independent variables, one or more independent variables, which are highly correlated to others, may be dropped from the model. This measure has some drawbacks. First, if data have been collected on all the regressor variables, by dropping one or more of these, no direct information is obtained about the dropped variables. Furthermore, the magnitude of the regression coefficients retained in the model is affected by the correlated regressors not included in the model.

In polynomial models, expressing the independent variable in the form of deviation from the mean may reduce multicollinearity among the first, second, or higher order terms.

Another approach could be to use a biased estimation process compared to least squares regression. In this context, ridge regression is an alternative. Although it introduces some bias in the estimator, this procedure has a much smaller variance. The net impact, as measured by the mean squared error, which is the expected value of the squared difference between the estimator and the true parameter value, could be smaller. The mean squared error can be expressed as the sum of the variance and the squared bias of the estimator. For an unbiased estimator, such as the least squares estimator, the mean squared error equals the variance of the estimator.

MULTIDIMENSIONAL APTITUDE BATTERY

The Multidimensional Aptitude Battery (published by Sigma Assessment Systems) was developed by Douglas N. Jackson and is currently in its second edition (MAB-II). Following the tradition established by Robert Yerkes during World War I with the Army Alpha and Beta for testing literate and illiterate recruits, respectively, the MAB categorizes abilities into verbal and nonverbal components. The MAB contains five verbal subtests (Information, Comprehension, Arithmetic, Similarities, and Vocabulary) and five nonverbal subtests (Digit Symbol, Picture Completion, Spatial, Picture Arrangement, and Object Assembly). Each of these 10 subtests is in a five-point multiple-choice format and has a 7-minute time limit. With instructions and practice items, the MAB-II takes about 90 minutes to complete. With the exception of Digit Span, which Wechsler adapted from the Binet, the MAB contains the same subtests as included in the Wechsler Bellevue, Wechsler Adult Intelligence Scale (WAIS), and Wechsler Adult Intelligence Scale Revised (WAIS-R). Correlations between corresponding subtests of the MAB and WAIS-R are of the same order of magnitude as the correlations between subtests of the WAIS and WAIS-R.

Subtest raw scores are converted to scaled scores with a *T* score metric (i.e., mean of 50, standard deviation of 10). The five verbal and five nonverbal scale scores are summed to produce a sum of scale scores for Verbal and Performance IQ, respectively. The sum of all 10 scale scores is used to calculate Full Scale IQ. Age groups for obtaining the three IQ scores are categorized into 16–17, 18–19, 20–24, 25–34, 35–44, 45–54, 55–64, 65–69, and 70–74. These nine age groups are also used to obtain age corrected scale scores for the 10 subtests. The three IQ scores have a mean of 100 and a standard deviation of 15.

The MAB-II can be administered in paper and pencil format with reusable question booklets and answer sheets to individuals or to groups. Where large volumes of clients are assessed comprehensively (i.e., 10 subtests) in contexts such as employee selection or

research, group administration makes such testing feasible. There are separate question booklets for the verbal subtests and performance subtests. In addition to hand scoring and mail in scoring, computerized administration with automated scoring and reporting is also available. Reports generated by the software are either clinical with some limited interpretation or ASCII (text) data file reports for research. The MAB-II is available in French and English.

MULTIPLE AFFECT ADJECTIVE CHECKLIST–REVISED

The Multiple Affect Adjective Checklist–Revised (MAACL-R, published by EdiTS/Educational and Industrial Testing Service) is a trait state test for the measurement of negative and positive affects. Both forms consist of 132 adjectives, but the instructions for the state form are to “check all adjectives which describe how you feel ‘now’ or ‘today,’” whereas those for the trait form say “check all the adjectives which describe how you ‘generally feel.’” Scales for both forms are provided for anxiety (A), depression

(D), hostility (H), dysphoria (Dys = the total A + D + H), sensation seeking (or surgency) affect (SS), and total positive affect (PASS = PA + SS). The negative affect scales were originally developed using an empirical item selection method, but the scales in the revised version are a result of factor analyses of both state and trait forms. In order to control acquiescence response set (total number of items checked), *T* scale norms are provided for each of three ranges of numbers checked. Norms are available for general adult, adolescent, college student, and elderly populations. The general adult norms are based on a national representative sample. There are also scales for random responding and intentional response manipulation (faking). The median reading level for the 132 adjectives is sixth grade, and 90% of the adjectives in the scales are at or below the eighth grade level.

Reliability

Internal (alpha) reliabilities have been determined within a wide variety of populations for both the state and trait forms. These reliabilities are high; most are .80 or higher. The highest reliability is for the Dys scale, which is .90 or higher in nearly all of the samples for the state form and all for the trait form. In conformance with the trait state distinction, retest reliabilities are expected to be high for the trait form but not for the state form. The state form of the PA scale is the only one showing low but consistently significant retest reliability. In contrast, retest reliabilities for the trait are moderately high even after an 8 week interval. Correlations between corresponding state and trait scales on a single day are significant but low, with the exception of the PA scale, which is high. Aggregated or averaged state scores over a few days to a week correlate more highly with trait scores.

Validity

The state scales have been used to measure change in many situations, including examination induced anxiety, aggression provocation, group therapy, listening to music, exercise, videos, and Air Force basic training, where it predicts discharge status after training.

The trait form correlates with many other scales for emotions, and peer and observer ratings. In a clinical diagnostic study, a combination of scales differentiated normals, schizophrenics, depressives, and patients with anxiety disorders.

MULTIPLE-CHOICE ITEMS

The multiple-choice (MC) item is the most common format for questions on educational tests. MC items are also used in other domains, including personality, interest, and attitude inventories and surveys. There are several forms of MC items and many guidelines available to item writers. Thomas Haladyna has provided leadership in this area, promoting a systematic approach to the development and validation of MC items.

In the design of any measurement instrument, two primary issues must be addressed early: what to measure and how to measure it. Both questions inform the choice of item format. Clearly, the construct being measured and the nature of the cognitive task required to measure the construct will play a role in deciding whether the MC format is appropriate.

The strengths of MC items were first debated in the literature shortly after the introduction of the Army Alpha test, a recruit screening and classification instrument used during World War I. Previously, aptitude and intelligence related measurement procedures included interactive tests administered one on one. It was proposed that test items could be constructed to be self-administered and yield sufficient

information about knowledge, skill, or level of ability or some other trait. The MC item allowed test developers to cover a wide range of content and skills and design instruments that could be group administered. With advances in machine scoring during the 1950s, the MC item quickly became the predominant testing format.

Measurement specialists now caution test designers and argue that validity, not convenience, should determine what types of item formats should be employed on a given measurement instrument. The objective is to craft the item in order to obtain the best measure of the construct or cognitive task of interest. The MC item offers a great deal to test designers because of its flexibility. However, as with any measurement procedure, MC items can be poorly written, leading to confusion and misinterpretation by the test taker, and thus scores of limited reliability and validity.

Forms of MC Items

The typical MC item consists of a stem and three or more options, where one option is the correct option and the others are incorrect options or distractors. The stem is the question or opening statement that is answered or completed by the options. Consider the following item:

1. What ratio of variances describes the reliability of test scores?
 - A. Errors of measurement and observed scores
 - B. Errors of measurement and true scores
 - C. True scores and observed scores

The question “What ratio of variances . . .” is the stem. The three choices that follow (A, B, and C) are the options. Option C is the correct option, and Options A and B are distractors or incorrect options. It is possible to construct this item as a completion statement:

2. The reliability of scores is regarded as the ratio between the variances of
 - A. errors of measurement and observed scores.
 - B. errors of measurement and true scores.
 - C. true scores and observed scores.

Both forms of the typical MC item have gained support from the measurement community, and neither is viewed as yielding greater validity than the other. However, there is some preference for the complete question format because the stem is more likely to contain the main idea of the item (an important guideline for MC items).

A slight variant of the typical MC item is the alternate choice item. This is identical to the typical MC item except that there are only two options. Another variant is the multiple true false, where there may be many options and each is evaluated in terms of being true or false. Another MC format is the complex MC or Type K format. In this format, there is a stem followed by potential answers, followed by a set of options to which the test taker responds. Consider this example:

3. When considering the need to design a test that will cover a lot of content in a brief period of time, which of the following item types could be employed effectively?
 1. Completion items
 2. Essay items
 3. Multiple-choice items
 4. True-false items
 - A. 1 and 2
 - B. 1, 3, and 4
 - C. 3 and 4

In this example, the options (A, B, and C) are composed of combinations of the potential answers to the question (1 to 4). This MC item format tends to be more difficult and is commonly found in the health sciences, where the object is to differentiate the appropriateness of various combinations of options (for example, combinations of health related symptoms).

On the question of optimal number of options, there is substantial evidence suggesting that for most purposes and in most settings, three options are optimal. The evidence suggests that three option items provide no greater chance of correct guessing than items with more options because, more so than not, additional options are less plausible and are not considered by most students, and that few, if any, individuals actually engage in blind guessing. Empirical

research has provided evidence that few four- or five-option items have that many functional distractors, essentially making the item a three-option or, in many cases, a two-option item. In addition, item writing effort and time can be reduced and more three-option MC items can be asked, allowing the test designer to include more items and improve content coverage.

MC Item Writing Guidelines

Guidelines are available for the MC item writer that consist of issues related to the stem, the options, and other general editorial and content concerns. These guidelines are covered to various extents by measurement textbook authors. Haladyna provides the most thorough review of guidelines available. Some of the guidelines include concerns about clarity of word choice and writing style. Content concerns include the idea that each item should regard a single idea on an important topic that is not opinion based (unless the focus of the item regards a specific opinion). Guidelines regarding the stem focus on the stem containing the main idea of the item without excessive wordiness and the selective use of formatting to bring attention to words that might be missed, such as NOT.

Most of the available guidelines cover issues related to the options. This points to the relative importance that most measurement specialists place on the role of the options in the quality of the item. Options should be independent, similar in content and grammatical structure, equal in length, and free of clues to the correct option (e.g., options that resemble or contain words also present in the stem). In most cases, options such as “none of the above” and “all of the above” should be avoided, as should negative options or options containing words such as “not.” Perhaps most importantly, only one option should be correct, and distractors (incorrect options) should be plausible. One of the best ways to achieve this is to use typical errors or misconceptions as distractors. It is also recognized that one way to control item difficulty is to vary the proximity or plausibility of the distractors. The closer in similarity the options, the more difficult the item.

Advantages and Disadvantages of MC Items

MC items have several advantages and disadvantages compared to constructed response item formats. Among the advantages, MC items can provide direct assessment of a wide range of skills, including higher order thinking and complex cognitive tasks. To achieve these goals, item writers need training and experience. MC items are efficient to administer and objectively scored, and they provide a mechanism for broad sampling of the content domain or the construct. Analysis of distractors selected by test takers provides a way to obtain diagnostic information. When distractors are designed to include common misconceptions or errors, knowing which distractors are being selected provides information on which misconceptions are still held or where additional instruction may be helpful.

Among the disadvantages, MC items provide limited or indirect measurement of some skills, including the abilities to recall, provide an explanation or examples, express or organize ideas, generate a novel solution, or construct something. Other formats are better suited for these skills. Because the number of MC options is typically small, the content of any one item tends to be based on artificially structured knowledge and is rather closed to interpretation; however, we recognize that a series of well constructed MC items may approach these objectives effectively. When reading is not the target objective, reading skills may interfere with responses to MC items and the possibility of correctly guessing is always present (but may be minimized with the use of effective distractors).

MULTIPLE COMPARISONS

In data analysis, the question of interest rarely can be answered by a single statistical test or comparison. The term *multiple comparisons* describes an analysis that involves more than one statistical test or comparison based on the same set of data.

Why Multiple Comparisons Need Special Treatment

Multiple comparisons add an additional level of complexity to the analysis. For any individual comparison or test, you set an alpha level that determines the probability of a Type I error (i.e., concluding that the difference is significant when, in reality, it is not).

Suppose you choose a customary alpha of .05 (5%). Now, if you perform two independent comparisons using the same alpha, the chance of making a Type I error on each of them is 5%, and the chance of avoiding a Type I error on each is 95%. So, the chance of avoiding a Type I error altogether is $0.95 \times 0.95 = 0.9025 = 90.25\%$. The complement of this, 9.75%, represents the probability of making at least one Type I error somewhere in the set of comparisons. This probability is sometimes called the *familywise alpha level* (or the *familywise error rate*).

You can see that the familywise alpha is significantly higher than the nominal alpha we specified as 5%. The situation gets worse as the number of comparisons increases: With five comparisons, the familywise alpha is about 22.6%. The general formula for calculating the familywise alpha is

$$\alpha_{\text{familywise}} = 1 - (1 - \alpha_{\text{nominal}})^k,$$

where k is the number of comparisons.

Figure 1 shows how familywise alpha varies in relation to the number of comparisons. By the time

Figure 1 Experimentwise Alpha Based on Number of Comparisons

Figure 2 Expected Number of Type I Errors Based on Number of Comparisons

you perform about 50 comparisons, you are almost certain to commit at least one Type I error. Fifty comparisons may sound like a lot, but consider that if you scan a correlation matrix for 10 variables for significant correlations, you are performing 45 tests.

Figure 2 shows the expected number of Type I errors based on the number of comparisons. The more comparisons, the more Type I errors. In the hypothetical example of a correlation matrix for 10 variables, you should expect to find two to three significant

(but spurious) correlations by chance alone, even if all the variables are independent.

Approaches for Handling Multiple Comparisons

To avoid the problem of familywise alpha exploding as the number of comparisons increases, various methods have been developed to control the familywise alpha. Most methods center around selecting a conservative nominal alpha level, so that the familywise alpha is controlled given the number of comparisons to be made.

In controlling the familywise alpha, it is important to account for the right number of comparisons. In some cases, this will *not* be the same as the actual number of tests or comparisons performed, as explained below.

Planned Versus Post Hoc Comparisons

Comparisons or tests in a statistical analysis can be broken down into two categories, *planned* and *post hoc*, based on how and when the decision is made to perform the specified comparisons or tests.

Planned comparisons are comparisons that are specified before the data are collected or analyzed, based on the theoretical foundations of the research (or the results of previous studies). A typical example would be a clinical study where each of several treatment groups is compared to a baseline or control group. In this case, there are $\frac{k!}{2(k-2)!}$ possible comparisons, but you are only performing $(k - 1)$ of them, where k is the number of groups including the control group. Because you are restricting the number of comparisons, you needn't be as conservative as you would if you were performing all possible comparisons. In fact, some researchers argue that as long as the number of planned comparisons is small, no special handling of multiple comparisons is needed.

Post hoc comparisons are comparisons that are made after the data have been analyzed and examined for patterns. To extend the example above, suppose we have five treatments and a control. After performing the planned comparisons as described above, we find that two of the five treatments show significant improvement over the baseline condition. If we want to test whether those two specific treatments are significantly different from each other, this is considered

a post hoc comparison because we didn't decide to make the comparison until after we noticed that those two treatments were significantly different from the control. In the case of post hoc comparisons, you should be more conservative than with planned comparisons. Because you didn't know what comparisons you were going to make up front, any of the possible comparisons might have looked interesting depending on the data, so you need to plan as if all possible comparisons were under consideration. In this case, you'd need a method that considered all $\frac{k!}{2(k-2)!}$ potential comparisons in adjusting the familywise alpha level, even though you're making only one post hoc comparison.

Familywise Error Rate and Power

As in the case of individual hypothesis tests, in a multiple comparison situation there is a trade off between Type I error rate and power. As you reduce your Type I error rate (alpha), you also reduce your power, or ability to detect true differences. This is especially true for multiple comparison procedures, where the nominal alpha often must be quite small to control the familywise alpha. Most multiple comparison procedures attempt to maximize power by using dependence among tests and other characteristics of the research design, while still controlling the familywise error rate.

Specific Procedures

Several popular procedures for performing multiple comparisons are briefly described below. Some of these methods have their own entries in the encyclopedia.

Bonferroni

A very conservative approach that sets the per comparison alpha to $\alpha_{\text{familywise}}/k$, where k is the number of comparisons. This is also known as the Dunn test or Dunn correction.

Fisher's Least Significant Difference

Fisher's least significant difference test takes a different approach to comparing multiple group means.

It is a two stage test. First, the overall analysis of variance (ANOVA) test is performed. If the overall test (the omnibus test) is not significant, then no specific mean comparisons are made. If the omnibus test is significant, then the means are compared using unadjusted test values. The significance of the omnibus test provides some protection against Type I errors by ensuring that at least some of the mean differences are definitely significant.

Tukey's Honestly Significant Difference

This test involves calculating the smallest difference that would be significant, controlling for familywise alpha. The formula is

$$d_{\text{Tukey}} = \frac{q_T \sqrt{\text{MSE}}}{\sqrt{n}},$$

where q_T is the studentized range statistic based on the desired familywise alpha, the number of groups (*not* the number of comparisons), and the sample size; MSE is the mean squared error for the overall ANOVA; and n is the sample size for each group. Any mean difference that is larger than this value is deemed significant.

Tukey-Kramer

This is an adaptation of the Tukey test to handle comparisons where the groups being compared have unequal sample sizes. In this case, the reciprocal of the harmonic mean of the individual group sample sizes is used in place of the equal sample size n :

$$n' = \frac{k}{\left(\frac{1}{n_1} + \frac{1}{n_2} + \dots + \frac{1}{n_k}\right)}$$

The test value d_{Tukey} is calculated as described above using n' instead of n , and testing proceeds as usual.

Scheffé

This procedure controls the familywise error rate by adjusting the critical F value used to perform

the post hoc tests. The test F statistic is calculated in the usual way for each comparison, and the critical value is calculated by multiplying the critical value for the overall test of differences among all the means (the omnibus test) by $(k - 1)$, where k is the number of groups (*not* the number of comparisons).

Dunnnett

This test applies to planned comparisons in the specific case where the mean for each of a set of treatment groups is being compared to the mean for a control group. This test is similar to the Tukey HSD test and involves calculating the smallest difference that would be significant, controlling for familywise alpha, assuming the specific set of control treatment comparisons. The formula is

$$d_{\text{Dunnnett}} = \frac{q_D \sqrt{2 \cdot \text{MSE}}}{\sqrt{n}},$$

where q_D is the critical value for Dunnnett's test based on the desired familywise alpha, the number of groups (*not* the number of comparisons), and the sample size; MSE is the mean squared error for the overall ANOVA; and n is the sample size for each group. Any mean difference between a treatment group and the control group that is larger than this value is deemed significant.

MULTIPLE CORRELATION COEFFICIENT

The multiple correlation coefficient generalizes the standard coefficient of correlation. It is used in multiple regression analysis to assess the quality of the prediction of the dependent variable. It corresponds to the squared correlation between the predicted and the actual values of the dependent variable. It can also be interpreted as the proportion of the variance of the dependent variable explained by the independent variables. When the independent variables (used for predicting the dependent variable) are pairwise orthogonal, the multiple correlation coefficient is equal to the sum of the squared coefficients of correlation between each independent variable and the dependent variable. This relation does not hold when the independent variables are not orthogonal. The significance of a multiple coefficient of correlation can be assessed with an F ratio. The magnitude of the multiple coefficient of correlation tends to overestimate the magnitude of the population correlation, but it is possible to correct for this overestimation. Strictly speaking, we should refer to this coefficient as the *squared* multiple correlation coefficient, but current usage seems to ignore the adjective “squared,” probably because mostly its squared value is considered.

Multiple Regression Framework

In linear multiple regression analysis, the goal is to predict, knowing the measurements collected on N subjects, a dependent variable Y from a set of J independent variables denoted

$$\{X_1, \dots, X_j, \dots, X_J\}. \quad (1)$$

We denote by \mathbf{X} the $N \times (J + 1)$ augmented matrix collecting the data for the independent variables (this

matrix is called augmented because the first column is composed only of ones), and by \mathbf{y} the $N \times 1$ vector of observations for the dependent variable. These two matrices have the following structure:

$$\mathbf{X} = \begin{bmatrix} 1 & x_{1,1} & \cdots & x_{1,j} & \cdots & x_{1,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 1 & x_{n,1} & \cdots & x_{n,j} & \cdots & x_{n,J} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 1 & x_{N,1} & \cdots & x_{N,j} & \cdots & x_{N,J} \end{bmatrix}$$

and $\mathbf{y} = \begin{bmatrix} y_1 \\ \vdots \\ y_n \\ \vdots \\ y_N \end{bmatrix}.$ (2)

The predicted values of the dependent variable \hat{Y} are collected in a vector denoted $\hat{\mathbf{y}}$ and are obtained as

$$\hat{\mathbf{y}} = \mathbf{X}\mathbf{b} \quad \text{with} \quad \mathbf{b} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y}. \quad (3)$$

The regression sum of squares is obtained as

$$SS_{\text{regression}} = \mathbf{b}^T\mathbf{X}^T\mathbf{y} - \frac{1}{N}(\mathbf{1}^T\mathbf{y})^2 \quad (4)$$

(with $\mathbf{1}^T$ being a row vector of 1s conformable with \mathbf{y}).

The total sum of squares is obtained as

$$SS_{\text{total}} = \mathbf{y}^T\mathbf{y} - \frac{1}{N}(\mathbf{1}^T\mathbf{y})^2. \quad (5)$$

The residual (or error) sum of squares is obtained as

$$SS_{\text{error}} = \mathbf{y}^T\mathbf{y} - \mathbf{b}^T\mathbf{X}^T\mathbf{y}. \quad (6)$$

The quality of the prediction is evaluated by computing the multiple coefficient of correlation, denoted $R_{Y,1,\dots,J}^2$. This coefficient is equal to the squared coefficient of correlation between the dependent variable (Y) and the predicted dependent variable (\hat{Y}).

An alternative way of computing the multiple coefficient of correlation is to divide the regression sum of squares by the total sum of squares. This

shows that $R_{Y,1,\dots,J}^2$ can also be interpreted as the proportion of variance of the dependent variable explained by the independent variables. With this interpretation, the multiple coefficient of correlation is computed as

$$R_{Y,1,\dots,J}^2 = \frac{SS_{\text{regression}}}{SS_{\text{regression}} + SS_{\text{error}}} = \frac{SS_{\text{regression}}}{SS_{\text{total}}}. \quad (7)$$

Significance Test

In order to assess the significance of a given $R_{Y,1,\dots,J}^2$, we can compute an F ratio as

$$F = \frac{R_{Y,1,\dots,J}^2}{1 - R_{Y,1,\dots,J}^2} \times \frac{N - J - 1}{J}. \quad (8)$$

Under the usual assumptions of normality of the error and of independence of the error and the scores, this F ratio is distributed under the null hypothesis as a Fisher distribution with $v_1 = J$ and $v_2 = N - J - 1$ degrees of freedom.

Estimating the Population Correlation: Shrunken and Adjusted R

Just like its bivariate counterpart r , the multiple coefficient of correlation is a *descriptive* statistic that always overestimates the population correlation. This problem is similar to the problem of the estimation of the variance of a population from a sample. In order to obtain a better estimate of the population, the value $R_{Y,1,\dots,J}^2$ needs to be corrected. The corrected value of $R_{Y,1,\dots,J}^2$ goes by different names: *corrected R* , *shrunken R* , or *adjusted R* (there are some subtle differences between these different appellations, but we will ignore them here), and we denote it by $\tilde{R}_{Y,1,\dots,J}^2$. There are several correction formulas available; the one most often used estimates the value of the population correlation as

$$\tilde{R}_{Y,1,\dots,J}^2 = 1 - \left[(1 - R_{Y,1,\dots,J}^2) \left(\frac{N - 1}{N - J - 1} \right) \right]. \quad (9)$$

Example 1: Multiple Correlation Coefficient With Orthogonal Predictors

When the independent variables are pairwise orthogonal, the importance of each of them in the regression is assessed by computing the squared coefficient of correlation between each of the independent variables and the dependent variable. The sum of these squared coefficients of correlation is equal to the multiple coefficient of correlation. We illustrate this case with the data from Table 1. In this example, the dependent variable (Y) is the number of sentences recalled by participants who learned a list of unrelated sentences. The first independent variable or first predictor, X_1 , is the number of trials used to learn the list. It takes the values 2, 4, and 8. It is expected that recall will increase as a function of the number of trials. The second independent variable, X_2 , is the number of additional interpolated lists that the participants are asked to learn. It takes the values 2, 4, and 8. As a consequence of retroactive inhibition, it is expected that recall will decrease as a function of the number of interpolated lists learned.

Using Equation 3, we found that \hat{Y} can be obtained from X_1 and X_2 as

$$\hat{Y} = 30 + 6 \times X_1 - 4 \times X_2. \quad (10)$$

Table 1 A Set of Data

Number of Learning Trials (X)	Number of Interpolated Lists (T)		
	2	4	8
2	35	21	6
	39	31	8
4	40	34	18
	52	42	26
8	61	58	46
	73	66	52

Source: Data from Abdi et al. (2002).

Notes: The dependent variable Y is to be predicted from two orthogonal predictors X_1 and X_2 . These data are the results of a hypothetical experiment on retroactive interference and learning. Y is the number of sentences remembered from a set of sentences learned, X_1 is the number of learning trials, and X_2 is the number of interpolated lists learned.

Using these data and Equations 4 and 5, we find that

$$SS_{\text{regression}} = 5824, SS_{\text{total}} = 6214, \text{ and } SS_{\text{error}} = 390. \quad (11)$$

This gives the following value for the multiple coefficient of correlation:

$$R^2_{Y.1,\dots,J} = \frac{SS_{\text{regression}}}{SS_{\text{total}}} = \frac{5824}{6214} = .9372. \quad (12)$$

In order to decide if this value of $R^2_{Y.1,\dots,J}$ is large enough to be considered significant, we compute an F ratio equal to

$$F = \frac{R^2_{Y.1,\dots,J}}{1 - R^2_{Y.1,\dots,J}} \times \frac{N - J - 1}{J} = \frac{.9372}{1 - .9372} \times \frac{15}{2} = 111.93. \quad (13)$$

Such a value of F is significant at all the usual alpha levels, and therefore we can reject the null hypothesis.

Because X_1 and X_2 are orthogonal to each other (i.e., their correlation is equal to 0), the multiple coefficient of correlation is equal to the sum of the squared coefficients of correlation between the independent variables and the dependent variable:

$$R^2_{Y.1,\dots,J} = .9372 = r^2_{Y_1} + r^2_{Y_2} = .6488 + .2884. \quad (14)$$

A better estimate of the population value of the multiple coefficient of correlation can be obtained as

$$\begin{aligned} \tilde{R}^2_{Y.1,\dots,J} &= 1 - \left[(1 - R^2_{Y.1,\dots,J}) \left(\frac{N - 1}{N - J - 1} \right) \right] \\ &= 1 - (1 - .9372) \frac{17}{15} = .9289. \end{aligned} \quad (15)$$

Example 2: Multiple Correlation Coefficient With Nonorthogonal Predictors

When the independent variables are correlated, the multiple coefficient of correlation is not equal to the

sum of the squared correlation coefficients between the dependent variable and the independent variables. In fact, such a strategy would *overestimate* the contribution of each variable because the variance that they share would be counted several times.

For example, consider the data given in Table 2, where the dependent variable is to be predicted from the independent variables X_1 and X_2 . The prediction of the dependent variable (using Equation 3) is found to be equal to

$$\hat{Y} = 1.67 + X_1 + 9.50X_2, \quad (16)$$

which gives a multiple coefficient of correlation of $R^2_{Y.1,\dots,J} = .9866$. The coefficient of correlation between X_1 and X_2 is equal to $r_{X_1.X_2} = .7500$, between X_1 and Y is equal to $r_{Y_1} = .8028$, and between X_2 and Y is equal to $r_{Y_2} = .9890$. It can easily be checked that the multiple coefficient of correlation is not equal to the sum of the squared coefficients of correlation between the independent variables and the dependent variables:

$$\begin{aligned} R^2_{Y.1,\dots,J} &= .9866 \\ &\neq r^2_{Y_1} + r^2_{Y_2} \\ &= .665 + .9780 = 1.6225. \end{aligned} \quad (17)$$

Using the data from Table 2 along with Equations 4 and 5, we find that

$$\begin{aligned} SS_{\text{regression}} &= 1822.00, \\ SS_{\text{total}} &= 1846.83, \text{ and} \\ SS_{\text{error}} &= 24.83. \end{aligned} \quad (18)$$

Table 2 A Set of Data

Y (Memory span)	14	23	30	50	39	67
X_1 (Age)	4	4	7	7	10	10
X_2 (Speech rate)	1	2	2	4	3	6

Source: Data from Abdi et al. (2002).

Notes: The dependent variable Y is to be predicted from two correlated (i.e., nonorthogonal) predictors: X_1 and X_2 . Y is the number of digits a child can remember for a short time (the “memory span”), X_1 is the age of the child, and X_2 is the speech rate of the child (how many words the child can pronounce in a given time). Six children were tested.

This gives the following value for the multiple coefficient of correlation:

$$R_{Y.1,\dots,J}^2 = \frac{SS_{\text{regression}}}{SS_{\text{total}}} = \frac{1822.00}{1846.83} = .9866. \quad (19)$$

In order to decide if this value of $R_{Y.1,\dots,J}^2$ is large enough to be considered significant, we compute an F ratio equal to

$$\begin{aligned} F &= \frac{R_{Y.1,\dots,J}^2}{1 - R_{Y.1,\dots,J}^2} \times \frac{N - J - 1}{J} \\ &= \frac{.9866}{1 - .9866} \times \frac{3}{2} = 110.50. \end{aligned} \quad (20)$$

Such a value of F is significant at all the usual alpha levels, and therefore we can reject the null hypothesis.

A better estimate of the population value of the multiple coefficient of correlation can be obtained as

$$\begin{aligned} \tilde{R}_{Y.1,\dots,J}^2 &= 1 - \left[(1 - R_{Y.1,\dots,J}^2) \left(\frac{N - 1}{N - J - 1} \right) \right] \\ &= 1 - (1 - .9866) \frac{5}{2} = .9776. \end{aligned} \quad (21)$$

MULTIPLE CORRESPONDENCE ANALYSIS

Multiple correspondence analysis (MCA) is an extension of correspondence analysis (CA), which allows one to analyze the pattern of relationships of several categorical dependent variables. As such, it can also be seen as a generalization of principal component analysis when the variables to be analyzed are categorical instead of quantitative. Because MCA has been (re)discovered many times, equivalent methods are known under several different names, such as optimal scaling, optimal or appropriate scoring, dual scaling, homogeneity analysis, scalogram analysis, and quantification method.

Technically, MCA is obtained by using a standard correspondence analysis on an indicator matrix (i.e., a matrix whose entries are 0 or 1). The percentages of explained variance need to be corrected, and the correspondence analysis interpretation of inter-point distances needs to be adapted.

When to Use It

MCA is used to analyze a set of observations described by a set of nominal variables. Each nominal variable is composed of several levels, and each of these levels is coded as a binary variable. For example, gender (F vs. M) is one nominal variable with two levels. The pattern for a male respondent will be 01, and 10 for a female. The complete data table is composed of binary columns with one and only one column taking the value “1” per nominal variable.

MCA can also accommodate quantitative variables by recoding them as “bins.” For example, a score with a range of -5 to $+5$ could be recoded as a nominal variable with three levels: less than 0, equal to 0, or more than 0. With this schema, a value of 3 will be expressed by the pattern 001. The coding schema of MCA implies that each row has the same total, which for CA implies that each row has the same *mass*.

An Example

We illustrate the method with an example from wine testing. Suppose that we want to evaluate the effect of the oak species on barrel aged red Burgundy wines. First, we aged wine coming from the same harvest of Pinot Noir in six different barrels made with two types of oak. Wines 1, 5, and 6 were aged with the first type of oak, whereas wines 2, 3, and 4 were aged with the second. Next, we asked each of three wine experts to choose from two to five variables to describe the wines. For each wine and for each variable, the expert was asked to rate the intensity. The answer given by the expert was coded either as a binary answer (i.e., fruity vs. non fruity) or as a ternary answer (i.e., no vanilla, a bit of vanilla, clear smell of vanilla). Each binary answer is represented by 2 binary columns (e.g., the answer “fruity” is represented by the pattern 10 and “nonfruity” is 01). A ternary answer is represented by 3 binary columns (i.e., the answer “some vanilla” is represented by the pattern 010). The results are presented in Table 1. The goal of the analysis is twofold. First, we want to obtain a typology of the wines, and second, we want to know if there is an agreement between the scales used by the experts. We will use the type of oak as a supplementary (or illustrative) variable to be projected on the analysis after the fact. Also, after the testing of the six wines was performed, an unknown bottle of Pinot Noir was found and tested by the wine testers. This wine will be used as a supplementary observation. For this wine,

when an expert was not sure of how to use a descriptor, a pattern of response such as .5.5 was used to represent the answer.

Notations

There are K nominal variables, each nominal variable has J_k levels, and the sum of the J_k levels is equal to J . There are I observations. The $I \times J$ indicator matrix is denoted \mathbf{X} . Performing CA on the indicator matrix will provide two sets of factor scores: one for the rows and one for the columns. These factor scores are, in general, scaled such that their variance is equal to their corresponding eigenvalue (some versions of CA compute row factor scores normalized to unity).

The grand total of the table is noted N , and the first step of the analysis is to compute the probability matrix $\mathbf{Z} = N^{-1}\mathbf{X}$. We denote \mathbf{r} the vector of the row totals of \mathbf{Z} (i.e., $\mathbf{r} = \mathbf{Z}\mathbf{1}$, with $\mathbf{1}$ being a conformable vector of 1s), \mathbf{c} the vector of the column totals, and $\mathbf{D}_c = \text{diag}\{\mathbf{c}\}$, $\mathbf{D}_r = \text{diag}\{\mathbf{r}\}$. The factor scores are obtained from the following singular value decomposition:

$$\mathbf{D}_r^{-\frac{1}{2}}(\mathbf{Z} - \mathbf{rc}^T)\mathbf{D}_c^{-\frac{1}{2}} = \mathbf{P}\mathbf{A}\mathbf{Q}^T. \tag{1}$$

Δ is the diagonal matrix of the *singular* values, and $\mathbf{\Lambda} = \Delta^2$ is the matrix of the eigenvalues. The row and (respectively) column factor scores are obtained as

$$\mathbf{F} = \mathbf{D}_r^{-\frac{1}{2}}\mathbf{P}\mathbf{\Lambda} \quad \text{and} \quad \mathbf{G} = \mathbf{D}_c^{-\frac{1}{2}}\mathbf{Q}\mathbf{\Lambda}. \tag{2}$$

Notes: “Oak Type” is an illustrative (supplementary) variable, The wine W? is an unknown wine treated as a supplementary observation.

The squared (χ^2) distances from the rows and columns to their respective barycenters are obtained as

$$\mathbf{d}_r = \text{diag}\{\mathbf{F}\mathbf{F}^T\} \quad \text{and} \quad \mathbf{d}_c = \text{diag}\{\mathbf{G}\mathbf{G}^T\}. \quad (3)$$

The squared *cosines* between row i and factor ℓ and column j and factor ℓ are obtained respectively as

$$o_{i,\ell} = \frac{f_{i,\ell}^2}{d_{r,i}^2} \quad \text{and} \quad o_{j,\ell} = \frac{g_{j,\ell}^2}{d_{c,j}^2} \quad (4)$$

(with $d_{r,i}^2$ and $d_{c,j}^2$ being, respectively, the i th element of \mathbf{d}_r and the j th element of \mathbf{d}_c). Squared cosines help locate the factors important for a given observation or variable. The *contribution* of row i to factor ℓ and of column j to factor ℓ are obtained respectively as

$$t_{i,\ell} = \frac{f_{i,\ell}^2}{\lambda_\ell} \quad \text{and} \quad t_{j,\ell} = \frac{g_{j,\ell}^2}{\lambda_\ell}. \quad (5)$$

Contributions help locate the observations or variables important for a given factor.

Supplementary or illustrative elements can be projected onto the factors using the so called *transition* formula. Specifically, let $\mathbf{i}_{\text{sup}}^T$ be an illustrative row and \mathbf{j}_{sup} be an illustrative column to be projected. Their coordinates \mathbf{f}_{sup} and \mathbf{g}_{sup} are obtained as

$$\mathbf{f}_{\text{sup}} = (\mathbf{i}_{\text{sup}}^T \mathbf{1}) \mathbf{i}_{\text{sup}}^T \mathbf{G} \mathbf{\Delta}^{-1} \quad \text{and} \quad \mathbf{g}_{\text{sup}} = (\mathbf{j}_{\text{sup}}^T \mathbf{1}) \mathbf{j}_{\text{sup}}^T \mathbf{F} \mathbf{\Delta}^{-1}. \quad (6)$$

Performing CA on the indicator matrix will provide factor scores for the rows and the columns. However, the factor scores given by a CA program will need to be rescaled for MCA, as explained in the next section.

The $J \times J$ table obtained as $\mathbf{B} = \mathbf{X}^T \mathbf{X}$ is called the *Burt matrix* associated to \mathbf{X} . This table is important in MCA because using CA on the Burt matrix gives the same factors as the analysis of \mathbf{X} but is often computationally easier. But the Burt matrix also plays an important theoretical role because the eigenvalues obtained from its analysis give a better approximation of the inertia explained by the factors than do the eigenvalues of \mathbf{X} .

Eigenvalue Correction for Multiple Correspondence Analysis

MCA codes data by creating several binary columns for each variable with the constraint that one and only one of the columns gets the value 1. This coding schema creates artificial additional dimensions because *one* categorical variable is coded with *several* columns. As a consequence, the inertia (i.e., variance) of the solution space is artificially inflated, and therefore, the percentage of inertia explained by the first dimension is severely *underestimated*. In fact, it can be shown that all the factors with an eigenvalue less or equal to $\frac{1}{K}$ simply code these additional dimensions ($K = 10$ in our example).

Two correction formulas are often used; the first one is due to Benzécri, and the second one to Greenacre. These formulas take into account that the eigenvalues smaller than $\frac{1}{K}$ are coding for the extra dimensions and that MCA is equivalent to the analysis of the Burt matrix, whose eigenvalues are equal to the squared eigenvalues of the analysis of \mathbf{X} . Specifically, if we denote by λ_ℓ the eigenvalues obtained from the analysis of the indicator matrix, then the corrected eigenvalues, denoted ${}^c\lambda$, are obtained as

$${}^c\lambda_\ell = \begin{cases} \left[\left(\frac{K}{K-1} \right) \left(\lambda_\ell - \frac{1}{K} \right) \right]^2 & \text{if } \lambda_\ell > \frac{1}{K} \\ 0 & \text{if } \lambda_\ell \leq \frac{1}{K} \end{cases} \quad (7)$$

Using this formula gives a better estimate of the inertia extracted by each eigenvalue.

Traditionally, the percentages of inertia are computed by dividing each eigenvalue by the sum of the eigenvalues, and this approach could be used here also. However, it will give an *optimistic* estimation of the percentage of inertia. A better estimation of the inertia has been proposed by Greenacre, who suggested instead to evaluate the percentage of inertia relative to the average inertia of the off diagonal blocks of the Burt matrix. This average inertia, denoted \bar{I} , can be computed as

$$\bar{I} = \frac{K}{K-1} \times \left(\sum_{\ell} \lambda_\ell^2 - \frac{J-K}{K} \right)^2. \quad (8)$$

According to this approach, the percentage of inertia would be obtained by the ratio

$$\tau_c = \frac{c\lambda}{I} \text{ instead of } \frac{c\lambda}{\sum_c \lambda_c} \quad (9)$$

Interpreting MCA

As with CA, the interpretation in MCA is often based upon proximities between points in a low-dimensional map (i.e., two or three dimensions). As well as for CA, proximities are meaningful only between points from the same set (i.e., rows with rows, columns with columns). Specifically, when two row points are close to each other, they tend to select the same levels of the

nominal variables. For the proximity between variables, we need to distinguish two cases. First, the proximity between levels of *different* nominal variables means that these levels tend to appear together in the observations. Second, because the levels of the *same* nominal variable cannot occur together, we need a different type of interpretation for this case. Here, the proximity between levels means that the groups of observations associated with these two levels are themselves similar.

The Example

Table 2 lists the corrected eigenvalues and proportion of explained inertia obtained with the Benzécri/Greenacre correction formula. Tables 3 and 4

give the corrected factor scores, cosines, and contributions for the rows and columns of Table 1. Figure 1 displays the projections of the rows and the columns. We have separated these two sets, but because the projections have the same variance, these two graphs could be displayed together (as long as one keeps in mind that distances between points are meaningful only within the same set). The analysis is essentially unidimensional, with wines 2, 3, and 4 clustered on the negative side of the factors and wines 1, 5, and 6 on the positive side. The supplementary wine does not seem to belong to either cluster. The analysis of the columns shows that the negative side of the factor is characterized as being nonfruity, nonwoody, and coffee by Expert 1; roasted, nonfruity, low in vanilla, and woody by Expert 2; and buttery and woody by Expert 3. The positive side gives the reverse pattern. The supplementary elements indicate that the negative side is correlated with the second type of oak, whereas the positive side is correlated with the first type of oak.

(b) The J set: columns (i.e., adjectives). Oak 1 and Oak 2 are supplementary elements (the projection points have been slightly moved to increase readability). (Projections from Tables 3 and 4.)

Alternatives to MCA

Because the interpretation of MCA is more delicate than simple CA, several approaches have been suggested to offer the simplicity of interpretation of CA for indicator matrices. One approach is to use a different metric from χ^2 , the most attractive alternative being the Hellinger distance. Another approach, called *joint correspondence analysis*, fits only the off-diagonal tables of the Burt matrix and can be interpreted as a factor analytic model.

MULTIPLE FACTOR ANALYSIS

Multiple factor analysis (MFA) analyzes observations described by several “blocks” or sets of variables. MFA seeks the common structures present in all or some of these sets. MFA is performed in two steps. First, a principal component analysis (PCA) is performed on each data set, which is then “normalized” by dividing all its elements by the square root of the first eigenvalue obtained from its PCA. Second, the normalized data sets are merged to form a unique matrix, and a global PCA is performed on this matrix. The individual data sets are then projected onto the global analysis to analyze communalities and discrepancies. MFA is used in very different domains such as sensory evaluation, economy, ecology, and chemistry.

MFA is used to analyze a set of observations described by several groups of variables. The number of variables in each group may differ, and the nature of the variables (nominal or quantitative) can vary from one group to the other, but the variables should be of the same nature in a given group. The analysis derives an integrated picture of the observations and of the relationships between the groups of variables.

The goal of MFA is to integrate different groups of variables describing the same observations. In order to do so, the first step is to make these groups of variables

comparable. Such a step is needed because the straightforward analysis obtained by concatenating all variables would be dominated by the group with the strongest structure. A similar problem can occur in a non-normalized PCA: Without normalization, the structure is dominated by the variables with the largest variance. For PCA, the solution is to normalize (i.e., to use z scores) each variable by dividing it by its standard deviation. The solution proposed by MFA is similar: To compare groups of variables, each group is normalized by dividing all its elements by a quantity called its *first singular value*, which is the matrix equivalent of the standard deviation. Practically, this step is implemented by performing a PCA on each group of variables. The first singular value is the square root of the first eigenvalue of the PCA. After normalization, the data tables are concatenated into a data table that is submitted to PCA.

An Example

To illustrate MFA, we selected six wines, coming from the same harvest of Pinot Noir, aged in six different barrels made with one of two different types of oak. Wines 1, 5, and 6 were aged with the first type of oak, and wines 2, 3, and 4 with the second. Next, we asked each of three wine experts to choose from two to five variables to describe the six wines. For each wine, the expert rated the intensity of the variables on a 9 point scale. The results are presented in Table 1 (the same example is used in the entry for STATIS). The goal of the analysis is twofold. First, we want to obtain a typology of the wines, and second, we want to know if there is an agreement between the experts.

Table 1 Raw Data for the Wine Example

Wines	Oak Type	Expert 1			Expert 2				Expert 3		
		Fruity	Woody	Coffee	Red Fruit	Roasted	Vanillin	Woody	Fruity	Butter	Woody
Wine 1	1	1	6	7	2	5	7	6	3	6	7
Wine 2	2	5	3	2	4	4	4	2	4	4	3
Wine 3	2	6	1	1	5	2	1	1	7	1	1
Wine 4	2	7	1	2	7	2	1	2	2	2	2
Wine 5	1	2	5	4	3	5	6	5	2	6	6
Wine 6	1	3	4	4	3	5	4	5	1	7	5

Notations

The raw data consist in T data sets. Each data set is called a *study*. Each study is an $I \times J_{[t]}$ rectangular data matrix denoted $\mathbf{Y}_{[t]}$, where I is the number of observations and $J_{[t]}$ the number of variables of the t th study. Each data matrix is, in general, preprocessed (e.g., centered, normalized), and the preprocessed data matrices actually used in the analysis are denoted $\mathbf{X}_{[t]}$.

For our example, the data consist in $T = 3$ studies. The data (from Table 1) were centered by column (i.e., the mean of each column is zero) and normalized (i.e., for each column, the sum of the squared elements is equal to 1). So the starting point of the analysis consists in three matrices:

$$\mathbf{X}_{[1]} = \begin{bmatrix} -0.57 & 0.58 & 0.76 \\ 0.19 & -0.07 & -0.28 \\ 0.38 & -0.50 & -0.48 \\ 0.57 & -0.50 & -0.28 \\ -0.38 & 0.36 & 0.14 \\ -0.19 & 0.14 & 0.14 \end{bmatrix},$$

$$\mathbf{X}_{[2]} = \begin{bmatrix} -0.50 & 0.35 & 0.57 & 0.54 \\ 0.00 & 0.05 & 0.03 & -0.32 \\ 0.25 & -0.56 & -0.51 & -0.54 \\ 0.75 & -0.56 & -0.51 & -0.32 \\ -0.25 & 0.35 & 0.39 & 0.32 \\ -0.25 & 0.35 & 0.03 & 0.32 \end{bmatrix}$$

and $\mathbf{X}_{[3]} = \begin{bmatrix} -0.03 & 0.31 & 0.57 \\ 0.17 & -0.06 & -0.19 \\ 0.80 & -0.61 & -0.57 \\ -0.24 & -0.43 & -0.38 \\ -0.24 & 0.31 & 0.38 \\ -0.45 & 0.49 & 0.19 \end{bmatrix}.$ (1)

Each observation is assigned a *mass* that reflects its importance. When all observations have the same importance, their masses are all equal to $m_i = \frac{1}{I}$. The set of the masses is stored in an $I \times I$ diagonal matrix denoted \mathbf{M} .

Finding the Global Space

Computing the Separate PCAs

To normalize the studies, we first compute a PCA for each study. The first singular value (i.e., the square root of the first eigenvalue) is the normalizing factor used to divide the elements of the data table. For example, the PCA of the first group gives a first eigenvalue ${}_1\varrho_1 = 2.86$ and a first singular value of ${}_1\varphi_1 = \sqrt{{}_1\varrho_1} = 1.69$. This gives the first normalized data matrix, denoted $\mathbf{Z}_{[1]}$:

$$\mathbf{Z}_{[1]} = {}_1\varphi_1^{-1} \times \mathbf{X}_{[1]} = \begin{bmatrix} -0.33 & 0.34 & 0.45 \\ 0.11 & -0.04 & -0.16 \\ 0.22 & -0.30 & -0.28 \\ 0.33 & -0.30 & -0.16 \\ -0.22 & 0.21 & 0.08 \\ -0.11 & 0.08 & 0.08 \end{bmatrix}. \quad (2)$$

Matrices $\mathbf{Z}_{[2]}$ and $\mathbf{Z}_{[3]}$ are normalized with their first respective singular values of ${}_2\varphi_1 = 1.91$ and ${}_3\varphi_1 = 1.58$. Normalized matrices have a first singular value equal to 1.

Building the Global Matrix

The normalized studies are concatenated into an $I \times T$ matrix called the *global data matrix*, denoted \mathbf{Z} . Here we obtain

$$\mathbf{Z} = [\mathbf{Z}_{[1]} \mathbf{Z}_{[2]} \mathbf{Z}_{[3]}] = \begin{bmatrix} -0.33 & 0.34 & 0.45 & -0.26 & 0.18 & 0.30 & 0.28 & -0.02 & 0.19 & 0.36 \\ 0.11 & -0.04 & -0.16 & 0.00 & 0.03 & 0.02 & -0.17 & 0.11 & -0.04 & -0.12 \\ 0.22 & -0.30 & -0.28 & 0.13 & -0.29 & -0.27 & -0.28 & 0.51 & -0.39 & -0.36 \\ 0.33 & -0.30 & -0.16 & 0.39 & -0.29 & -0.27 & -0.17 & -0.15 & -0.27 & -0.24 \\ -0.22 & 0.21 & 0.08 & -0.13 & 0.18 & 0.20 & 0.17 & -0.15 & 0.19 & 0.24 \\ -0.11 & 0.08 & 0.08 & -0.13 & 0.18 & 0.02 & 0.17 & -0.29 & 0.31 & 0.12 \end{bmatrix}. \quad (3)$$

Computing the Global PCA

To analyze the global matrix, we use standard PCA. This amounts to computing the singular value decomposition of the global data matrix

$$\mathbf{Z} = \mathbf{U}\mathbf{\Delta}\mathbf{V}^T \quad \text{with} \quad \mathbf{U}^T\mathbf{U} = \mathbf{V}^T\mathbf{V} = \mathbf{I}, \quad (4)$$

where \mathbf{U} and \mathbf{V} are the left and right singular vectors of \mathbf{Z} , and $\mathbf{\Delta}$ is the diagonal matrix of the singular values.

For our example, we obtain

$$\mathbf{U} = \begin{bmatrix} 0.53 & -0.35 & -0.58 & -0.04 & 0.31 \\ -0.13 & -0.13 & 0.49 & 0.51 & 0.54 \\ -0.56 & -0.57 & 0.01 & -0.36 & -0.25 \\ -0.44 & 0.62 & -0.48 & 0.15 & 0.03 \\ 0.34 & 0.04 & 0.16 & 0.39 & -0.73 \\ 0.27 & 0.40 & 0.40 & -0.65 & 0.11 \end{bmatrix} \quad (5)$$

and

$$\text{diag}\{\mathbf{\Delta}\} = [1.68 \quad 0.60 \quad 0.34 \quad 0.18 \quad 0.11]$$

and

$$\begin{aligned} \text{diag}\{\mathbf{\Lambda}\} &= \text{diag}\{\mathbf{\Delta}^2\} \\ &= [2.83 \quad 0.36 \quad 0.11 \quad 0.03 \quad 0.01] \end{aligned} \quad (6)$$

($\mathbf{\Lambda}$ gives the eigenvalues of the PCA) and

$$\mathbf{V} = \begin{bmatrix} -0.34 & 0.22 & 0.03 & 0.14 & 0.55 \\ 0.35 & -0.14 & -0.03 & 0.30 & 0.02 \\ 0.32 & -0.06 & -0.65 & -0.24 & 0.60 \\ -0.28 & 0.34 & -0.32 & 0.31 & -0.18 \\ 0.30 & -0.00 & 0.43 & 0.11 & 0.19 \\ 0.30 & -0.18 & -0.00 & 0.67 & 0.11 \\ 0.30 & 0.09 & -0.22 & -0.36 & -0.38 \\ -0.22 & -0.86 & 0.01 & -0.12 & -0.00 \\ 0.36 & 0.20 & 0.45 & -0.30 & 0.19 \\ 0.37 & 0.01 & -0.21 & 0.18 & -0.28 \end{bmatrix} \quad (7)$$

The global factor scores for the wines are obtained as

$$\mathbf{F} = \mathbf{M}^{-1}\mathbf{U}\mathbf{\Delta} \quad (8)$$

$$= \begin{bmatrix} 2.18 & -0.51 & -0.48 & -0.02 & 0.08 \\ -0.56 & -0.20 & 0.41 & 0.23 & 0.15 \\ -2.32 & -0.83 & 0.01 & -0.16 & -0.07 \\ -1.83 & 0.90 & -0.40 & 0.07 & 0.01 \\ 1.40 & 0.05 & 0.13 & 0.17 & -0.20 \\ 1.13 & 0.58 & 0.34 & -0.29 & 0.03 \end{bmatrix} \quad (9)$$

In \mathbf{F} , each row represents an observation (i.e., a wine) and each column a component. Figure 1 displays the wines in the space of the first two principal components. The first component has an eigenvalue equal to $\lambda_1 = 2.83$, which corresponds to 84% of the inertia ($\frac{2.83}{2.83+0.36+0.11+0.03+0.01} = \frac{2.83}{3.35} \approx .84$). The second component, with an eigenvalue of .36, explains 11% of the inertia. The first component is interpreted as the opposition between the first (wines 1, 5, and 6) and the second oak type (wines 2, 3, and 4).

Partial Analyses

The global analysis reveals the common structure of the wine space. In addition, we want to see how each expert “interprets” this space. This is achieved by projecting the data set of each expert onto the global analysis. This is implemented by multiplication of a cross product matrix by a projection matrix. The projection matrix is obtained by

Figure 1 Global Analysis: Plot of the Wines on the First Two Principal Components

Notes: First component: $\lambda_1 = 2.83$, explains 84% of the inertia; second component: $\lambda_2 = 0.36$, explains 11% of the inertia.

rewriting Equation 8 to show that the global factor scores could be computed as

$$\mathbf{F} = \mathbf{M}^{-\frac{1}{2}}\mathbf{U}\mathbf{\Delta} = (\mathbf{Z}\mathbf{Z}^T) \times (\mathbf{M}^{-\frac{1}{2}}\mathbf{U}\mathbf{\Delta}^{-1}). \quad (10)$$

This shows that $\mathbf{P} = \mathbf{M}^{-\frac{1}{2}}\mathbf{U}\mathbf{\Delta}^{-1}$ is a projection matrix that transforms the matrix $\mathbf{Z}\mathbf{Z}^T$ into factor scores. Here, we obtain

$$\mathbf{P} = \mathbf{M}^{-\frac{1}{2}}\mathbf{U}\mathbf{\Delta}^{-1} = \begin{bmatrix} 0.77 & -1.43 & -4.20 & -0.55 & 6.68 \\ -0.20 & -0.55 & 3.56 & 6.90 & 11.71 \\ -0.82 & -2.33 & 0.05 & -4.85 & -5.53 \\ -0.65 & 2.54 & -3.46 & 2.01 & 0.66 \\ 0.50 & 0.15 & 1.13 & 5.27 & -15.93 \\ 0.40 & 1.61 & 2.91 & -8.78 & 2.43 \end{bmatrix}, \quad (11)$$

which is then used to project the studies onto the global space. For example, for the first expert we obtain

$$\mathbf{F}_{[1]} = T \times (\mathbf{Z}_{[1]}\mathbf{Z}_{[1]}^T)\mathbf{P} \quad (12)$$

$$= \begin{bmatrix} 2.76 & -1.10 & -2.29 & -0.39 & 0.67 \\ -0.77 & 0.30 & 0.81 & 0.31 & -0.27 \\ -1.99 & 0.81 & 1.48 & 0.08 & -0.39 \\ -1.98 & 0.93 & 0.92 & -0.02 & 0.59 \\ 1.29 & -0.62 & -0.49 & 0.10 & -0.51 \\ 0.69 & -0.30 & -0.43 & -0.07 & -0.08 \end{bmatrix}. \quad (13)$$

(Multiplying by T is needed in order to scale one expert with all $T = 3$ experts of the global solution.) The same procedure is used for Experts 2 and 3:

$$\mathbf{F}_{[2]} = \begin{bmatrix} 2.21 & -0.86 & 0.74 & 0.27 & 0.06 \\ -0.28 & -0.13 & 0.35 & 0.55 & 0.52 \\ -2.11 & 0.50 & -0.77 & -0.49 & -0.01 \\ -2.39 & 1.23 & -1.57 & -0.20 & -0.68 \\ 1.49 & -0.49 & 0.62 & 0.40 & 0.13 \\ 1.08 & -0.24 & 0.63 & -0.53 & -0.03 \end{bmatrix}, \quad (14)$$

and

$$\mathbf{F}_{[3]} = \begin{bmatrix} 1.54 & 0.44 & 0.09 & 0.07 & -0.47 \\ -0.61 & -0.76 & 0.06 & -0.17 & 0.19 \\ -2.85 & -3.80 & -0.69 & -0.07 & 0.19 \\ -1.12 & 0.56 & -0.55 & 0.42 & 0.11 \\ 1.43 & 1.27 & 0.26 & 0.03 & -0.22 \\ 1.62 & 2.28 & 0.82 & -0.28 & 0.20 \end{bmatrix}. \quad (15)$$

Figure 2 shows the first two principal components of the global analysis along with the wine projections for the experts. Note that the position of each wine in the global analysis is the barycenter (i.e., centroid) of its positions for the experts. To facilitate the interpretation, we have drawn lines linking the expert wine projection to the global wine position. This picture shows that Expert 3 is at variance with the other experts, in particular for Wines 3 and 6.

The Original Variables and the Global Analysis

As in standard PCA, the variable loadings are the correlation between the original variables and the global factor scores (cf. Table 2). These loadings are plotted in Figure 3 along with the “circles of correlation.” This figure shows that Expert 3 differs from the other experts and is mostly responsible for the second component of the compromise.

The Original PCAs and the Global Analysis

MFA starts with a series of PCAs. Their relationship with the global analysis is explored by computing loadings (i.e., correlations) between the components of each study and the components of the global analysis. These loadings, given in Table 2, are displayed in Figure 3. They relate the original PCA and the global analysis.

Analyzing the Between-Study Structure

The relationships between the studies and between the studies and the global solution are analyzed by

Figure 2 Projection of the Experts Onto the Global Analysis

Notes: Experts are represented by their faces. A line segment links the position of the wine for a given expert to its global position. First component: $\lambda_1 = 2.83$, explains 84% of the inertia; second component: $\lambda_2 = 2.83$, explains 11% of the inertia.

computing the partial inertia of each study for each dimension of the global analysis. This is computed, for each study, as the sum of the squared projections of the variables on the right singular vectors of \mathbf{Z} (cf. Equation 7) multiplied by the corresponding eigenvalue. Because the singular vectors are normalized, the sum of the partial inertias for all the studies for a given dimension is equal to its eigenvalue. For example, for Study 1 and Component 1, the partial inertia is obtained as

$$\lambda_1 \times \sum_j q_{j,1}^2 = 2.83 \times [(-.34)^2 + (.35)^2 + (.32)^2] = 2.83 \times .34 = .96. \tag{16}$$

Similar computations give the values reported in Table 3. These values are used to plot the studies as shown in Figure 4. The plot confirms the originality of Expert 3 and its importance for Dimension 2.

MULTIPLE IMPUTATION FOR MISSING DATA

In many, if not most, studies, some data that were meant to be collected are missing. For example, in a survey, some people may not respond to all the questions. Or, in a randomized experiment, some units' outcomes may not be measured because of equipment failure. Multiple imputation is one principled method for handling such missing data. The general idea is to fill in the missing data with plausible values, analyze the completed data set, and repeat the process multiple times. The analyses from each completed data set are combined to result in inferences that properly account for the missing data. Multiple imputation has been used in large governmental surveys such as the National Health and Nutrition Examination Survey and the Survey of Consumer Finances, and in numerous studies by individual researchers.

Before we review multiple imputation, it is worthwhile to consider the most common and convenient approach to handling missing data: Analyze only the cases that have complete data for the variables of interest. This available cases approach can lead to inaccurate estimates. For a simple illustration of this point, consider the hypothetical data in Table 1 for a random sample of five people. Suppose that weights of all people over 6 feet tall are missing—so that the observed data are 130, 140, and 150—because the height/weight instrument is unable to record information for people over 6 feet tall. Researchers interested in estimating the population average weight are in

Table 1 Hypothetical Data for Illustrating Multiple Imputation

65	130
68	140
70	150
72	160
75	170

trouble if they use only the three available cases: their sample average is a severe underestimate.

Many times, researchers are interested in relationships among variables, such as regression coefficients. In the hypothetical example, the fitted regression of weight on height obtained using the three available cases results in reasonable (unbiased) estimates of the slope and intercept, because the regression holds for all heights. However, in data sets with many variables and complicated missing data patterns, using only the available cases might exclude a large fraction of the observations, which could dramatically increase the variability of the estimates. Additionally, different specifications of models may use different units for estimation, making theoretical properties of resulting inferences nearly impossible to understand and practical comparisons of different models difficult.

Illustration of Multiple Imputation

In contrast to available cases analyses, multiple imputation uses all records for estimation, which takes advantage of the information from partially completed records. To illustrate multiple imputation, we again use the hypothetical example. We first demonstrate how to analyze a set of multiply imputed data sets, and then discuss methods of generating imputations.

Suppose that five plausible values for each missing weight have been generated to create five completed data sets. These are displayed in Table 2, along with the estimated slope and its variance obtained from fitting standard linear regression in each completed data set. Inferences for the population regression slope β

are based on three quantities. First, compute the average of the five estimated slopes, which equals 4.01. Second, compute the variance of these five estimated slopes, which equals .0523. Third, compute the average of the variances of the slopes, which equals .0209. The point estimate of the population slope is 4.01, and the variance associated with this point estimate is $(1 + 1/5)(0.0523) + 0.0209 = 0.0836$. An approximate 95% confidence interval for β is $4.01 \pm 1.96\sqrt{.0836}$. A similar process can be followed to obtain inferences for the population average weight, using the sample average weights and their variances. This resulting approximate 95% confidence interval is $149.5 \pm 1.96\sqrt{48.63}$.

Generically, suppose the goal is to estimate some parameter Q , such as a population mean or a regression coefficient. Let q be the estimator of Q , and let u be the estimator of the variance of q . In each completed data set l , where $l = 1, \dots, m$, let q_l and u_l be the values of q and u obtained from that data set. The following quantities are required for inferences:

$$\bar{q}_m = \sum_{l=1}^m q_l$$

$$b_m = \sum_{l=1}^m (q_l - \bar{q}_m)^2 / (m - 1)$$

$$\bar{u}_m = \sum_{l=1}^m u_l.$$

The point estimate of Q is \bar{q}_m , and its variance is estimated by

$$T_m = (1 + 1/m)b_m + \bar{u}_m.$$

An approximate 95% confidence interval is

$$\bar{q}_m \pm 1.96\sqrt{T_m}.$$

The use of a normal distribution for confidence intervals is most appropriate when the number of records in the completed data set is large, say, 40 or more, and the number of completed data sets m is

large, say, 20 or more. When the number of records is large but m is moderate, inferences should be made using a t distribution with degrees of freedom v_m , where

$$v_m = (m - 1) \left(1 + \frac{\bar{u}_m}{(1 + 1/m)b_m} \right)^2.$$

When the number of records and m are moderate, we use a t distribution with a complicated degrees of freedom formula that can be found in the references below. Using these t distributions rather than normal distributions improves the coverage properties of the confidence intervals.

Imputing missing values is a complicated process for complex patterns of missing data. In general, the analyst first specifies a statistical model relating all the variables in the data set. The analyst then uses that model and the observed data to estimate the distributions of the model parameters (e.g., the intercept, slope, and regression variance in the hypothetical data). Based on these estimated distributions, the analyst generates plausible values of the model parameters. Using these values and the observed data, the analyst generates values of the missing data. This creates one completed data set. The process is repeated m times.

Generating imputations from scratch requires knowledge of Bayesian statistics and Markov chain Monte Carlo methods. Fortunately, software exists that makes it unnecessary to generate imputations from scratch.

Software for Multiple Imputation

When data can be reasonably described by a multivariate normal distribution, analysts can use the free software package NORM, written by Joe Schafer, to generate and analyze multiply imputed data sets. This is a standalone package that runs on PCs. The NORM Web site also has links to software that does multiple imputation for purely categorical data (CAT), data that are mixed categorical and multivariate normal (MIX), and longitudinal data (PAN). These packages run within the S Plus software environment.

Another approach is to construct a series of regression models, using each variable with missing values as the outcome variable in one of the regressions. For example, suppose age is measured in the hypothetical

data set, and its value is missing for some people. Missing weights are imputed from a regression of weight on height and age, and missing ages are imputed from a regression of age on height and weight. This approach allows analysts to specify models one variable at a time, which eases computations. This approach is implemented in the free software IVEWARE for SAS, written by Trivellore Raghunathan. It is also implemented in the free software package MICE for S Plus.

Assumptions of Multiple Imputation

Two conditions are needed for inferences from the multiply imputed data sets to be valid, in the sense that 95% of all 95% confidence intervals contain their parameter of interest over repeated application. First, if there were no missing data, the estimator q and its variance u should produce a valid 95% confidence interval for the parameter of interest. For example, the relationship between weight and height needs to be well described by a linear regression if we are to trust the 95% confidence interval for the slope. Second, the imputations need to be plausible values, in the sense that they come from a model that faithfully reflects the relationships in the data. For example, if weights are implausibly imputed by plugging in the average weight rather than using the regression on heights, the relationship between weight and height would be distorted.

The imputation process does not affect the validity of the first condition, but it is central to the second condition. It is essential that imputations be made from expansive models. For example, include as many predictors as possible in the regression models. This ensures that those relationships will be reflected in the imputations.

It is necessary that $m > 1$; otherwise, it is not possible to estimate b_m . Intuitively, if the analyst imputes just one data set and then analyzes it, the analyst essentially would be acting as if the imputed values were genuine values, when in reality, they were simulated from probability models. Generating multiple plausible values allows the uncertainty due to imputation to be passed on to inferences. In general, the larger m is, the more accurate inferences tend to be. Research has shown that $m = 5$ is often adequate, especially when the fraction of missing values is not large.

Extensions to Multiple Imputation

In addition to the inferential methods for scalar estimands presented here, researchers have developed methods for doing significance tests for multi component estimands. For example, it is possible to perform likelihood ratio tests of nested models using multiply imputed data sets. Multiple imputation also has been suggested as a way to protect data confidentiality.

MULTITRAIT MULTIMETHOD MATRIX AND CONSTRUCT VALIDITY

A multitrait multimethod matrix (MTMM) refers to a matrix of correlations derived from a factorial design in which each of a set of constructs has been assessed with each of a set of different methods of measurement. Originally developed by Donald T. Campbell and Donald W. Fiske, the MTMM was proposed to assess construct validity (i.e., the degree to which an operationalization reflects its intended construct) using two subcategories of validity. “Convergent validity” is the extent to which measures intended to assess the same construct are associated with one another. “Discriminant validity” is the extent to which measures designed to assess different constructs are, in fact, distinct from one another.

The goal of the MTMM is to provide a framework to assess the effects of trait variance (variance attributed to the intended construct of interest) and

method variance (variance attributable to the specific method of measurement) by examining convergent and discriminant validity. More generally, the MTMM also provides information about patterns of associations between methods, and patterns of associations between constructs and possible interactions between methods and constructs.

Selecting Traits and Methods for an MTMM

The selection of traits and methods for an MTMM analysis should follow a set of guidelines. First, each method should be well suited to evaluating all of the constructs of interest. Second, measurement methods should be as independent of each other as possible. Finally, constructs should be included that are expected to vary in their degree of association. In other words, the matrix should include some constructs postulated to be highly related and some constructs thought to be unrelated. This range of association is recommended in order to provide a basis of comparison for discriminant validity.

Organization of an MTMM

Once MTMM data are collected, correlations among the observed scores are computed and arranged with a specific organization. This can be illustrated with a hypothetical example (see Table 1). This example has three traits (feelings, beliefs, and intentions to act), each of which has been assessed using three measurement methods: a Thurston equal appearing interval scale, a Likert summated ratings scale, and a Semantic Differential scale. Thus, there are nine observations for each person, thereby producing a 9×9 correlation matrix.

The MTMM is organized by method, with each of the three constructs embedded in each method block. The interpretation of the MTMM involves identifying the four different types of construct method pairings within the matrix, which take the form of either a diagonal or a triangle. These pairings are evaluated using a set of guidelines.

The first type of construct method pairing is the monotrait heteromethod diagonals, which are

correlations between different measures of the same construct. These correlations are in bold and include, for example, the correlation between feelings evaluated by both the Likert Scale and the Thurstone scale ($r = .75$). These correlations are also known as the validity diagonals.

The second type of construct method pairing is the heterotrait heteromethod triangles, which are the correlations between different measures of different traits (i.e., correlations between pairings that have neither trait nor measure in common). These correlations are unmarked in the matrix and include, for example, the correlations between feelings evaluated by the Likert scale and beliefs evaluated by the Thurstone scale ($r = .60$).

The third type of construct method pairing is the monotrait monomethod diagonals, which are the correlations between the same constructs using the same measures. These correlations are highlighted in the matrix via parentheses and include feelings evaluated by both measures of the Thurstone scale ($r = .98$). These are essentially the correlation of the measure with itself, and for that reason, these correlations are estimates of the reliability of each measure.

The fourth type of construct method pairing is the heterotrait monomethod triangles, which are the correlations between different constructs evaluated using the same measure. These correlations are underlined in the matrix and include feelings and beliefs evaluated by the Thurstone scale ($r = .62$).

Interpreting the MTMM

The guidelines for interpreting an MTMM begin by evaluating the monotrait monomethod (reliability) diagonal. These coefficients should be consistently the highest in the matrix because it is unlikely that a measure will correlate more highly with anything but itself. Following our example, the monotrait monomethod correlations are indeed the highest of the matrix, ranging from .92 to .99.

Second, the monotrait heteromethod correlations are used to assess convergent validity. Large correlations of this sort indicate convergent validity because the different methods are in agreement on the same underlying constructs. In our example, the monotrait heteromethod correlations are high (ranging from .74 to .88), thereby suggesting that different methods produce similar results for the three constructs.

Although high monotrait heteromethod correlations are a necessary condition for convergent validity, they are not sufficient for its existence. Specifically, even when monotrait heteromethod correlations are large, it is possible that they may be artificially inflated based on an irrelevant factor (e.g., different measures may be highly correlated because of method variance). Thus, the values in the monotrait heteromethod diagonals should be compared to the values in the heterotrait heteromethod triangles. Specifically, the values of the monotrait heteromethod diagonal should be higher than those of the heterotrait heteromethod correlations that share the same column or row. Essentially, if these different methods are truly measuring the same construct (i.e., it is mainly trait variance responsible for the high monotrait heteromethod correlations), these values should be correlated more strongly than unrelated constructs that are measured using different methods (i.e., values having neither construct or method in common). For example, in the sample matrix, the correlation between the Thurstone and Likert scales evaluating feelings ($r = .75$) is higher than the correlation between the Likert scale evaluating feelings with the Thurston scale evaluating behavior ($r = .60$), the Likert scale evaluating feelings with the Thurstone scale evaluating intentions ($r = .18$), and so on. A visual examination reveals that the monotrait heteromethod values are higher than the heterotrait heteromethod values for each comparison in the matrix. Furthermore, heterotrait heteromethod correlations for constructs hypothesized to be related should be higher than for those not hypothesized to be related.

Next, monotrait heteromethod values should be compared to the heterotrait monomethod triangles. Specifically, the values in the monotrait heteromethod diagonal should be higher than those of heterotrait monomethod triangles, because different methods measuring the same trait should be more highly correlated than the same methods measuring different traits. If the heterotrait monomethod correlations are larger, it suggests that the method of measurement may account for a larger proportion of the observed variance in the scores. In our example,

the correlation between the Thurstone and Likert evaluations of feelings ($r = .75$) is higher than the Thurstone values for feelings and belief ($r = .62$), the Thurstone values for feelings and intentions ($r = .19$), and the Thurstone values for beliefs and intentions ($r = .17$). This criterion is met for each comparison in the matrix.

Finally, researchers should evaluate both the heterotrait monomethod and the heterotrait heteromethod triangles. If two traits are correlated, this relationship should hold irrespective of the method used to evaluate them, and therefore, the same pattern of interrelationships between different traits should be visible in all of the monomethod and heteromethod blocks. In examining the sample matrix, this criterion is satisfied (e.g., feelings and beliefs are always more highly correlated than are feelings and intentions).

Limitations of the MTMM

Although the MTMM remains a popular and useful approach, it does have limitations. For example, many key underlying assumptions are not clearly defined (e.g., the MTMM assumes the existence of both method and trait factors but does not specify their relationships with each other). It also provides no manner of testing its underlying assumptions and is unrealistic in that it neglects to account for random measurement error. Additionally, there are practical problems associated with the use of MTMM. For example, complete cross factoring of methods and constructs is not always possible, and very large matrices can be difficult to evaluate. The MTMM approach has also been criticized for its ambiguity. MTMM matrices sometimes produce conflicting results within a given matrix. Thus, in practice, some aspects of the matrix may be consistent with the guidelines, whereas others may not. In such cases, evaluations of the matrix can be very subjective.

In order to address the difficulty of quantifying the extent to which MTMM criteria have been satisfied, statistical procedures have been proposed to complement the visual evaluations of the matrix. The most common approach is the use of confirmatory factor

analysis. A number of different factor analytic models have been proposed to evaluate MTMM data. Unfortunately, many of these models have conceptual and practical limitations. Research evaluating the strengths and weaknesses of these models remains an active area of inquiry in the quantitative methods literature, and some promising techniques have been identified (e.g., the Composite Direct Product Model). However, definitive comparisons of many of these models have yet to be conducted.

MULTIVARIATE ANALYSIS OF VARIANCE (MANOVA)

Multivariate analysis of variance, or MANOVA, is a data-modeling technique that is a powerful alternative to its univariate analysis of variance (ANOVA) counterpart. With traditional ANOVA, mean differences between groups on a single quantitative variable can be analyzed. For instance, consider a school psychologist who is interested in examining the average performance of Asian, Caucasian, and Hispanic children on a standardized test of intelligence that yields

continuous scores on three subscales: Mathematics, Verbal, and Processing Speed. Adopting a univariate frame of mind, the psychologist could conduct three separate ANOVAs to determine if the means of the ethnic groups are equivalent on each of the three subscales. If the psychologist viewed the data from a multivariate standpoint, however, he or she could conduct a single MANOVA to examine differences between the Asian, Caucasian, and Hispanic children on linear combinations of the three intelligence subscales. In other words, he or she could combine the Mathematics, Verbal, and Processing Speed scores to form one or more multivariate composites on which the three ethnic groups could be compared. Perhaps a combination of high Mathematics, high Processing Speed, and low Verbal scores will provide the most effective composite for discriminating among the three groups? Perhaps the simple difference between the Mathematics and Verbal subscale scores will instead provide the most effective composite? Such questions are multivariate in nature because they address the interrelationships among the continuous measures of intellectual ability.

The primary strength of MANOVA is thus the capability to examine group differences on linear combinations of quantitative variables. For the sake of convenience, grouping variables will herein be referred to as *independent variables*, and the quantitative variables will be referred to as *dependent variables*. In the example above, ethnicity (with three levels: Asian, Caucasian, and Hispanic) is the independent variable, and the three intelligence subscales are the dependent variables. Mathematically speaking, there are no limits to the number of independent variables or dependent variables that can be included in the analysis, and the independent variables can be composed of two or more groups. When only one independent variable is included, the analysis is referred to as a one-way (or one-factor) MANOVA, and when two or more independent variables are included, the analysis is referred to as a factorial MANOVA. In the special case of one independent variable with two levels, the analysis is often referred to as a Hotelling's *T*, which is the multivariate generalization of the independent samples *t* test. Regardless

of the study design, the goal of the MANOVA is to determine if the independent variable groups differ in their means on at least one linear combination of the dependent variables.

An Example

Consider a study of the *Sesame Street* television series reported by James P. Stevens. Children in the 3–5 year age range were studied and assessed on a variety of measures both before and after watching episodes of *Sesame Street*. One question that could be addressed in this data regards differences between boys and girls prior to viewing the episodes. Measures of knowledge in four areas are of particular interest: body parts, letters, forms, and numbers. Scale values on these measures range from 0–58, 0–20, 0–54, and 0–32, respectively. Are the mean performances of the boys and girls similar on these scales? Gender, with two levels (boys and girls), will be treated as the independent variable, and the four knowledge scales will serve as the dependent variables.

For pedagogical reasons only, the data are first analyzed with four ANOVAs, examining each knowledge area separately. The null hypothesis for each analysis represents equality between population means on the variable; $H_0: \mu_{\text{boys}} = \mu_{\text{girls}}$, where μ represents the population mean. The resulting F values and associated statistics computed from SPSS are shown in Table 1. Using an unadjusted a priori p value of .05, it can be seen that the ANOVAs are not statistically significant (all observed, “Sig.,” observed p values > .05). The results therefore suggest that the population means for the boys and girls are equal in each of the four knowledge areas.

These data are also suitable for a one way MANOVA given the single independent variable and multiple dependent variables. The null hypothesis for this analysis states that the two groups

are equal on a linear combination of all four dependent variables— $H_0: \mu_{\text{linear,boys}} = \mu_{\text{linear,girls}}$. The mathematics underlying the MANOVA will produce the linear combination in such a way as to maximize the mean difference between the boys and girls. The mean difference on the linear combination then can be tested for statistical significance, as shown in Table 2.

Four tests of statistical significance are commonly available for MANOVA, and three of these tests have well known sampling distributions from which p values can be estimated. The significance level of the remaining test, Roy’s *greatest characteristic root* (or g.c.r., with s , m , and n degrees of freedom from Table 2), can also be estimated with special software developed by Richard J. Harris.

In this example, the tests show that the results of the MANOVA are statistically significant; in other words, the population means for the boys and girls

are judged to be different on a linear combination of the four areas of knowledge. The F values and p values are all identical because only one independent variable with two levels is included in the analysis. In other study designs, these values will not necessarily be equal. Furthermore, in this example, only one linear combination of the dependent variables (to be shown below) is being tested. With more complex designs, two or more linear combinations will be simultaneously computed and included in these statistical tests, and the four multivariate tests above will not be equivalent. In such instances, one of the four tests must be used, and Wilks's Lambda is the most popular choice. Roy's g.c.r., however, is arguably most suitable for conducting follow-up statistical tests on the linear combinations of dependent variables. The readings cited below provide explanations of the differences among the tests.

The next crucial step in the analysis is to determine how the dependent variables are combined to significantly discriminate between the boys and girls. A number of methods are available for determining the importance or relevance of each dependent variable to the multivariate effect. The approach adopted here relies on the *discriminant function coefficients* produced from the MANOVA. These coefficients are regression weights derived to maximally discriminate between the groups that comprise the independent variable. The coefficients can be computed in both raw and standardized form, and the values for the current example are reported in Table 3.

If the dependent variables are measured on different scales, as in this example, the standardized coefficients should be examined; otherwise, the raw

coefficients can be used. In either case, the absolute relative magnitudes of the coefficients are examined, and the current results indicate that the Forms and Body Parts dependent variables are contributing most to the multivariate effect. The signs of the discriminant function coefficients for the important variables are next considered to interpret the linear combination. In this example, the multivariate composite clearly conveys a discrepancy effect; specifically, the boys and girls differ in their mean discrepancy between the Forms and Body Parts variables. The nature of this effect can be understood by examining the means of the standardized dependent variables for both boys and girls in Figure 1.

As can be clearly seen, compared to the girls, the boys performed better on the Forms knowledge scale and worse on the Body Parts knowledge scale. This effect is also reflected in the means for the boys ($M = -.22$, $SD = .85$) and girls ($M = .21$, $SD = 1.12$) on the standardized multivariate composite (i.e., the standardized linear combination). The lower mean value for the boys indicates superior performance on the Forms scale relative to the Body Parts scale. This intriguing multivariate effect was completely missed by the univariate ANOVAs reported above!

Additional Issues

The example above includes four dependent variables and only a single independent variable with two groups. It is therefore among the simplest of designs for a MANOVA, and it yielded only a single multivariate composite (linear combination). For more complex designs, additional composites will be produced from the analysis depending on the number of groups in the independent variables, the number of independent variables, and the number of dependent variables. The multivariate tests, except Roy's g.c.r., will then address a null hypothesis that posits equality among population group means on all of the multivariate composites, considered simultaneously. Roy's g.c.r. addresses the null hypothesis that the groups differ in the population means on only the first multivariate composite. When multiple composites are produced, the first will maximally discriminate

among the groups, and the remaining composites will be ordered according to the magnitudes of group differences they yield. The composites will all be orthogonal (or uncorrelated), however, and thus can be examined and interpreted separately, using the techniques described above. To make matters even more complex, factorial MANOVAs yield tests of interactions and main effects. For each interaction and main effect, a unique set of multivariate composites will be generated that must be evaluated. With complex study designs, it is easy to see that performing a MANOVA is no simple task.

Regardless of study design, it should be stressed that the heart of MANOVA is the multivariate composite or set of composites generated from the analysis. Unfortunately, many investigators fail to examine the linear combinations of the dependent variables. Instead, two misuses of the analysis are common. First, univariate ANOVAs are conducted after a MANOVA to determine the importance of the dependent variables in the multivariate effect. This strategy is gravely erroneous because, as was clearly demonstrated in the example above, the multivariate effect conveyed in the discriminant

function coefficients will not necessarily correspond to the univariate effects found in the separate ANOVAs. Second, MANOVA is often used as a method for controlling Type I error inflation. Many investigators will first conduct a MANOVA, and if the result is statistically significant, they will then conduct separate ANOVAs and judge the results using an unadjusted a priori p value of, for example, .05. Unfortunately, conducting a MANOVA alone will not normally provide protection against Type I error inflation, and this analysis strategy is not to be condoned.

Finally, MANOVA is a statistical modeling technique and thus involves inferential judgments about population parameters. As with all statistical tests, the validity of such inferential leaps relies on a number of assumptions. In MANOVA, these are (a) independence of observations, (b) the dependent measures follow a multivariate normal distribution for each level of the independent variable, and (c) the population covariance matrices for the dependent variables are equal for all levels of the independent variable. Assessing each of these assumptions is an important part of any MANOVA.

MULTIVARIATE NORMAL DISTRIBUTION

In 1984, Anderson stated, “A major reason for basing statistical analysis on the normal distribution is that this probabilistic model approximates well the distribution of continuous measurements in many sampled populations.” He goes on to mention that normality based methods have the advantage that the theory is developed in great detail. In univariate analysis, the central limit theorem steers us toward the normal distribution. Similarly, we are steered toward the multivariate normal distribution in multivariate analysis by the general, or multivariate, central limit theorem.

As its name would indicate, the multivariate normal distribution is the multidimensional extension of the familiar univariate normal distribution, or “bell curve.” The bivariate normal distribution will arise when a pair of variables X and Y has not just individual (or marginal) distributions that are normal, but also a joint distribution that is normal. The bivariate normal distribution can be visualized as a three-dimensional bell. The distribution can be extended

with three or more variables sharing this relationship.

Properties

The probability density function for a univariate normal distribution is $f(x) = \frac{1}{\sqrt{2\pi}\sigma} e^{-[(x-\mu)/\sigma]^2/2}$, where $-\infty < x < \infty$; μ represents the mean of the distribution and can take on any real number value; and σ represents the standard deviation of the distribution, which can take on any positive value. This formula is extended to the multivariate distributions as $f(x) = \frac{1}{(2\pi)^{p/2} |\Sigma|^{0.5}} e^{-[(x-\mu)'\Sigma^{-1}(x-\mu)]/2}$. Many online sites, including Weisstein’s MathWorld, cover many of the mathematical properties of this distribution.

For the bivariate distribution, $p = 2$, and in general, p is the number of variables. μ is a vector of size $p \times 1$ that contains the means, and Σ is the variance covariance matrix of size $p \times p$. In this matrix, the main diagonal elements are the variances of the p component variables, and the off diagonal elements are the covariances. For example, if we let σ_{ij} represent the element in the i th row and j th column of this matrix, then σ_{11} would represent the variance of the first variable, σ_{12} is the covariance between the first and second variables, and the correlation between these two variables would be $r_{12} = \frac{\sigma_{12}}{\sqrt{\sigma_{11}\sigma_{22}}}$, or the covariance divided by the product of the two standard deviations.

Some properties of the multivariate normal distribution are very important to consider when performing multivariate analyses. When considering a random vector \mathbf{X} that follows a multivariate normal distribution, the following properties will hold:

1. All linear combinations of the components of \mathbf{X} are normally distributed.
2. All possible subsets of the components of \mathbf{X} will be normally distributed.
3. Zero covariance between two components implies that those components are independent.
4. The conditional distributions of the components are normal.

Figure 1 Example of a Multivariate Normal Distribution

It is important to realize that even though each univariate component of \mathbf{X} follows the univariate normal distribution, the univariate normality of each component of some other random vector \mathbf{X}^* does not necessarily imply that \mathbf{X}^* is multivariate normal. In other words, the univariate normality of each variable is necessary but not sufficient to establish multivariate normality. Thus, a strategy of assessing multivariate normality that merely assesses each component variable separately will not be successful in detecting all deviations from multivariate normality. The relationship between the variables, numerically expressed in the variance covariance matrix, must be considered for the problem of testing multivariate normality.

Implications for Analysis

Looney stated that “the assumption of multivariate normality underlies many commonly used multivariate statistical procedures.” Examples include multivariate analysis of variance (MANOVA), discriminant analysis, and canonical correlation. Looney commented that several Monte Carlo studies found that the performance of these multivariate procedures can be adversely affected by a violation of the assumption of multivariate normality.

It is evident that the question of testing for multivariate normality is significant for several reasons. First, ignoring the assumption of multivariate normality when conducting multivariate analyses that call upon that assumption can lead to either increased Type I error rate or a reduction in power. Neither of these possibilities is desirable; in fact, we wish to avoid Type I error and also highly favor statistical methodology that will maximize power. Testing the assumption of multivariate normality will help avoid these undesirable outcomes.

Testing for Goodness of Fit

Many tests exist that will test for multivariate normality. Henze and Mecklin and Mundfrom have provided recent reviews summarizing the dozens of tests that exist. Henze focused primarily on a certain class of

tests that is “affine invariant” and is mathematically consistent against all possible alternatives (i.e., possible deviations from multivariate normality). Although this property of consistency stressed by Henze is mathematically desirable, Mecklin and Mundfrom’s paper also considered many other procedures as well. They felt that other factors besides theoretical properties such as consistency against alternatives should be considered. Mecklin and Mundfrom tended to favor tests that had strong performances in comparison to other candidates in Monte Carlo simulation studies, had test statistics with good asymptotic null distributions and did not require specialized tables, and tests simple enough that those who are not specialists in goodness of fit could perform them. Mecklin and Mundfrom would also value test statistics such as Mardia’s measure of skewness and kurtosis (i.e., multivariate analogues of univariate skewness and kurtosis) that can also serve as multivariate descriptive measures over procedures whose results do not lead themselves well to describing the data.

Many Monte Carlo studies have looked to compare the relative effectiveness of these procedures. Mecklin and Mundfrom compared the Type I and Type II error rates of 13 of these procedures against 25 alternative distributions. As others in the past had found, no single test of goodness of fit to the multivariate distribution is the most powerful in all circumstances. The Henze Zirkler statistic was identified as a test that has both strong theoretical properties and strong performances in Monte Carlo studies. Because the value of the Henze Zirkler test statistic does little to help the researcher diagnose the reason for the deviation from normality, Mecklin and Mundfrom suggested that researchers complement the Henze Zirkler test with the chi square plot described by Healy, and also Mardia’s measures of skewness and kurtosis. Mardia’s measures, particularly kurtosis, are frequently used by structural equation modelers.

Despite the plethora of methods for testing multivariate normality and several power studies assessing their performance, many users of multivariate analyses do not use these tests or seriously consider the assumption of multivariate normality that is made by many multivariate methods. Looney gave five reasons

why he felt that many practitioners do not test for multivariate normality:

1. The practitioner does not know of the existence of tests for multivariate normality.
2. Software for easily calculating the test statistic or p value for a test of multivariate normality is not readily available.
3. Even if software is used to calculate the test statistic, often the significance can be determined only by referencing a special table, which may not be readily available.
4. The practitioner does not want to use a procedure (such as a test of multivariate normality) when little is known about the statistical power of the test.
5. The practitioner is reluctant to test for multivariate normality because he or she does not know how to proceed if non normality is detected.

One reason that an investigator doing applied research in a field outside of statistics might be interested in conducting a test of normality upon a multivariate data set would be to determine the validity of the assumption of normality. Determining whether or not multivariate normality is a tenable assumption is important for deciding on how to proceed in the data analysis. If the assumption is tenable, then the investigator can feel confident in employing the usual parametric techniques of multivariate analysis. However, if the assumption is not tenable, alternatives to parametric statistics need to be considered. Some available options include robust methods, nonparametric procedures, transformations of the data, or computer intensive techniques such as bootstrapping.

MYERS-BRIGGS TYPE INDICATOR

The Myers-Briggs Type Indicator (MBTI), a self-report, forced-choice questionnaire, assesses personality according to typologies proposed by Carl Jung. Administration of the MBTI takes approximately 10 minutes. The MBTI is used worldwide in diverse settings; most commonly, it assists in career development, professional team building, personnel selection, and counseling.

Isabel Myers and Katharine Briggs authored the first version of the MBTI in 1962 to measure individual preferences between Jung's personality types. The test, most recently updated in 2001, identifies 16 types. Each is designated by its four-letter code. Each letter of the code indicates a preference for one manner of experiencing the world over another. For instance, an INTJ shows preferences for Introversion (over Extraversion), Intuition (over Sensing), Thinking (over Feeling), and Judging (over Perceiving).

The Introversion Extraversion dimension characterizes how people direct their energy. Introverts direct it internally, toward ideas and the subjective, and extraverts direct it externally, toward people and materials. The Intuition Sensing dimension identifies how people focus their perception. Intuitive types focus readily on abstraction and pattern, whereas

Sensing types focus on concrete stimuli perceived by the senses. Individuals' scores on the Thinking Feeling dimension indicate the types of information on which they base decisions. Thinking types base decisions on attempted rationality and objectivity, whereas Feeling types prioritize maintenance of harmony with others and with their own values. The last dimension, Judging Perceiving, characterizes people's preferences for resolution, among Judging types, or open-ended situations, among Perceiving types. In the most recent revision, each dimension has been parsed into five facets for more nuanced interpretation.

These dimensions allow organizations, for instance, to use the MBTI for team building. After administering the test to a group, members' results can be used to stimulate conversation about their similarities or differences in work style and preferred level of socializing in completing tasks, among other topics. The MBTI provides a common vocabulary with which members can introduce themselves.

Scores are calculated for each dimension based on forced choices between the two sides of the dimension; for example, each item that loads on the Introversion Extraversion scale offers one choice that is weighted in favor of Introversion, and another weighted toward Extraversion. The sides of the four

dimensions for which people most frequently show a preference comprise their type codes. Data used to select items and to provide evidence of validity for MBTI scores were collected from a nationally representative sample. The psychometric qualities for the scales and type codes are somewhat equivocal. Indicators of consistency over time for both scales and type codes and item to item on scales show poorer consistency than other measures frequently used to similar ends.

NATIONAL COUNCIL ON MEASUREMENT IN EDUCATION

According to the National Council on Measurement in Education (NCME) bylaws, “NCME is an organization that is incorporated exclusively for scientific, educational, literary, and charitable purposes.” One primary purpose of NCME is the encouragement of scholarly efforts (a) to “advance the science of measurement in the field of education”; (b) to “improve measurement instruments and procedures for their administration, scoring, interpretation, and use”; and (c) to “improve applications of measurement in assessment of individuals and evaluation of educational programs.”

In addition, NCME has a second primary purpose, the dissemination of information about assessment theory and practices. According to its Web site, NCME disseminates information about (a) “theory, techniques, and instrumentation available for the measurement of educationally relevant human, institutional, and social characteristics”; (b) “procedures appropriate to the interpretation and use of such techniques and instruments”; and (c) “applications of educational measurement in individual and group evaluation studies.”

NCME is a professional organization for persons who are involved in assessment, evaluation, and related aspects of the assessment process. These persons might be involved in test construction; test evaluation; or the generation of new theories and methods for constructing and evaluating tests and test scores, equating test scores, and managing testing at computers, among other things. The membership is diverse, including university faculty, test developers, state and federal testing and research directors, persons working for credentialing organizations, graduate students in measurement and assessment programs, and others who work in the testing field. About 10% to 15% of the 2,000 or so members are from outside the United States, most of them from Canada.

Formation

NCME was established in 1937 and was called the National Association of Teachers of Education Measurement. In 1942, the name was changed to National Council on Measurements Used in Education. The change to the current name came in 1969, along with incorporation.

Publications

NCME publishes through five organs:

1. *Journal of Educational Measurement*
 - Quarterly
 - Publishes technical and theoretical developments in measurement and improvements in the applications of measurement methods
2. *Educational Measurement: Issues and Practice*
 - Quarterly
 - Promotes better understanding of educational measurement and focuses on timely issues and debates in the educational measurement field
3. *Instructional Topics in Educational Measurement Series*
 - Occasional
 - Provides instruction on timely educational measurement topics for practitioners and graduate students
4. Newsletter
 - Quarterly
 - Keeps the membership up to date on current events in the educational measurement field and disseminates information about the activities of the NCME Board and its committees
5. Web site
 - Contains information about the organization, membership, history, awards, publications, and more

Annual Convention

In March or April the organization holds an annual 3-day meeting in conjunction with the American Educational Research Association annual meeting. A high percentage of the membership attends, and one of the highlights is the NCME Breakfast, with attendance of 300 to 400 members. The annual meeting also includes a brief business meeting, awards, and a presidential address.

Achievement Awards

The number of awards given by NCME each year has been on the increase. Currently the following awards are given: Brenda H. Loyd Dissertation Award; Brad Hanson Award; Jason Millman Promising

Measurement Scholar Award; Award for Career Contributions to Educational Measurement; and awards for such things as Outstanding Dissemination of Educational Measurement Concepts to the Public, Outstanding Example of an Application of Educational Measurement Technology, and Technical Contribution to a Field of Educational Measurement. More details about these awards are available at the NCME Web site.

NATIONAL SCIENCE FOUNDATION

The National Science Foundation (NSF) is an independent federal agency created by the U.S. Congress in 1950 to promote scientific progress; advance the health, prosperity, and welfare of the nation; and secure national defense. The NSF's motto, "where discoveries begin," reflects the goal of the foundation, which is to support the people, ideas, and tools that make new knowledge possible. The foundation supports all fields of fundamental science and engineering except the medical sciences. With a current annual budget of \$5.5 billion, the NSF funds one fifth of all federally supported basic research conducted in U.S. colleges and universities and supports more than 200,000 scientists each year. The NSF issues about 10,000 new limited-term (typically 3-year) grants annually, as well as funding for research centers, other research facilities, and scientific equipment.

Organizational Structure

Management at the NSF has two major components: the director, who oversees the staff responsible for

the creation and administration of programs, merit review, and daily operations of the foundation, and the 24-member National Science Board, which establishes the policies of the NSF. The director and all board members serve 6-year terms; they are appointed by the President of the United States and confirmed by the U.S. Senate. The foundation currently employs 1,700 individuals at its headquarters in Arlington, Virginia.

The NSF comprises seven directorates: Biological Sciences; Computer and Information Science and Engineering; Education and Human Resources; Engineering; Geosciences; Mathematics and Physical Sciences; and Social, Behavioral and Economic Sciences. Each directorate has its own assistant director, who oversees its subdivisions. Special divisions, such as the Office of International Science and Engineering, fall under the director's portfolio.

Grants and Merit Review

Grant proposals are submitted by individual scientists or research teams and then assessed through a rigorous merit review system. The NSF offers a number of annual workshops and conferences to discuss scientific discoveries and explore areas requiring new research. The foundation publishes notices (or "solicitations") for new funding opportunities each year and also encourages scholars to submit unsolicited requests for funding in any existing or emerging field of research. The NSF currently receives 40,000 proposals per year, all of which are reviewed by panels of experts not employed by the NSF or by an institution employing a scientist whose proposal is under review. Reviewers are selected from a national pool of experts in each field and asked to provide confidential reviews of proposals.

A Legacy of Discovery

In 2000, in honor of its 50th anniversary, the NSF published *America's Investment in the Future*, providing a history of the organization and its support of science and innovation, including details about more than 100 NSF-funded Nobel Prize winners. The foundation

publishes annual reports on its Web site, as well as the "Nifty 50," a list of NSF-funded inventions, innovations, and discoveries, including the development of the American Sign Language dictionary, nanotechnology, and speech recognition technology.

NEO PERSONALITY INVENTORY

The NEO Personality Inventory–Revised (NEO PI-R; published by Psychological Assessment Resources) is a revision of the NEO PI first published by Paul Costa and Robert McCrae in 1985. The instrument was constructed to measure the "Big Five" personality domains: neuroticism, extroversion, openness, conscientiousness, and agreeableness. In addition to the global measures of these domains, the NEO PI-R includes 30 facet scales, which are subscales related to each of the five major domains.

Two versions of the test booklet are available: a self-report version (Form S) and an observer-report version (Form R). The item content of the two versions is identical, but questions are worded in the first person in Form S and in the third person in Form R. The options of hand scoring and machine scoring are available for both forms, and a computer-based version of the NEO PI-R, which includes administration, scoring, and interpretation, is also available. The most recent manual has been translated into 12 languages other than English.

The NEO PI-R is recommended for use with persons 17 years old and older who do not have psychological disorders that would impair completion of a self-reported measure. Recent research, which included the rewording of some items to increase understanding by adolescents, suggested the NEO PI-R also may be useful with students in high school. To interpret scores, an extensive norm group that includes men and women, including those of

college age, has been collected. The college-age sample is recommended for use with test takers between the ages of 17 and 20 because of elevated scores on the excitement-seeking scale for this age group.

Evidence of validity and reliability has been collected for the NEO PI-R. Extensive research about the structure of the factors (construct validity), as well as correlational data with other measures of personality (convergent validity) and theoretically unrelated constructs (discriminant validity), has been published.

Short-term test-retest reliability coefficients are around .80 for each of the five domains. A 6-year test-retest study found stability coefficients of .68 to .83 for neuroticism, extroversion, and openness. Another study, spanning 7 years, found stability coefficients ranging from .63 to .81 for all five domains. Interitem reliability alpha coefficients for the facet scales range from .86 to .92 for Form S and from .89 to .95 for Form R.

The NEO PI-R has many uses for clients, counselors, and researchers, including increasing clients' self-awareness and helping counselors develop appropriate treatment plans. Additionally, results from a self-report that diverge from a significant other's ratings can give clients insight into the way in which others see them. Coupled with vocational assessments, the NEO PI-R can help clients and counselors discuss possible career decisions on the basis of clients' personality and interests. Furthermore, researchers can benefit by including a measure of personality in their studies.

NEONATAL BEHAVIORAL ASSESSMENT SCALE

The Neonatal Behavioral Assessment Scale (NBAS, published by MacKeith Press) assesses the full range

of neonatal behavior by describing infants' competencies and identifying potential areas of difficulty. The scale was originally developed in 1973 by T. Berry Brazelton on the premise that rather than being passive recipients of their environments, infants actively contribute to the parent-infant relationship. In addition, the scale was designed not only to identify abnormal infant behavior but also to describe the full range of normal infant behavior—a departure from most assessments of neonatal behavior at the time, which focused on identifying developmental delays.

The most recent edition of the NBAS scale takes 20 to 30 minutes to administer and is used to assess full-term infants up to the end of the second month of life. The scale may be adapted to assess preterm and at-risk infants as well. The NBAS is administered by a trained individual, who scores 53 items based on infants' behavior and state. These items assess infants' level of functioning in seven primary domains: (a) infants' reflexes, including the sucking reflex, the plantar reflex, and the rooting response, are assessed; (b) the motor system is assessed by, for example, examining the range of motion and the resistance of infants' limbs; (c) the autonomic system is assessed by examining the degree to which infants are startled during the procedure, how much they tremble during the procedure, and the color of their skin; (d) the capacity of infants to habituate to disturbing stimuli is assessed by shaking a bell nearby or shining a light in the eyes and examining how long it takes infants to disregard the stimulus; (e) infants' state organization is assessed by examining how irritable and excited they are during the procedure, as well as how much their state changes during the procedure; (f) the degree to which infants are capable of state regulation is assessed by examining how cuddly they are in response to being held, how consolable they are while crying, and how well they can quiet themselves while crying; and (g) the social interaction of infants is assessed by examining how well they track both auditory stimuli (e.g., an adult voice) and visual stimuli (e.g., a face).

The NBAS has proven to be a valid and reliable measure of infant behavior in early life and has been used extensively in both research and clinical contexts. Researchers, for example, have used the NBAS

to investigate the effects of maternal substance abuse, cross-cultural differences in infant behavior, the possible developmental outcomes of children, the effects of tactile stimulation on preterm infants, and the effects of obstetric medication on later development. In clinical settings, the NBAS has been administered in the presence of parents to help them better understand the capacities of their infants. By administering the scale in the presence of parents, clinicians can stress the uniqueness of an infant, share concerns about the infant, and foster a positive relationship between the family and themselves. In sum, the NBAS is a valid assessment of infant behavior that has been used widely in both research and clinical contexts.

NEWMAN-KEULS TEST

Newman and Keuls proposed a procedure for pairwise testing of means in a one-way analysis of variance. The procedure is routinely applied after a significant overall F test. A series of critical differences (CDs) is used to evaluate the significance of the difference between each pair of means. The pairs are investigated systematically from the largest to the smallest difference. CDs are all based on the Studentized range distribution. The largest CD is applied to the difference between the largest and smallest means and is the same as the CD of Tukey's honestly significant difference procedure.

The second largest CD is applied to two differences: (a) the difference between the largest mean and the next-to-smallest mean and (b) the smallest mean and the next-to-largest mean. If there are k means altogether, there will be $k - 1$ CDs. The second largest CD is identical to the CD for Tukey's honestly significant difference, which would be applied to a set of $k - 1$

means. Testing is continued until all pairs are tested, but with the restriction that no pair can be significantly different if that pair is between two means that are not significantly different. This restriction requires careful ordering of the testing of each pair. However, with equal sample sizes, the process is not too difficult.

Even when applied correctly, the original Newman-Keuls procedure has several problems. First, it can have excessively high Type I error rates. Second, it can have lower power (i.e., higher Type II error rates) than procedures that have good control of Type I errors. Third, when it appears to be more powerful than alternative methods, it may actually be less powerful than an alternative that provides equivalent Type I error control. Fourth, it is not suited for data sets with unequal sample sizes, and some approximation must be considered.

In the case of exactly $k = 3$ means, Fisher's least significant difference procedure can be more powerful than the original Newman-Keuls, and least significant difference limits the probability of a Type I error rate to the nominal level α of the test. For $k \geq 4$, Roy Welsch provided a table of modified values from the Studentized range distribution. Those values produce CDs that limit the probability of one or more Type I errors to the level α of the statistical test. The Welsch CDs remove most of the objections to the original Newman-Keuls procedure.

The Welsch modification of the Newman-Keuls can be slightly modified further to give an additional increase in power. The original Newman-Keuls and the Welsch modified Newman-Keuls use the Studentized range statistic to test the full null hypothesis that all k population means are equal. That is, the overall F test is not required for either of these procedures. However, Juliet Shaffer noted that a step-down procedure such as the Newman-Keuls can be modified to test the full null hypothesis with the overall F test of the analysis of variance. In that case, the largest and smallest means are tested for a significant difference with the CD for $k - 1$ means, provided the overall F test is significant. All other pairs are tested as before. This Shaffer-Welsch version of the Newman-Keuls eliminates all Type I error problems in the equal-sample-size case and is more powerful than most other procedures of equal difficulty.

Table 1 A Control and Several Treatment Means

	Control	Treat 1	Treat 2	Treat 3	Treat 4
Mean	4.05	3.25	3.18	3.15	2.24
N	42	24	38	40	40

Note: Treat = treatment group.

All versions of the Newman-Keuls procedure discussed above become excessively complex with unequal sample sizes. However, the harmonic means of sample sizes (illustrated below) covers many empirical data sets. If the largest sample size is no more than twice the smallest sample size, then the harmonic means of sample sizes provides a good approximate solution to the testing of pairwise differences.

Illustrative Example

Consider the following data, in which four treatment groups are being compared to a control. Lower scores indicate better performance.

The within-groups mean square (MS_{WG}) for these data is 3.0326, with degree of freedom (df_{WG}) = 179. The harmonic mean of sample sizes is

$$\tilde{N} = \frac{k}{\frac{1}{N_1} + \frac{1}{N_2} + \dots + \frac{1}{N_k}}$$

For this example, we get

$$\tilde{N} = \frac{5}{\frac{1}{42} + \frac{1}{24} + \frac{1}{38} + \frac{1}{40} + \frac{1}{40}} = \frac{5}{.14179} = 35.2629.$$

Thus, we approximate all five groups as having a sample size of approximately 35.2629. The analysis of variance for these data would give $F = 5.75 > 2.43 = F_{.65}(4,160) > F_{.65}(4,179) = \text{critical value (CV)}$. Therefore, we reject the full null hypothesis at the .05 level and proceed to pairwise testing.

The largest CD is obtained with the Welsch critical value (WCV) and the formula

$$CD = WCV \sqrt{\frac{MS_E}{\tilde{N}}}$$

$$CD = 3.68 \sqrt{3.0326/35.2629} = 3.68 \sqrt{0.8600}$$

$$CD = 3.68(.29325) = 1.07918 = 1.079.$$

For smaller differences, we have

$$CD_2 = 3.64 \sqrt{\frac{MS_E}{\tilde{N}}}$$

$$CD_3 = 3.33 \sqrt{\frac{MS_E}{\tilde{N}}}$$

$$CD_2 = 3.64(.29325)$$

$$CD_3 = 3.33(.29325)$$

$$CD_2 = 1.0674 = 1.07$$

$$CD_3 = 0.97652 = .977.$$

Table 2 shows the differences between ordered means.

Table 2 Difference Between Ordered Means

	Tr 4	Tr 3	Tr 2	Tr 1	Control	CD
	2.24	3.15	3.18	3.52	4.05	
Tr 4 = 2.24	—	.91	.94	1.28*	1.81*	1.08
Tr 3 = 3.15		—	.03	.37	.90	1.08
Tr 2 = 3.18			—	.34	.87	1.07
Tr 1 = 3.52				—	.53	.975

Note: Tr = treatment group; CD = critical difference.

* $p < .05$

The largest difference is 1.81 between Treatment 4 and the control. This exceeds the largest CD of 1.08 and is therefore significant. The individuals in Treatment 4 have significantly lower average scores than does the control. The two second differences are 1.28 and .90. The value of 1.28 also exceeds 1.08 and is significant. Those in Treatment 4 are significantly lower than are those in Treatment 1. However, .90 is less than the CD of 1.08 and is not significant. There is no significant difference between the mean for Treatment 3 and the control.

At this point, all further testing of the step-down procedure must be done very carefully. The next set of

differences is .94, .37, and .87. The difference of .94 is compared to the CD of 1.07 and is not significant. The mean for Treatment 4 is not significantly different from the mean of Treatment 2. The differences .37 and .87 cannot be significant because they are smaller than .90, which was nonsignificant.

The final four differences, .91, .03, .34, and .53, would ordinarily be compared to the CD of .975 for significance. However, they are nonsignificant without comparison to .975 because they are all contained within a nonsignificant difference.

NOMINAL LEVEL OF MEASUREMENT

As its name suggests, nominal (“in name”) level measurement refers simply to labeling or classifying data that belong to different categories within one variable. Some common examples of nominally measured variables in social research include sex, race, political party, religious preference, geographical location, and college major. In these variables, each response fits into one and only one category. A respondent is *either* female *or* male, Republican, Democrat, *or* Independent. To evaluate each of these variables, a researcher

would assign a different number to all categories belonging to the variable. For example, all females might be labeled “1” and all males “2.”

It is important to keep in mind that these values are arbitrary and are only placeholders for longer names. The example above would not mean that males are twice as gendered as females; it simply asserts that female is different from male. The labels easily could be reversed or could be 3s and 9s and still provide the exact same information. Likewise, we would not say that a Native American does not have more race than an African American or that an English student is more majored than a biology student. In fact, the only reason to measure data nominally is if the different categories within one variable *do not* differ in any “direction”—that is to say, we cannot determine which category represents more or less of a trait or variable. The numbers simply help shorten the category names and often are more convenient when researchers use statistical software to analyze data.

Because the only information we can gain from nominal data is “same” or “different,” nominal is considered the “weakest” or least precise level of measurement (followed by ordinal, interval, and then the most precise level, ratio). Beyond the fact that mathematical operations do not apply to them, nominal data are limited because the only appropriate measure of central tendency to use with them is the mode. Similarly, no notion of standard deviation exists with such data. Analysis of nominal data should never include a mean or a *t* test, which would quantitatively compare one category to another.

One should use a more precise level of measurement whenever possible. For instance, when evaluating high school football teams’ performances, finding out how many more points the Mustangs scored per game this season than the Broncos (interval measurement) would provide more useful information than finding out only which team had more points per game but not knowing how many more points (ordinal measurement) or than merely stating that the Mustangs and the Broncos are different teams without specifying a direction that indicates which,

on average, scored more points per game this season (nominal measurement). Only when different responses to an item measuring the same variable *cannot* reveal any directionality is nominal the most appropriate level of measurement to employ.

NOMOTHETIC VERSUS IDIOGRAPHIC

The nomothetic (from the Greek term for *lawgiving*) approach to science seeks lawfulness by testing hypotheses. It applies research-supported general formulations to particular cases and uses deductive reasoning. The idiographic (from the Greek term for *oneself, one's own*) approach seeks lawfulness by inspecting individual cases and accounting for them; it uses inductive reasoning. General rules are inferred from individual cases.

The nomothetic approach to assessment interprets measurements and observations by comparing them with group norms. The individual case is understood as an instance of a hypothetical general case. The idiographic approach seeks to understand measurements and observations as a function of the individual's history and environment. The individual case is understood in its own context. For example, a newborn might weigh 5 pounds at birth. Nomothetic data show that this is in the 2nd percentile; since 6% of babies weigh too little for their own good, this weight may be

cause for concern. Idiographic data—which may include behavioral and other physiological observations of the infant, along with information about the due date—can be used to understand whether this particular baby needs intervention. Nomothetic and idiographic data can thus be used integratively.

Psychological science currently favors the nomothetic approach over the idiographic. A study that shows that, in general, siblings placed together in foster care fare better than siblings placed apart is seen these days as more scientific than a study that examines whether a particular sibling pair should be placed together or apart. Psychological assessment is similarly inclined at this time, with behavior analysis and projective testing disfavored in comparison with scores on scales that have meaning only in relation to normative data. The nomothetic approach decreases variation associated with any given psychologist, but it applies to the individual case only roughly. The idiographic approach, conversely, highlights the case at hand but depends for validity on the particular psychologist.

No assessment device or strategy is entirely nomothetic or idiographic. Even personality inventories, whose individual items are ignored by psychologists in favor of scaled scores, show idiographic features when the psychologist considers whether a particular individual is adequately represented by group norms. Sources of inadequate representation might include some distinguishing feature of the individual or of the situation or of the way the test was administered. Can a personality test normed on the general population be used to categorize or describe a woman of Icelandic heritage? A man recently diagnosed with diabetes? Custody litigants?

Even purely idiographic, unnormed assessment techniques, such as asking about childhood memories or about hobbies, reveal nomothetic features when psychologists consider whether their own personal or cultural backgrounds are affecting their interpretations. In this context, cultural competence might be defined as awareness of one's personal norms and their potential inapplicability to other people.

NONPARAMETRIC STATISTICS

A common statistical problem is to estimate a parameter of the population (such as the mean) or to test whether a parameter is different from some specified value. To carry out inferences, some specific assumptions are made about the distribution of the population; the most common assumption is that the population follows the normal distribution. The various statistical methods developed for these situations are collectively known as *parametric* statistical methods.

Many of the most widely used *nonparametric* procedures provide an alternative to a standard parametric procedure. These nonparametric methods are valid under assumptions more general than those required for parametric inference. In particular, many of these nonparametric procedures are *distribution-free*; they do not require one to make specific assumptions about the form of the distribution of the population. Usually, the only assumption needed to carry out nonparametric procedures is that the population distribution is continuous and, in certain cases, symmetric. In some cases, a nonparametric procedure is not an analogue to a given parametric procedure. This occurs in statistical problems in which one might want to make inferences more general than those involving an individual parameter. For example, there exist nonparametric procedures to test whether two populations have the same underlying distributions or to determine a confidence band for a distribution function.

Advantages of Nonparametric Procedures

When one is presented with the choice between a nonparametric procedure and its parametric counterpart, the former has several advantages. When a

distribution-free nonparametric method exists, exact p values for tests and exact coverage probabilities for confidence intervals can be calculated under fairly general assumptions about the population. Conversely, the p values reported for parametric tests under the assumption of normality are exact only when the population distribution is normal; for other distributions, typically the p values are approximate, with the approximation being better for larger sample sizes. Many nonparametric statistics are relatively simple functions of the ranks of the observations. This implies that one can make inferences about the population without having to know the magnitudes of the sample observations. In addition, when a nonparametric procedure is only a function of the ranks of the observations, the procedure will be insensitive to outliers.

One can compare the performance of a nonparametric method to its parametric counterpart (if one exists) by examining the *asymptotic relative efficiency* of the two techniques. A given estimator of a parameter (say, the sample average for the center of a symmetric population) is more efficient than a competing estimator if the variance of the former is less than the variance of the latter when the sample size is extremely large. When the underlying population distribution is normal, nonparametric analogues of many of the classical procedures based on the assumption of normality are only slightly less efficient. That is, as the sample size gets large, the variance of the nonparametric estimator is not much larger than the variance of the parametric estimator. When the population distribution is not normal, the nonparametric method can be significantly more efficient than the competing parametric method.

Standard Nonparametric Methods

The more common nonparametric procedures used in practice will be described briefly below. Many of these techniques are discussed in more detail in their respective entries in this encyclopedia. The following description of nonparametric procedures is limited to the context of hypothesis testing. For most of the problems discussed here, methods exist to estimate a population parameter and to form a confidence

interval about the parameter. For information on those topics, as well as nonparametric procedures not listed here, the reader is referred to the textbook *Nonparametric Statistical Methods* by Myles Hollander and Douglas Wolfe.

When one is conducting a hypothesis test, nonparametric test statistics are generally calculated by counting, ranking, or both. Counting statistics involve counting the number of observations that exceed a specified value. Statistical tests based on counting statistics are referred to as *sign tests*. For ranking statistics, the observations are ordered from least to greatest. The test statistic is then a function of the ranks of the observations. Tests based on ranking statistics are called *rank tests*. *Signed rank tests* utilize a statistic that involves both counting and ranking.

One-Sample Location Problem

A common problem in statistical inference is to determine whether the center of the population distribution equals some particular value. For normal populations, one uses the mean as a measure of the center and the t test for a population mean for making inferences. In nonparametric statistics, the median (denoted θ) is used as a measure of the center. The question of interest is then whether θ equals some specified value θ_0 . Two nonparametric tests that can be used are the sign test and the Wilcoxon test (also known as the Wilcoxon rank-sum test). For both tests, we assume we have a set of n observations Z_1, Z_2, \dots, Z_n obtained via random sampling from a continuous population. For the Wilcoxon test, we add the assumption that the underlying distribution is also symmetric.

To test the null hypothesis that θ equals θ_0 with the sign test, we count the number of observations greater than or equal to θ_0 . Our test statistic is

$$B = \text{number of } Z_i\text{s greater than } \theta_0.$$

The total number of observations greater than θ_0 has a binomial distribution with parameters n and p , where $p = P(Z_i \geq \theta_0)$, the probability that Z_i is greater than or equal to θ_0 . This result holds because of the

independence of the observations. Under the null hypothesis that θ_0 is the true population median, $p = 1/2$ (since by definition of the median, one half of the population distribution is above θ_0). Exact p values for the test can then be calculated from this null distribution and will provide a distribution-free test of the null hypothesis that θ equals θ_0 .

If one is willing to impose the assumption that the underlying population distribution is both continuous and symmetric, one can use the Wilcoxon test. This procedure tends to be more efficient than the sign test for testing the null hypothesis that θ equals θ_0 , but is less general since it carries an additional assumption about the population distribution. For our random sample of n observations Z_1, Z_2, \dots, Z_n , the test procedure is (a) identify the observations that exceed θ_0 , (b) calculate $|Z_i - \theta_0|$ for each observation, and (c) rank the differences calculated in step (b) from smallest to largest. The Wilcoxon test statistic is then the sum of the ranks of the differences for only the observations that exceed θ_0 .

The theoretical basis of the Wilcoxon test arises from the distribution of ranks. Let R_i denote the rank of the i th value of $|Z_i - \theta_0|$. The set of ranks R_1, R_2, \dots, R_n are a specific permutation of the integers from 1 to n ; there are $n!$ possible permutations. The set of ranks has a jointly uniform distribution, where the probability of a particular set of ranks is $1/n!$. Moreover, whether a particular observation is greater than or equal to θ_0 is independent of the magnitude of the difference between that observation and θ_0 when the observations are taken from a symmetric distribution. Thus, the Wilcoxon test is distribution-free with a null distribution that can be found by means of the uniformity of the ranks, the binomial nature of the counting, and the independence of the counting and ranking procedures. Tables of the null distribution are available in most nonparametric texts.

Both the sign test and the Wilcoxon test can be applied to problems involving *paired replicates data*; paired replicates data would occur if two measurements were taken from the same group of participants at two different times. For example, one can measure opinions about a political candidate before and after a

debate or patients' medical condition before and after a treatment. One generally wishes to test whether the characteristic in question changed systematically from the first measurement to the second. Let $(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)$ represent our n pairs of measurements, where X_i represents the first measurement and Y_i represents the second measurement. Then we can define Z_i to equal $(Y_i - X_i)$ and carry out the sign or Wilcoxon test using these Z_i s. In parametric inference, the standard approach to this type of problem is to use the paired samples t test.

Two-Sample Problems

Suppose we have two independent random samples from two different populations. Several nonparametric procedures exist to test whether the two underlying population distributions are identical against the alternative that one population tends to have larger values than the other.

The Mann-Whitney U test (Wilcoxon rank-sum test) is the most commonly used nonparametric procedure for this problem. Its comparable test in parametric inference is the t test for two population means. Let X_1, X_2, \dots, X_m and Y_1, Y_2, \dots, Y_n denote our two independent random samples. Note that the sample sizes need not be equal. We assume that the samples were taken from populations with continuous distributions and that the distributions of both populations have the same shape. The only difference between the two population distributions is that one may be a shifted version of the other. The shift in the distribution may be attributable, for example, to one group's receiving a medical treatment and another group's being a control group. To test the null hypothesis that there is no shift in the distributions, we first rank the combined group of $m + n$ observations. The test statistic is then

$$W = \text{sum of the ranks for the } Y_i \text{ observations.}$$

Since this test statistic involves the ranking of observations, the theoretical basis for the null distribution is similar to that used for the Wilcoxon test. Here, there are $\binom{m+n}{n}$ possible sets of ranks for Y ,

each equally likely, and the Wilcoxon test is distribution-free.

Let U denote the test statistic for the Mann-Whitney U test. Then U can be computed from W by the relationship

$$W = U + \frac{n(n+1)}{2}.$$

The two tests are therefore equivalent. Tables of the null distribution of W or U are available in most nonparametric texts.

Other nonparametric tests exist for detecting differences in population distributions. One popular test is the Kolmogorov-Smirnov test for two samples. This procedure tests the null hypothesis that the population distributions are identical against the null hypothesis that the distributions differ at one or more points. Tests also exist for detecting differences in the dispersion parameter of two distributions, including one based on the *jackknife*.

Other Statistical Problems

Nonparametric procedures exist to address numerous other statistical problems. For one-way analysis of variance problems, several distribution-free methods exist, and the choice depends on the alternative hypothesis of interest. To test the null hypothesis that all treatment effects are equal against the alternative that at least two treatment effects differ, the most common nonparametric procedure is the Kruskal-Wallis one-way analysis of variance. The Jonckheere Terpstra test is applicable when the alternative hypothesis is that the treatments are ordered. For the two-way layout, the Friedman two-way analysis of variance is a nonparametric alternative to the two-way layout procedure based on the normal distribution.

Two nonparametric methods are commonly used to test for the independence between two variables from a bivariate distribution. Kendall's tau statistic allows for a nonparametric test based on the number of concordant and discordant pairs of observations. Spearman's rank correlation is an alternative to the Pearson product-moment correlation, which uses the

ranks of the observations in place of the actual data values.

The *bootstrap* is a computationally intensive technique that can be used to obtain confidence intervals for complicated estimators. The procedure resamples from the data to approximate the standard error of the estimator. The bootstrap is nonparametric in that it does not require any assumptions about the form of the underlying distribution.

Nonparametric methods have also been adapted to regression problems. One approach is to use traditional least squares procedures for estimation but remove the assumption of normality of the errors when making inferences. A significant amount of recent nonparametric research has been devoted to *nonparametric regression*. This approach does not assume a prior regression model; rather, the data are used to develop the regression relationship. Nonparametric regression relies on computational methods to “smooth” the data and does not generally utilize ranking procedures.

Computer Software

Most of the major software packages for statistical analysis can perform nonparametric procedures. Minitab Release 14 can conduct one-sample sign and Wilcoxon tests, the Wilcoxon rank-sum test, and analysis of variance using the methods of Kruskal-Wallis and Friedman. These procedures are generally based on large sample approximations. SAS Version 9, StatXact, and SPSS Exact are three packages that can compute exact p values and coverage probabilities. For SAS, the default is to use approximations, but the user can specify an exact test in the option statement. StatXact is a specialized software package available from the Cytel Corporation for nonparametric and categorical data analysis. It is available as a stand-alone package or as a series of PROCs that can be used in SAS. The Web site for Cytel at the end of this entry compares the procedures that can be performed by StatXact, SPSS Exact, and SAS.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Du, Y., Akritas, M. G., Arnold, S. F., & Osgood, D. W. (2002). Nonparametric analysis of adolescent deviant behavior. *Sociological Methods & Research*, 30(3), 309–340.

There are many different models of quantitative analysis, parametrics and **nonparametrics** just

being two. In this study, Yunling Du and his colleagues studied the impact of certain personal characteristics on marijuana use while controlling for routine everyday activities. The assumptions underlying several logistic regression models, as well as the parametric analysis of covariance (ANCOVA) model, are violated in this example. More critical from the practical point of view is the fact that the covariate is measured on an ordinal (noninterval) scale, implying that the results from such analyses depend on the chosen scale. The analysis of main effects and interactions is compared with similar analyses by means of the parametric ANCOVA and logistic regression models. The formal analysis is supplemented by new exploratory data analysis plots. Significance tests for certain ordered and other patterned alternatives are proposed and evaluated via simulations. Results are compared with those from logistic regression models treating the levels of the factors as ordinal.

NONPROBABILITY SAMPLING

Nonprobability sampling includes several versions of survey sampling that often are expedient to implement but do not allow calculation of the probability of selection of the sample from among possible samples from a population. The goal of a survey is to gather data in order to describe the characteristics of a population. A population consists of units, or elements, such as individuals, households, businesses, tracts of land, or inventory records. A survey collects information on a sample, or subset, of the population. In some surveys, specific units or elements are chosen by the survey designers to be in the sample. Interviewers are assigned to interview the members of or gather data on the units in the selected sample. Sometimes multiple attempts at contacting and collecting data from the selected sample members are made. In many situations, it is possible to compute the probability that any member of the population is in a sample of a certain size selected with a specified design or protocol. It also is possible in many situations to compute the

probability overall that the sample is selected from the population. Such a design is a *probability sampling* design. Examples of probability sampling include simple random sampling, stratified random sampling, and cluster sampling.

In *nonprobability sampling* designs, it is not possible to compute the probabilities of selection for the samples overall or, usually, for individuals. Examples of nonprobability sampling include convenience sampling and quota sampling. In convenience sampling, interviewers themselves are given some latitude in selecting the population members to interview or the units on which to record data. That is, the survey designers and planners do not strictly control the selection of the sample. Convenience sampling occurs in many forms, including selection by an interviewer of people at a shopping mall, selection by a waiter of customers at a restaurant, and Internet and call-in polls. Quota sampling is similar to convenience sampling but requires interviewers to collect certain data on certain numbers of individuals from each of several population subgroups or strata. For example, a quota sample could require interviewers to interview a specified number of females and males within age groups in administrative regions within a state. One could implement such a study by randomly calling phone numbers from a telephone book, asking to speak to a person in the household who belongs to one of the available strata, and conducting an interview if possible. If no one is available at a household in an allowable stratum, then the interviewer simply calls the next telephone number.

Estimates of population characteristics based on nonprobability samples are affected by *selection bias*. Since the interviewers choose respondents that they want to interview, there is a potential for selection bias. If the respondents in the survey are systematically different from the general population on the variables being measured, then estimates of characteristics will be different on average from what they would have been with a controlled probability-sampling scheme. In probability sampling, the survey planner or researcher controls which units are in the sample and selects the sample using known

probabilities of selection. The probabilities of selection can be used to produce estimates of population characteristics without the problem of selection bias.

Probability sampling is the standard methodology for large-scale surveys intended to support scientific studies and decision making for government policy. Nonprobability sampling, on the other hand, is quite common in marketing surveys and less formal studies. Nonprobability sampling certainly can produce useful information for some purposes. One attempt to adjust for the fact that probabilities of selection are unknown is to use weights, usually called *survey weights*, in analysis. These weights are computed so that the weights for sampled individuals in a particular stratum sum to a number proportional to the actual number of people known to exist in the population in the stratum. Although this adjustment can help make the sample more representative of the population in analysis, it cannot overcome the fact that there could be a remaining bias due to noncontrolled random selection of the sample.

NORMAL CURVE

A normal curve is the graph of the probability density function (PDF) for a normal distribution (see Figure 1). It is not just one but a family of curves of the same general form characterized by two parameters: the location parameter, or mean, and the scale parameter, or standard deviation. The formula for this family of curves is

Figure 1 Deutsche Mark Bill With Gauss and Bell-Shaped Normal Curve

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}} \text{ for } -\infty < x < +\infty,$$

where

mean $\mu \in (-\infty, +\infty)$,

standard deviation $\sigma \in (0, +\infty)$.

For a continuous random variable X that is normally distributed with parameters μ and σ^2 , the distribution is usually denoted by $X \sim N(\mu, \sigma^2)$.

A Brief History of the Normal Curve

The discovery of the normal curve, also known as the “bell-shape” curve or the Gaussian curve, can be dated to the 17th century, when Galileo Galilei, an Italian physicist and astronomer, noted that the measurement errors in astronomical observations were very systematic and that small errors were more likely to occur than large errors. In 1778, Pierre-Simon Laplace, while working on his famous *central limit theorem*, noted that the sampling distribution of the sample mean approximated a normal distribution and that the larger the sample size, the closer the distribution would be to a normal distribution, no matter what the population distribution might be. Also in the 18th century, a French statistician, Abraham de Moivre, who was often asked to do statistical consulting for gamblers, found that when the number

of events (e.g., coin flips) increased, the shape of the binomial distribution would approximate a symmetrical and smooth curve. However, the mathematical formula for this curve was not discovered until the 19th century, by Adrian Marie Legendre in 1808 and Carl Friedrich Gauss in 1809. The German 10 deutsche mark bill (see Figure 1) had Gauss's picture on it, along with the well-known bell-shaped normal curve and its formula.

Important Properties of a Normal Curve

This family of curves has the following characteristics, which are important to know. For those who are unfamiliar with the calculus calculation, all functions involving integration can be safely skipped. Graphical illustrations are used to facilitate an understanding of the concepts presented, and knowledge of basic algebra is assumed.

1. The mode, the mean, and the median are all at the same point on the abscissa, the horizontal axis of the curve (see Figure 2). That is to say, mode = mean = median for a normal distribution.

2. The curve is symmetrical about the point on the abscissas that denotes the mean, the mode, or the median, with equal numbers of observations above and below the point (see Figure 2).

Figure 2 Typical Normal PDF Curve

3. The skewness and the kurtosis for a normal distribution are both 0. However, statisticians who omit the subtraction of 3 from the kurtosis formula will report the kurtosis value to be 3 for a normal distribution.

4. The area jointly determined by two points (a, b) on the abscissa and the normal probability density curve indicates the probability that an observation falls within the intervals of $[a, b]$, $[a, b)$, $(a, b]$, or (a, b) . In other words,

$$\begin{aligned} p(a \leq X \leq b) &= p(a \leq X < b) = p(a < X \leq b) \\ &= p(a < X < b) = \int_a^b f(x) dx. \end{aligned}$$

Note that the probability associated with a particular value of a continuous variable is 0. For example, when $X \sim N(\mu, \sigma^2)$, $p(X = a) = 0$. Thus,

$$\begin{aligned} p(a \leq X < b) &= p(X = a) + p(a < X < b) \\ &= 0 + p(a < X < b) \\ &= p(a < X < b). \end{aligned}$$

5. When $a \rightarrow -\infty$, $b \rightarrow +\infty$, the probability mentioned in Paragraph 4 approaches 1. In other words, the total probability under the normal curve is always 1, or

$$\int_{-\infty}^{+\infty} f(x) dx = 1,$$

which also indicates that the probability of a sure event that $X \in (-\infty, +\infty)$ is 1.

6. Based on the probability theory, the cumulative distribution function (CDF) $F(x)$ is defined as the probability that a random variable X takes on a value that is less than or equal to a given x . For $X \sim N(\mu, \sigma^2)$, the corresponding CDF is calculated as follows:

$$F(x) = p(X \leq x) = \int_{-\infty}^x f(t)dt$$

$$= \frac{1}{\sigma\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{(t-\mu)^2}{2\sigma^2}} dt.$$

Note that the normal PDF is substituted for $f(t)$ in the formula. A normal PDF, along with its CDF, is illustrated in Figure 3, with the solid curve representing the PDF and the dashed curve the CDF. The area under the normal probability density curve when $x \leq a$ is equal to the value $F(x)$ assumes when $x = a$, or $F(a)$ in the normal CDF curve. This is an important property of the normal curve in that it relates the normal PDF to the normal CDF.

7. The normal curve indicates that all values of x are normally distributed with mean μ and standard deviation σ . In a statistical analysis, it is not uncommon that some normal random numbers have to be generated. In that case, those normal random numbers should be generated from the x -axis in a normal curve by means of a random number table or a computer software package.

8. When $X \sim N(0,1)$ or $\mu = 0, \sigma = 1$, the normal distribution is known as the standard normal

Figure 3 Normal PDF and CDF Curves

distribution. The standard normal curve is centered at 0, and the standard deviation is 1.

9. Any normal distribution $X \sim N(\mu, \sigma^2)$ can be transformed to a standard normal distribution by the following formula:

$$Z = \frac{X - \mu}{\sigma} \sim N(0, 1).$$

When standardization is performed, the normal curve will change its shape, with standard deviation increasing or decreasing to 1, and its location on the abscissa, with the midpoint of the normal curve moving to 0.

10. If the normal curve is divided into standard deviation units, a known proportion of observations fall within each portion of the curve. An empirical rule states that

- About 68.26% of the observations fall within 1 standard deviation below and above the mean.
- About 95.44% of the observations fall within 2 standard deviations below and above the mean.
- About 99.73% of the observations fall within 3 standard deviations below and above the mean.

To find out the proportion of observations that fall under a normal curve, not necessarily the standard normal one, between any arbitrary pair of points, we can consult a table containing the areas under a standard normal curve. Such a table can be found at the end of most statistics books as an appendix. Software packages containing modules or procedures for computing the areas are also widely available.

A Typical Problem

A typical example is illustrated below to demonstrate what people usually do with a normal curve. Notice that, for a normal curve, what is usually of interest is not the value of the function $f(x)$ but the area, or the probability, under the curve.

Suppose that the grades in a statistics exam have an $X \sim N(70, 10^2)$ distribution and that the grading scale is as follows:

- 91 to 100: Excellent
- 60 to 90: Good
- Below 60: Fail

What is the proportion of students passing the exam?

Figure 4 is a graphical illustration of this problem.

Figure 4 Normal PDF Curve for the Grades

The proportion of students passing the exam is the area under the curve between $x = 60$ and $x = 100$, which is indicated by the shaded area in Figure 4.

$$\begin{aligned}
 p(\text{Pass}) &= p(\text{Good}) + p(\text{Excellent}) \\
 &= p(60 \leq X \leq 100) \\
 &= p\left(\frac{60 - 70}{10} \leq Z = \frac{X - 70}{10} \leq \frac{100 - 70}{10}\right) \\
 &= p(-1 \leq Z \leq 3) = 0.84.
 \end{aligned}$$

An alternative method is to use the probability of *Fail* to solve this problem:

$$\begin{aligned}
 p(\text{Pass}) &= 1 - p(\text{Fail}) = 1 - p(X < 60) \\
 &= 1 - p\left(Z = \frac{X - 70}{10} < \frac{60 - 70}{10}\right) \\
 &= 1 - p(Z < -1) = 0.84.
 \end{aligned}$$

It should be noted that, in the solution to the problem, the area under a nonstandard normal curve, as indicated by the shaded area in Figure 4, is expressed in terms of the area under a standard normal curve by the transformation

$$Z = \frac{X - \mu}{\sigma}.$$

Although the two areas are different in shape, they are equal in size, indicating that the probabilities are equal. After the transformation is performed, the standard normal areas table could be employed to find the corresponding probability under the standard normal curve, which should be equal to the probability under the original normal curve.

Impact on Psychological Measurement

The importance of the normal curve can never be emphasized enough in the field of measurement and statistics. First, many variables in the science of psychological measurement are at least approximately normally distributed, and the approximation is very close. Measures of reading ability, job satisfaction, and memory are only a few examples in this field. Second, most statistical tests work well even if the distributions are only approximately normal. Third, assuming normality simplifies the mathematical procedures required to compute probabilities.

Caveats

1. Although the normal curve appears to be bell shaped, not all bell-shaped curves come from a normal distribution. A case in point is the Student t distribution, which is the ratio of a standard

Figure 5 Comparison of a Normal and a *t* PDF Curve

normal random variable to the square root of an independently distributed chi-square random variable divided by its degrees of freedom. The *t* PDF also features a family of curves depending on only one parameter: the degrees of freedom ν , with each one of them being bell shaped and symmetric around 0. Figure 5 compares a Student *t* distribution with $\nu = 5$ (solid line) to the standard normal distribution (dashed line). As can be seen, the curve for the *t* distribution appears to be very similar to that for a normal distribution.

2. Although most normal curves appear to be moderately sharp and moderately spread out, like the one in Figure 2, some normal curves could be the other way around, depending on the value of the scale parameter or standard deviation σ . Figure 6 shows two of them that do not fit the stereotype of a normal curve. As can be seen, as the value of σ goes down, the steepness of the normal curve goes up. Observations cluster more and more in the middle of the distribution. The steeper normal curve, on the top, has a relatively small σ value of 1 while the normal curve on the bottom is the opposite case, with its σ value being 8 times as large, hence a flat curve. However, although one normal curve may be different from another in terms of steepness, the total area under the curve, or the probability that x assumes a value between negative infinity and positive infinity, or the probability of a sure event, or

Figure 6 Comparison of a *Steep* and a *Flat* Normal PDF Curve

$$\int_{-\infty}^{+\infty} f(x)dx,$$

is always 1.

3. Nowadays, most computations involving a normal curve or a normal distribution can be performed with a computer software package. Generally speaking, five types of problems are related to this topic.

- Find the cumulative probability p that a value from a normal distribution with specified mean and standard deviation is equal to or less than a specified value x_0 . This type of problem is often related to the concepts of percentile and quantile.
- Find the value from a normal distribution with specified mean and standard deviation at which the cumulative probability is a specified value p_0 . This type of problem also is often related to the concepts of percentile and quantile.
- Find the value of the PDF of a normal distribution with specified mean and standard deviation at a specified value x_0 .
- Generate random numbers from a normal distribution with specified mean and standard deviation.
- Plot a normal probability density curve with specified mean and standard deviation.

Many available software packages could be utilized for these five types of problems. Table 1 summarizes the packages.

Table 1 Related Functions Available in Four Popular Software Packages

Names	Problem 1	Problem 2	Problem 3	Problem 4	Problem 5
Excel	NORMDIST	NORMINV	NORMDIST	N/A	CHART
SPSS	CDF.NORMAL	IDF.NORMAL	PDF.NORMAL	RV.NORMAL	N/A
SAS	CDF	QUANTILE	PDF	RAND	PROC PLOT

For some of the most popular software packages, Table 1 provides the names of functions, modules, and procedures that can be applied to the five very typical problems related to the normal curve and the normal distribution. Note that none of the names is case sensitive, with the exception of Matlab functions and modules, which have to be used in lowercase letters.

4. The family of normal curves that are bell shaped is only for the univariate case, in which only one variable x is involved. However, in the case of multivariate data analysis, the multivariate normal model, which extends the univariate normal distribution model, is commonly used. One example is a bivariate normal distribution model, which applies to two variables. In that case, the bell-shaped normal curve becomes a bell-shaped surface in three dimensions. Accordingly, the probability is indicated by the volume under the bivariate normal distribution surface.

NULL HYPOTHESIS SIGNIFICANCE TESTING

Null hypothesis significance testing (NHST) dominates experimental and correlational methods in psychological research. Investigators are typically concerned with demonstrating the existence of an effect, that is, systematic variation in the data that can be distinguished from random noise, sampling error, or variation due to uncontrolled or nuisance variables. The null hypothesis is often, but does not have to be, identified with chance, and a p value is computed to express how improbable observed empirical data are under the assumption that the null hypothesis is true. When this probability falls below the conventional value of .05, it is concluded that the null hypothesis is false and that it is safe to presume the presence of a systematic source of variation. This inference is not strictly logical because *modus tollens* is not valid when stated probabilistically: From the statement “If the null hypothesis is true, then extreme data are improbable,” it does not follow that “If the data are probable, the null hypothesis is false.” Because NHST is a method of inductive, not logical, inference, researchers nevertheless believe that the rejection of the null hypothesis indicates the presence of an effect. In the long run, the argument goes, decisions reached

by NHST will generate knowledge faster than would guessing or doing nothing.

Variants of NHST have been developed by various, and sometimes warring, schools of statistical thought. These schools differ in the assumptions they make about the nature of the data and the hypotheses and about how to make inferences. The following illustrations of possible inference strategies begin with information- and assumption-rich scenarios and proceed to the more degraded scenarios typical of most psychological research.

Full-Suite Analysis

Suppose extensive testing has revealed that average self-esteem scores are $\mu = 68$ and 72 for women and men, respectively, and that the standard deviation within each gender is $\sigma = 20$. A sample of 200 scores with a mean of 71 is drawn from one of the two populations. The null hypothesis H_0 is that women were sampled, and the alternative hypothesis H_1 is that men were sampled. Analysis begins with the calculation of the probability of obtaining a mean of 71 or higher if H_0 is true. The z score for the sample mean is

$$(71 - 68)\sqrt{200}/20 = 2.12,$$

and the probability of a score at least this extreme is .017.

Evaluation of the data under the alternative hypothesis H_1 yields $z = .71$, $p = .24$. That is, the data are not improbable under the assumption that men were sampled. The likelihood ratio (LR) of the two p values, $p(D|H_1)/p(D|H_0)$, is 14.12, meaning that it is more than 14 times more likely that a sample of men rather than women would yield data of the kind found in the empirical sample. But how likely is it that the sample consisted of men? It is necessary to be explicit about the prior probability of sampling men. A simple intuition is that women and men were equally likely to be sampled, that is, $p(H_0) = p(H_1) = .5$. The summed

products of these prior probabilities and their respective p values is the overall probability of the observed data. Here, $p(D) = p(H_0)p(D|H_0) + p(H_1)p(D|H_1) = .13$. This probability is critical for the calculation of the probability of the null hypothesis given the observed data. Bayes' theorem gives $p(H_0|D)$ as $p(H_0)p(D|H_0)/p(D) = .07$. Because the prior probabilities of the two hypotheses are the same, the ratio of the two posterior probabilities is the same as the LR. It can now be said that the sample is more than 14 times more likely to comprise men than women. The assumption of equal priors was just that, an assumption. Suppose the researcher knew that self-esteem scores were collected at four different sites, only one of which comprised men. Now $p(H_0|D) = .18$, meaning that it is only 4.7 times more likely for the sample data to come from men than from women. Although the prior probability that men were sampled was low, the evidence is still strong enough to reject the null hypothesis that women were sampled and to accept the alternative.

Now consider a study in which 200 women and 200 men are sampled. The null hypothesis is that there is no gender difference in average self-esteem scores ($H_0: \mu_{\text{women}} = \mu_{\text{men}} = 70$, $\sigma = 20$), and the alternative is that there is a 4-point difference ($H_1: \mu_{\text{women}} = 72$, $\mu_{\text{men}} = 68$, $\sigma = 20$). During the early phase of the research program, the two hypotheses may appear to be equally likely to be true. If the gender difference in the sample means is 3.5 points, the revised probability of the null hypothesis is $p(H_0|D) = .09$. As evidence accumulates, researchers become aware that some hypotheses are riskier than others. Suppose gender differences in self-esteem have become well established, so that $p(H_0) = .1$. Now a 3.5 gender difference still renders the null hypothesis less probable ($p(H_0|D) = .01$), but there is less room to move.

These examples are idealized: The properties of the two populations (μ and σ) are known, and credible estimates of their prior probabilities are available. Scientific research must often proceed without this full suite of information. Researchers handle the lack of information by suspending certain kinds of inference or by making defensible assumptions where

good information is missing. If the prior probabilities of competing hypotheses are unavailable in a quantifiable and agreed-on format, they can sometimes be estimated on the basis of prior research or derived from theory.

Power

Many researchers are careful to situate their findings within the context of relevant empirical or theoretical work but refrain from making explicit estimates for their hypotheses to be true. Suppose again that a 3.5 gender difference in self-esteem is found. Evaluation of the data under the two hypotheses yields $p(D|H_0) = .04$ and $p(D|H_1) = .401$, and thus $LR = 10$. With prior probabilities barred from quantitative inferences, researchers can still estimate their study's statistical power to detect a 4-point gender difference. The power of the study is the probability that the null hypothesis will be rejected if it is indeed false. To obtain this probability, it is necessary to find the minimum gender difference leading to the rejection of H_0 . This difference is given by the product of the z score at which $p(D|H_0) = .05$ and the standard error of the difference. (The standard error of the difference between means \bar{X}_1 and \bar{X}_2 is

$$\sigma_{\bar{x}_1 - \bar{x}_2} = \sqrt{\sigma_{\bar{x}_1}^2 + \sigma_{\bar{x}_2}^2};$$

here, $1.65 \times 2 = 3.3$.)

The power of the study is the complement of the probability of such an effect under the alternative hypothesis. Here, $1 - p(D|H_1) = .64$. In other words, the prior odds that this study would detect an existing difference of 4 points were about 5 to 3.

In principle, many researchers agree that the null hypothesis should not be rejected when $p(D|H_0) > .05$. In practice, however, they tolerate a good number of exceptions, thus opening the door to the murky world of "marginal significance." Researchers typically care more about limiting the probability that a true null hypothesis is rejected than about increasing the

probability that a true effect is detected. Designing a study with a power of .8 is a widely held but seldom attained ideal. One reason for this shortfall is that power consumes resources. In the present example, a total sample of 1,152 individuals would be required to reach the ideal.

Making Decisions

In the decision-theoretic school of hypothesis testing, $p(D|H_0) = .05$ signifies the probability with which a true null hypothesis is rejected. This decision outcome constitutes a Miss (M). Conversely, $p(D|H_1)$ is the probability that a false null hypothesis is not rejected, a circumstance called a False Positive (FP). The complement of an M is a Hit (H), that is, the retention of a true null hypothesis; the complement of an FP is a Correct Rejection (CR), that is, the rejection of a false null hypothesis. The probability of CR is the power of the study. If there are no resources to increase power, it is tempting to admit more FP. If the null hypothesis is rejected with $p(D|H_0)$ as high as .10, power increases from .64 to .76. The practice of adjusting $p(D|H_0)$ is frowned on, however, when it reflects, not the state of the field and thus appropriate prior probabilities, but rather the researcher's desire to obtain significant results.

Without prior beliefs, there is no way of estimating how probable the four outcomes are. It is only possible to state the conditional probability of $p(H)$ relative to $p(M)$ and of $p(FP)$ relative to $p(CR)$. To illustrate what can be gained from estimating the prior of the null, consider $p(H_0) = .75$, $.5$, and $.25$. The top panel of Figure 1 shows the four conditional probabilities obtained in a high-powered study. Each quadrant of the bottom panel gives three unconditional probabilities that are obtained as products of the conditional probabilities and the prior probabilities of the hypotheses. When, as in the typical empirical case, the probability of rejecting a true null hypothesis (M) is smaller than the probability of accepting a false one (FP), any decrease in the prior probability of H_0 decreases the overall probability of correct decisions

Filling In

When a new area of research opens up, it is marked by great uncertainty. The null hypothesis may not have a defensible prior probability, and there may not be a well-formulated alternative hypothesis. Without being able to estimate the posterior probability of the null and with no opportunity to estimate the power of the study, researchers seek to collect only enough data to reject the null. When they do, they can declare only that an effect has been found, and they can report its size (for example with Cohen's *d* or Pearson's *r*). Power analyses can be performed with the obtained effect size, but the wisdom of this practice is a matter of debate. Nevertheless, when enough empirical effect sizes have been reported to justify their aggregation by meta-analysis, these combined effect sizes can serve as point-specific research hypotheses for replication and extension studies.

The life course of a typical research area entails a paradox. In the early stages, NHST can be performed only in its most rudimentary form. At this stage, misinformation and miseducation are most likely to contribute to fallacious conclusions, such as the widespread belief that the *p* value of the data signifies the improbability of the null hypothesis. In the late stages, when specific alternative hypotheses are available, when the power of a study can be determined, and when the probability of hypotheses can be estimated, new data contribute little incremental knowledge. Although NHST can then be used with great precision, its purpose is now to produce judgments about the acceptability of the data and not about the truth or falsity of the hypotheses.

(here, $p(H) + p(CR) = .91, .88,$ and $.84,$ respectively, for $p(H_0) = .75, .5,$ and $.25$). This is an odd, but logical, result. As an area of research becomes more mature, null hypotheses become less probable, and the typical conservatism of decision making (i.e., power $< 1 -$ desired significance level) makes it more likely that true effects are missed. Failures to replicate then accumulate, not because previously demonstrated phenomena do not exist, but because studies lack power. Hence, even the principled use of NHST delays scientific progress. The data of solidly designed but underpowered studies are dismissed for ad hoc reasons, or worse, they are seen to add up to a store of anomalies that potentially undermines hard-won knowledge.

O'BRIEN TEST FOR HOMOGENEITY OF VARIANCE

The homogeneity of variance assumption is one of the critical assumptions underlying most parametric statistical procedures, such as the analysis of variance (ANOVA), and it is important to be able to test this assumption. In addition, showing that several samples do not come from populations with the same variance is sometimes of importance per se. Among the many procedures used to test this assumption, one of the most sensitive is the O'Brien test, developed by Ralph G. O'Brien. The null hypothesis for this test is that the samples under consideration come from populations with the same variance; the alternative hypothesis is that the populations have different variances.

Compared with other tests of homogeneity of variance, the advantage of the O'Brien test resides in its versatility and its compatibility with standard ANOVA designs. It is also optimal because it minimizes both Type I and Type II errors. The essential idea behind the O'Brien test is to replace, for each sample, the original scores by transformed scores such that the transformed scores reflect the variance of the sample. Then, a standard ANOVA based on the transformed scores will test the homogeneity of variance assumption.

Motivation and Method

Several tests are available for detecting whether several samples come from populations having the same variances. In the case of two samples, the ratio of the population estimates (computed from the samples) is distributed as a Fisher distribution under the usual assumptions. Unfortunately, there is no straightforward extension of this approach to designs involving more than two samples. By contrast, the O'Brien test is designed to test the homogeneity of variance assumption for several samples at once and with the versatility for ANOVA designs, including contrast analysis and analysis of subdesigns.

The main idea behind the O'Brien test is to transform the original scores so that the transformed scores reflect the variation of the original scores. An ANOVA on the transformed scores will then reveal differences in the variability (i.e., variance) of the original scores, and therefore this analysis will test the homogeneity of variance assumption. A straightforward application of this idea will be to replace the original scores with the absolute value of their deviation to the mean of their experimental group. So, if we denote by Y_{as} the score of participant s in experimental condition a whose mean is denoted by M_a , this first idea amounts to transforming Y_{as} into v_{as} as follows:

$$v_{as} = |Y_{as} - M_a|.$$

This transformation has the advantage of being simple and easy to understand, but unfortunately, it creates some statistical problems (i.e., the F distribution does not model the probability distribution under the null hypothesis), and in particular, it leads to an excess of Type I errors (i.e., we reject the null hypothesis more often than the α level indicates).

A better approach is to replace each score by its absolute distance to the *median* of its group. Specifically, each score is replaced by

$$w_{as} = |Y_{as} - Md_a|,$$

where Md_a = median of Group a . This transformation gives very satisfactory results for an omnibus testing of the homogeneity of variance assumption. However, in order to implement more-sophisticated statistical procedures (e.g., contrast analyses, multiples comparisons), an even better transformation was proposed by O'Brien. Here, the scores are transformed as follows:

$$u_{as} = \frac{N_a(N_a - 1.5)(Y_{as} - M_a)^2 - .5SS_a}{(N_a - 1)(N_a - 2)},$$

where

N_a is the number of observations of Group a ,

M_a is the mean of Group a ,

SS_a is the sum of the squares of Group a :

$$SS_a = \sum_s (Y_{as} - M_a)^2.$$

When all the experimental groups have the same size, this formula can be simplified as

$$u_{as} = \frac{N(N - 1.5)(Y_{as} - M_a)^2 - .5SS_a}{(N - 1)(N - 2)},$$

where N = number of observations per group.

One Is a Bun . . .

To detail the computation of the median and the O'Brien transforms, we will use data from a memory experiment reported by Hunter. In this experiment, Hunter wanted to demonstrate that it is easier to remember an arbitrary list of words when we use a mnemonic device such as the peg-word technique. In this experiment, 64 participants were assigned to either the control or the experimental group. The task for all participants was to learn an arbitrary list of pairs of words such as "one-sugar," "two-tiger," . . . "ten-butterfly." Participants in the control group were told to try to remember the words as best as they could. Participants in the experimental group were given the following instructions: A good way to remember a list is to first learn a "nursery-rhyme" such as "*One is a bun, two is a shoe, three is a tree, four is a door, five is a hive, six is a stick, seven is heaven, eight is a gate, nine is a mine, and ten is a hen.*" When you need to learn a pair of words, start by making a mental image of the number, and then make a mental image of the second word and try to link these two images. For example, in order to learn "one-cigarette," imagine a cartoon-like bun smoking a cigarette.

Ten minutes after they had received their list, all the participants were asked to recall as many pairs as they could. The results are given in Table 1.

The results of this experiment are illustrated in Figure 1; they show that the participants from the experimental group did better than the participants from the control group did. To confirm this interpretation, an ANOVA was performed (see Table 2), and the F test indicates that, indeed, the average number of words recalled is significantly larger in the experimental group than in the control group.

Figure 1 also shows that a large proportion of the participants of the experimental group got a perfect score of 10 out of 10 words (cf. the peak at 10 for this group). This is called a *ceiling* effect: Some of the participants of the experimental group could have performed even better if they had had more words to learn. As a consequence of this ceiling effect, the variance of the experimental group is likely to be

smaller than it should be because the ceiling effect eliminates the differences between the participants with a perfect score. In order to decide whether this ceiling effect does in fact reduce the size of the variance of the experimental group, we need to compare the variance of the two groups.

The first step to test the homogeneity of variance is to transform the original scores. For example, the transformation of Y_{as} into w_{as} for Observation number 5 from the control group gives

$$w_{as} = |Y_{as} - Md_a| = 5 - 6.5 = 1.5.$$

The transformation of Y_{as} into u_{as} for Observation number 5 from the control group gives

$$u_{as} = \frac{N(N - 1.5)(Y_{as} - M_a)^2 - .5SS_a}{(N - 1)(N - 2)}$$

OBSERVATIONAL STUDIES

Both observational and experimental studies attempt to provide a valid estimate of the causal effect of some independent variable. Major differences exist, however, between these two types of investigation with respect to design, practicality, interpretation, and appropriate methods of analysis. For the sake of exposition, we will primarily consider two-group situations, although these two types of studies can involve comparisons of more than two groups. The principles and issues involved easily generalize to situations with more than two groups.

Design and Practicality Issues

Two key design issues distinguish observational and experimental studies: (a) the method used to form the comparison groups and (b) the nature of the process that determines whether a participant receives the treatment condition or the control condition. The

two-group experiment involves two essential characteristics: (a) random assignment of available participants to form two comparison groups and (b) experimenter-dictated assignment of the treatment condition to all participants in one group and the control condition to all participants in the other group. Because random assignment yields two groups that are probabilistically equivalent on all variables (before treatments are applied), a simple comparison of the group means (or medians) usually provides a meaningful estimate of the causal effect. In many situations, however, random assignment and experimenter-controlled treatment manipulation are impractical or unethical. For example, if one suspects that cocaine use by mothers causes brain damage in neonates, it would be unethical to randomly assign a sample of pregnant mothers to two groups, with one group receiving cocaine and the other (cocaine-free) group serving as the control group. Observational studies are often useful in such situations.

The observational study has neither random assignment of participants to form comparison groups nor experimenter-controlled assignment of treatment and control conditions to the groups. Rather, data are obtained from participants in nonrandomly formed groups: one that received the treatment condition and one that did not receive the treatment condition. Participants' exposure to the treatment occurs for some reason(s) other than the action of an experimenter. Suppose, for example, that two samples of mothers are identified: One sample used cocaine during pregnancy and the other did not. Although a comparison of the two samples on a measure of neonatal brain damage may seem interesting, this comparison does not necessarily provide an estimate of the causal effect. Such a comparison is often called the *naive effect estimate* because it almost certainly provides an invalid (biased) estimate of the causal effect.

Key Interpretational Concern

Naive estimates almost always contain bias because differences between treatment and control groups on the outcome may exist for many systematic reasons other than causal effects of treatments. Consequently, one does not know how much of this difference

should be attributed to initial group differences and how much (if any) should be attributed to treatment effects. It is naive to presume that the outcome difference reflects only treatment effects.

Analytic Issues

A thorough evaluation of an observational study will include statistical analyses that go beyond naive estimation to yield better estimates of the putative causal effect of the treatments. These analyses focus on two types of bias-producing variables: *overt*, which have been accurately measured on each participant before treatments were applied, and *hidden*, which have not been so measured.

Overt Bias Adjustment

The analysis of covariance (ANCOVA or the equivalent regression model), simple matched sampling, and subclassification are the traditional methods of adjusting for overt bias. Modern approaches represent extensions and refinements of these methods. One of the more useful modern approaches involves the *propensity score*, a number that indicates the propensity for a participant to fall in the treatment group rather than in the control group. Propensity scores can identify participants who are essentially equivalent on a very large number of variables. Once appropriate comparison participants are identified by means of propensity scores, the outcome analysis may take the form of a simple comparison by means of conventional parametric or nonparametric methods or may involve a more complex strategy that uses a modified form of ANCOVA. The latter approach often leads to a solution that is both less biased and more powerful than that of the simpler methods.

A classic example of observational research involved a large study of the effects of smoking. Three groups were compared: The average mortality rates were 13.5, 13.5, and 17.4 for nonsmokers, cigarette smokers, and cigar and pipe smokers, respectively. A comparison of these rates (i.e., the naive estimates) suggested that there was no effect of cigarette smoking relative to not smoking and that cigar and pipe smoking increased mortality. After adjusting the

mortality rates for age, however, these rates were 13.5, 21.2, and 13.7 for nonsmokers, cigarette smokers, and cigar and pipe smokers, respectively. Hence, after adjusting for overt bias associated with age differences among groups, cigarette smoking appeared to increase mortality.

Hidden Bias Adjustments

Although modern methods of analysis provide satisfactory solutions to the problem of overt bias, one always has to acknowledge that unknown but important (i.e., bias-causing) variables probably have been left out of the overt bias adjustments. For example, Sir Ronald Fisher seriously entertained the notion that there may be genetic differences between smokers and nonsmokers before they begin to smoke. If unmeasured genetic characteristics have a causal influence on the between-group difference on mortality rates, they qualify as sources of hidden bias.

Because the exclusion of such variables can completely change the size and sign of the treatment-effect estimate, a statement acknowledging this possibility should be included in every document reporting the results of an observational study. It is often possible, however, to apply additional methods to examine the plausibility of the hidden variable explanation for the results. Consequently, many observational studies rely on assembling information outside the group comparison to bolster causal conclusions. This additional information often takes the form of (a) a second control group, (b) additional results that are consistent with a theory, and (c) sensitivity analysis.

Suppose an observational study of two methods of teaching reading has found an important difference between the treatment and control groups on the outcome reading measure. Further, suppose that the variable of age, which was not included in the original analysis (and can no longer be obtained), is a source of hidden bias. In this case, it would be reasonable to identify an additional group (the second control), believed to differ in age relative to the original control group. A comparison is then made between the two control groups on the outcome measure; if the two

differ on the reading outcome in the suggested direction (i.e., the control group with the higher average age also has the higher reading score), this information provides support for the hypothesis that age is a hidden bias in the comparison of the treatment and control groups. In this case, the original interpretation of a differential treatment effect is in doubt.

One can often use a theory to predict a pattern of differences between the means of certain groups. For example, suppose that the reading study mentioned above involved a direct instruction group and a conventional reading (control) group. Perhaps the amount of time a person is exposed to a specific aspect of direct reading instruction is the critical component of the causal mechanism, and the observational study supports the superiority of this treatment. If existing evaluative data comparing three other reading programs are available, and if each of these programs differs on a measured amount of the critical component, a pattern of results can be predicted from this information. If the pattern reveals a clear association between the amount of critical component of the direct reading method and the effectiveness of the three treatments, the claimed treatment effect in the observational study is supported. Alternatively, if both the difference in the original observational study and the differences found among the means in the supplemental data are associated with age, the hidden bias explanation is supported.

The third approach for considering hidden bias requires no additional data. Instead, the original observational study data are subjected to what is known as a *sensitivity analysis*. This type of analysis evaluates how large a potential hidden bias would have to be to produce meaningful changes in the results of the observational study. Some versions of sensitivity analysis produce bounds on p values that are associated with a specified size of hidden bias. Other methods provide a measure of how much two groups must differ on a hidden variable for the results to change from statistically significant to nonsignificant.

OCKHAM'S RAZOR

Ockham's razor is a methodological principle introduced by the medieval Franciscan friar and philosopher-theologian William of Ockham. He was born in 1285 in the village of Ockham, in Sussex, England, and died probably around 1347, during the plague epidemic in Munich, where he had spent his latter years at the court of the outlawed German-Roman emperor Ludwig of Bavaria as one of his theological-political advisers.

The razor principle was stated by Ockham several times in his writings. It is introduced as a kind of theorem or axiom that is never proven but taken as evident and hence not in need of further proof. In a well-known version, it reads "pluralitas non est ponenda sine necessitate—a plurality [of entities] should not be postulated without necessity." To understand what Ockham meant by that, it is necessary to introduce very briefly the theological and philosophical background discussions during his time, as well as key aspects of his life.

Historical Background

At the beginning of the 13th century, two new spiritual movements arose within a very short period of two decades and grew to a powerful position in medieval society: the so-called mendicant friars of the Franciscan and Dominican orders. The key elements of

the Dominican calling were preaching to Christians and heretics alike and most important, converting all who were considered "heathens" (i.e., people of Jewish, Muslim, or nonorthodox Christian faiths) and establishing the knowledge, background, and learning to be able to do so. Therefore, Dominicans pressed into the newly founded universities in Paris, Oxford, and Cambridge to install a pertinent training, teaching, and research base for their enterprise. They were soon followed by the Franciscan friars. Although learning and academic work had not been a primary aspect of early Franciscan spirituality, Franciscans, too, soon understood that the Franciscan order also had to train its new members well if they were to complete their mission of reinvigorating Christian life and service to the community. Thus, the academic life and debates in the 13th century were largely dominated by these new movements and their academic beacons at the universities. One major challenge for these academics was to integrate Aristotelian science and philosophy into the traditional Christian teaching. Knowledge about Aristotle's philosophy had been scarce and based on only a few writings known to the West. Through both peaceful contacts with Islamic science, mainly in Spain and Sicily, and the combats surrounding the Crusades, such as the crusaders' sacking of Constantinople, more Aristotelian writings came to the West, and as a consequence, Aristotelian teaching became known. Thomas Aquinas (1225–1274), the mastermind of the Dominican order at that time, clearly saw that only a Christian reinterpretation of Aristotle would save a coherent picture of the world and give enough rational appeal to Christian theology, both for the satisfaction of critical Christian thinkers and philosophers and for armament against the Muslim theologians who had already integrated Aristotle into their worldview. Thus, Thomas Aquinas devoted his academic career to interpreting and amending Aristotle and reconciling him with Christian teachings. Part of this enterprise was the adoption of Aristotle's theory of perception and mental activity as expounded in his book *De Anima* [*On the Soul*]. The theory, briefly, supposes that in visual perception, for instance, the eyes extract what in Latin was called a *species sensibilis*, a perceptual template, if we may interpret freely. This

template is presented to the mind, which from it abstracts another template, which in this case is mental. This second template is the basis for further operations. Thus, a whole series of intermediaries were introduced that would mediate between the object of perception and the mental operations of the mind.

The Franciscan calling was, in general, different from that of the Dominicans, and a latent competition ran through all the two orders' activities. Franciscans put more emphasis on personal piety, inner experience, and the fostering of a religious life in general. One group in particular, whose members called themselves "Spirituals," tried to go back to what was seen as Saint Francis's original testament: a poor life as a mendicant order, little interaction with the authorities of church or world, and a support of private piety through prayer and contemplation, which should lead each Christian to an intimate personal relationship with Christ.

When William of Ockham entered the Franciscan order, presumably around the age of 14, and his scholarly training started, this debate was reaching a first climax, and it can be safely assumed that he was drawn into it. He was sent to Paris by his order, as every intelligent and promising young student would have been in those days, to finish his studies. When he arrived there, the debates around the Aristotelian-Thomistic theory of perception were at their height. Ockham, however, had had other training: One of his teachers, Roger Bacon, another Franciscan, advocated experiential knowledge and in particular inner experience as an important way to know both the world and God's will. Experience always had an element of immediacy, of unmediated access to its object. Now, if you were to apply the then-current general Aristotelian theory of knowledge to direct experiences, say of an inner mystical relationship with God, what would that entail? You would have to abstract from your own inner experience a species, which would again be abstracted by another inner act until it reached your mind as a diluted and colorless mental template of what originally was a rich experience. Even with very simple personal experiences, such as hunger, thirst, or pleasure, the Aristotelian concept of perception would distort experience by abstractions. And thus, a systematic philosophical and epistemological

place for direct experience could not be had as long as this philosophy of perception was the generally accepted one.

This state of the debate was certainly one motive for Ockham's critique, for he had understood a very important precondition: If there should ever be a systematic place for a direct inner (and outer) experience of mental events in any epistemology, then the Scholastic concept of perception introduced by Thomas Aquinas must be critiqued. If there were to be any possibility of a direct inner contact of a soul with God, as Franciscan piety was striving for, then the Scholastic theory of perception must be replaced by something simpler. Thus, one very powerful motive, among others, for Ockham was the wish to establish a place for direct inner experience within epistemology and for experience in general as an access both to the world and to one's inner being. Thus, as a theorem from which to start his critiques, he introduced his razor principle: No entities beyond necessity.

Consequences and Place Within the Scientific Enterprise

This principle of parsimony, as it is also called, is intuitively appealing. It was introduced as a guideline that should inform our thinking and theorizing. Ockham used it to deconstruct the Thomistic and Scholastic theory of perception and to find a place for experience and immediate access to reality.

Another important debate of the time pitted the theory of universals against nominalism. While a universalist can sit in a study thinking about universals and their relationship with the world, a nominalist eventually has to go outside and study all individual specimens of, say, horses to understand what it is to be a horse. Ockham's razor, applied to this debate, led directly to an empiricist approach to reality. Thus, Ockham's endeavor, philosophical and abstract as it might seem today, was the very precondition for modern science as an empirical enterprise.

This might be the reason that the principle of parsimony is held dear by modern science. Whenever someone announces the discovery of something new—a new species of animal, energy, or any other

entity—science as a body reacts skeptically, sharpening Ockham's razor. (In this way, Ockham's razor is perhaps also a way to keep jerks and quacks out of science.) It is at the base of science's inherently reductionist approach: Whenever some seemingly unknown phenomenon is discovered or whenever something is not well understood, the historically most promising approach is not to postulate a new entity but to try to understand it through already known principles and reduce the phenomenon to a set of theories or rules that are already understood.

An Example

A well-known historical example is the explanation of mesmerism as hypnotic effects. In the 18th century, the German physician Franz Anton Mesmer had postulated a new type of energy, which he called "animal magnetism." He thought that this energy would emanate from every living being, with humans being especially endowed with it, and that in illness, this energy was disturbed. Consequently, he used his own "animal magnetism" to heal sick patients. He was a center of attention in pre-Revolutionary Paris, with poor people and the aristocracy alike using his healing powers, apparently quite successfully. Mesmer's claims were scrutinized by the French Academy of Sciences. When shielded by a curtain, the purported magnetic phenomena did not occur, but they were clearly evident provided the healer was able to stay in visual contact with his patient. The Academy concluded that animal magnetism had not been proven and that the phenomena were likely due to suggestion and hypnotism. In other words, Ockham's razor was implicitly used to "cut out" the newly introduced notion of animal magnetism and reduce it to known phenomena: suggestion and hypnotism.

Thus, the razor principle introduces a sound element of skepticism and in fact conservatism into the scientific debate, although it had been used by its inventor as a weapon against conservative mainstream theorizing and as a motor of progressive methodology. It is quite fitting that William Ockham was called *inceptor venerabilis* (venerable initiator) in his day. Nowadays, the razor principle has turned from a

sword of the vanguard to a shield of the establishment. Now Ockham's razor has to be balanced with a stance that is true to what we see and experience.

Thus, Ockham's razor, the methodological principle of parsimony, has to be seen in context. Its function is to prevent scientists and the scientific community at large from leaping to accept new explanations for phenomena before it is clear that the phenomena cannot be explained by existing models. Only if these models fail can new categories of phenomena, new theories, or a new worldview be considered.

Ockham's razor is the first methodological principle introduced by a medieval scholar without an apparent source in earlier or antique writings. It marks the beginning of a modern era of potentially unprejudiced investigation and discovery and has served scholars and scientists well for more than 700 years. It is part and parcel of the scientific enterprise. In order not to be perverted into an instrument of hegemony of one doctrine, it needs balancing by a generic stance of openness toward phenomena, a stance some of us refer to as Plato's Life Boat.

OGIVE

An ogive is a line plot of the cumulative frequency distribution against values of the random variable. Francis Galton coined the term *ogive* to describe the shape of the normal cumulative distribution function, as it has a form similar to the S-shaped Gothic ogival arch.

Note: Solid line is ogive plot of student test scores with frequency distribution, and dashed line is normal cumulative distribution curve

The ogive can display the population cumulative frequency distribution or an estimate from a sample. The random variable can be continuous or discrete (as long as there is a natural ordering of the outcomes). The range of possible outcomes is divided into classes. A line is drawn to connect points at the upper limit of each class interval and the cumulative frequency distribution. For a discrete random variable, each possible outcome can be a class, and therefore the upper limit of the class is the outcome itself.

The student test scores in Table 1 are split up into five class intervals. The ogive is often overlaid with the frequency distribution, as in Figure 1. The solid line is the empirical cumulative distribution, and the

ONE- AND TWO-TAILED TESTS

The one-tailed or two-tailed test is a part of a much more elaborate procedure called hypothesis testing or tests of statistical significance. Prior to doing a hypothesis test, a researcher will have formulated a problem, identified the variables, formulated the hypotheses, and collected the data.

In hypothesis testing, there are five basic steps:

- Stating the null hypothesis
- Stating the alternative hypothesis
- Computing the test statistic
- Formulating the decision rule and making a decision
- Drawing a conclusion

At the very basic level, the researcher would be comparing either a sample mean against a population mean or the difference between two sample means. Hypothesis tests are not restricted to tests on means. Other comparisons and evaluations could involve

variances, proportions, and correlations, to name a few. Furthermore, these tests are not restricted to comparing only two means.

The statement of the alternative hypothesis is a statement expressed in statistical terms concerning an investigator's research interest. For example, the investigator may have a question concerning the effects of alcohol consumption on perceptual judgment. If the investigator feels from personal experience or observation that alcohol would have a negative effect on perceptual ability, the alternative hypothesis would reflect that. For research problems in which the data are considered parametric, the null and alternative hypotheses would be expressed by the use of population parameters. The simplest case would be between two means, μ_1 and μ_2 .

In the example, alcohol is given to an experimental group of participants, μ_1 and a placebo, an inactive simulation of alcohol, is given to a control group, μ_2 . Each participant is measured on the number of correct judgments made on a perceptual task. The alternative hypothesis would state that the group receiving alcohol (the experimental group) would perform worse than the group receiving the placebo (the control group). Statistically, the alternative hypothesis would be written as $H_1: \mu_1 - \mu_2 < 0$ or $H_1: \mu_1 < \mu_2$. The alternative hypothesis is not directly testable. Note that it just says that one group is worse than the other. It does not say by how much. To test this hypothesis directly would require a large, perhaps infinitely large, number of tests in which each difference was to be tested. It is much easier to create a hypothesis that is the opposite of the alternative hypothesis and, with empirical evidence, demonstrate that it cannot be tenable. If this opposite hypothesis is not tenable, then by inference, the alternative hypothesis must be true. This opposite hypothesis is called the null hypothesis. Some part of the null hypothesis points directly to a testable value, such as zero. So for this example, the null hypothesis, written as H_0 , is $H_0: \mu_1 - \mu_2 \geq 0$. Note that the null hypothesis contains the equal sign.

The null hypothesis is used to help direct the hypothesis test. The investigator would assume the null hypothesis to be true and then, through empirical data, demonstrate that it cannot be tenable. As a result

of this, the alternative hypothesis is shown to be tenable. However, it is the alternative hypothesis that dictates whether the test against the null hypothesis should be one-sided or two-sided. Whenever the investigator's research question indicates that one treatment group is better, more improved, more impaired, weaker, faster, or something else along these lines, than another group, the alternative hypothesis would be considered as one-tailed, or one-sided. When no direction is given by the investigator as to which group will be better or worse than the other group, the alternative hypothesis would be two-tailed. Consider the example given. The investigator had hypothesized that alcohol consumption would lead to impaired performance compared to the performance of those who did not consume alcohol. The alternative hypothesis was $H_1: \mu_1 < \mu_2$. This is a one-tailed test. If the investigator had hypothesized that those that consumed alcohol would demonstrate improved performance over those with no alcohol, the alternative hypothesis would have been written as $H_1: \mu_1 > \mu_2$. This still would have been a one-tailed test. However, if the investigator had stated uncertainty as to whether or not alcohol consumption would lead to a positive or negative change in performance in comparison to those that did not consume alcohol, the test would be two-tailed. It is two-tailed because the uncertainty would make it possible that either $\mu_1 < \mu_2$ or $\mu_1 > \mu_2$ could be true if the null hypothesis were shown not to be tenable. For this situation, the null hypothesis would have been stated as $H_0: \mu_1 - \mu_2 = 0$ or $H_0: \mu_1 = \mu_2$. Such a test is also called a *nondirectional* test.

A *two-tailed*, or *two-sided*, test is so named because if the normal distribution, or the t distribution, is used, the two tails, or the two sides, of the distribution are employed in the estimation of probabilities. Consider a .05 probability of a Type I error. With a normal-shaped sampling distribution, .025 of the area of the curve falls to the right of 1.96 standard deviation units above the mean, and .025 falls to the left of 1.96 standard deviation units below the mean (See Figure 1). The sum of these areas is 5% of the total area under the curve ($\alpha = .05$). In a hypothesis test, the chances are 2.5 in 100 of getting a difference of 1.96 standard deviation units in one direction due to

chance factors alone, and 2.5 in 100 in the other direction. Hence the total by chance alone in both directions is 5 in 100. For significance at the 1% level, a value of 2.575 is required for a nondirectional test. For one-tailed tests, if the normal, or t , distribution is used, only one of the tails is used to estimate the required probabilities. For a Type I error probability of .05, the entire amount is placed into one of the tails of the distribution. For a right-tailed, one-tailed test, the required critical value needed to reject the null hypothesis is +1.645 (see Figure 2). For a left-tailed test, the critical value is -1.645 (see Figure 3). With one-tailed tests, the investigator could make an error in choosing the wrong direction or tail contrary to the statement made by the alternative hypothesis.

In summary, for a one-tailed case, an investigator has only one critical value to contend with when doing the hypothesis test, and the two-tailed test has two critical values. For a fixed probability of a Type I

Figure 1 A Two-Tailed Test of the H_0 With $\alpha = .05$

Figure 2 A One-Tailed Test (*Right*) of the H_0 With $\alpha = .05$

Figure 3 A One-Tailed Test (Left) of the H_0 With $\alpha = .05$

error, α , the chances of rejecting the null hypothesis are higher for a one-tailed test than for a two-tailed test. The reason is that the α value is divided in half and placed across two tails of distribution in the two-tailed situation whereas in the one-tailed case, the entire amount is spread over only one of the tails of the distribution. In terms of statistical power, the one-tailed test is more powerful than the two-tailed test provided the investigator has hypothesized the proper direction of the statistical test.

In the social and behavioral sciences, there has been much discussion concerning the use of one- and two-tailed tests. One of the major issues these discussions have centered on is an investigator's decision to change from an originally stated two-tailed test to a one-tailed test after the hypothesis test has been done. The two-tailed test yielded a nonsignificant result, but on reflection, the investigator decided a one-sided test would have produced a significant result. Some have claimed that the decision to choose the alternative and null hypotheses post hoc is unethical. Plus, investigators should always remind themselves that significant results could still be due to chance.

Another issue is what an investigator should do if a two-tailed test turns out significant. With a significant nondirectional test, the investigator knows only that the two groups are different. A very stringently agreed on nondirectional test does not allow the investigator to make statements of a negative or positive effect when inspecting the group means. Some statisticians have proposed a "three-decision procedure." In this procedure, the investigator has three possibilities:

- Do not reject H_0 .
- Reject H_0 in favor of alternatives on one side.
- Reject H_0 in favor of alternatives on the other side.

In this three-decision procedure, however, there are six kinds of possible errors instead of two, with the probabilities of the errors varying. In some cases, the probabilities are small enough to ignore. Some have considered this three-decision procedure to be a composite of two one-tailed tests.

ONE-WAY ANALYSIS OF VARIANCE

One-way analysis of variance is part of the family of tests known as analysis of variance (ANOVA). Typically, it is used to analyze experimental designs in which only one independent variable has been manipulated. Usually, one-way ANOVA is used to test whether differences exist between three or more means; however, it can be applied to situations in which there are only two means to be compared. Although the t test is preferred by many in such situations, the F test produced in one-way ANOVA is a direct function of t , and so it also is a legitimate way to compare two means.

The two types of one-way ANOVA differ in terms of the experimental design to which they are applied. If data representing different levels of an independent variable are independent (i.e., collected from different entities), then a *one-way independent* ANOVA (also called a *between-groups* ANOVA) can be used. When data are related, such as when different entities have provided data for all levels of an independent variable, a *one-way repeated measures* ANOVA (also

called a *within-subjects* ANOVA) can be employed. In both cases, the underlying principal is the same: A test statistic F is calculated that is the ratio of systematic variance (variance explained by the independent variable, that is, the experimental manipulation) to unsystematic variance (variance that cannot be explained, or error). If the observed value exceeds the critical value for a small probability (typically .05), we tend to infer that the model is a significant fit of the observed data or, in the case of experiments, that the experimental manipulation has had a significant effect on performance.

An Example

One study looked at the processes underlying obsessive-compulsive disorder by inducing a negative mood, a positive mood, or no mood in people and then asking them to imagine they were going on holiday and to generate as many things as they could that they should check before they left. The data are in Table 1. Three different groups of people participated in this experiment, each group representing a level of the independent variable, mood: negative mood, positive mood, and no mood induced. These data are independent because they came from different people. The dependent variable was the number of items that needed to be checked.

The starting point for ANOVA is to discover how much variability there is in the observed data. To do this, the difference between each observed data point and the grand mean is calculated. These values are then squared and added together to give us the total sum of squared error (SS_T):

$$SS_T = \sum_{i=1}^n (x_i - \bar{x}_{grand})^2.$$

Alternatively, this value can be calculated from the variance of all observations (the *grand variance*) by multiplying it by the sample size minus 1:

$$SS_T = s^2 (N - 1).$$

Grand Mean = 9.43		Grand Variance = 21.43	

Source: Davey et al. (2003).

Note: \bar{x} = mean; S^2 = variance.

The degrees of freedom for this value are $N - 1$, where N is the total number of observations (in this case, 30). For these data, the total degrees of freedom are 29. For the data in Table 1, we get

$$SS_T = s_{grand}^2 (N - 1) = 21.42(30 - 1) = 621.18.$$

Having established the total variance to be explained, this variance is partitioned into two parts: variance explained by the linear model fitted to the data (expressed as the model sum of squared error, SS_M) and variance that the model cannot explain (expressed as the residual sum of squared error, SS_R). The model sum of squares is the squared difference between the grand mean and the values predicted by the linear model. When analyzing data from groups (i.e., when an experiment has been conducted), the linear model takes the form of the group means. The variance explained by the model is, therefore,

$$SS_M = \sum_{i=1}^k n_i (\bar{x}_i - \bar{x}_{grand})^2,$$

in which k is the number of groups. For the data in Table 1, we would get

$$SS_M = 10(12.60 - 9.43)^2 + 10(7.00 - 9.43)^2 + 10(8.70 - 9.43)^2 = 164.87.$$

The degrees of freedom (df_M) for this sum of squared error are 1 less than the number of parameters estimated: When data from groups are analyzed, this is the number of groups minus 1 (denoted as $k - 1$), in this case 2, and when continuous predictors are used, it is the number of predictors.

Finally, we need to establish the error in the model, or the variance not explained by the model. This is simply the squared difference between the values predicted by the model and the observed values. When analyzing data from groups, the model used is the group means, so we are looking at the squared difference between the observed value and the mean of the group from which that observation came:

$$SS_R = \sum_{i=1}^n \sum_{j=1}^k (x_{ij} - \bar{x}_j)^2.$$

This can be simplified by using the variance within each group (S_j^2) and reexpressing the equation as

$$SS_R = \sum_{j=1}^k s_j^2 (n_j - 1).$$

For the data in Table 1, this gives us

$$\begin{aligned} SS_R &= 36.27(10 - 1) + 8.89(10 - 1) + 5.57(10 - 1) \\ &= 326.43 + 80.01 + 50.13 \\ &= 456.57. \end{aligned}$$

Alternatively, the value can be derived from $SS_R = SS_T - SS_M$ (which gives the same answer to within

rounding error). The degrees of freedom for SS_R (df_R) is the total degrees of freedom minus the degrees of freedom for the model ($df_R = df_T - df_M = 29 - 2 = 27$). Put another way, it is $N - k$ (the total sample size, N , minus the number of groups, k).

SS_M tells us how much variation the model (e.g., the experimental manipulation) explains, and SS_R tells us how much variation is due to extraneous factors. However, because both of these values are summed values, they will be influenced by the number of scores that were summed. To eliminate this bias, we can calculate the average sum of squared error (known as the mean squared error, MS), which is simply the sum of squares divided by the degrees of freedom:

$$MS_M = \frac{SS_M}{df_M} = \frac{164.87}{2} = 82.44$$

$$MS_R = \frac{SS_R}{df_R} = \frac{456.57}{27} = 16.90$$

MS_M represents the average amount of variation explained by the model (e.g., the systematic variation attributable to the experimental manipulation), whereas MS_R is a gauge of the average amount of variation explained by extraneous variables (the unsystematic variation).

The F ratio is a measure of the ratio of the variation explained by the model and the variation explained by unsystematic factors. It can be calculated by dividing the model mean squared error by the residual mean squared error:

$$F = \frac{MS_M}{MS_R} = \frac{82.44}{16.90} = 65.54.$$

The F ratio is, therefore, a measure of the ratio of systematic variation to unsystematic variation, or a comparison of how good the model is compared to how bad it is. In experimental scenarios, it is the ratio of the experimental effect to the individual differences in performance. The observed value of F is compared to critical values of F from a special distribution known as the F distribution with df_M and df_R degrees of freedom, which represents the values of F that can

be expected at certain levels of probability. If this value is significant, then the model is a good fit of the data, or in experimental designs, the independent variable is believed to have had an effect on the dependent variable.

Following Up One-Way ANOVA

ANOVA is an omnibus test and so tells us only that the means of the groups differ from one another. When more than two means have been compared, the F test indicates only whether two or more of those means differ. Therefore, one-way ANOVA is usually followed up either with planned comparisons of specific sets of means or with post hoc tests, which compare all combinations of pairs of means (see, for example, the entries on Bonferroni Test and Newman-Keuls Test).

Assumptions

For the F ratio to be accurate, the following assumptions must be met: (a) Observations should be statistically independent, (b) data should be randomly sampled from the population of interest and measured at an interval level, (c) the outcome variable should be sampled from a normal distribution, and (d) there must be homogeneity of variance.

Differences With Repeated Measures

When data are related (i.e., the independent variable has been manipulated by use of the same entities), the basic logic described above still holds true. The resulting F can be interpreted in the same way, although the partitioning of variance differs somewhat. However, when a repeated measures design is used, the assumption of independence is violated, and this gives rise to an additional assumption of *sphericity*. This assumption requires that the variances of difference scores between conditions be roughly equal. When this assumption is not met, the degrees of freedom associated with the F value must be corrected with one of two estimates of sphericity: the Greenhouse-Geisser estimate or the Huynh-Feldt estimate.

ORDINAL LEVEL OF MEASUREMENT

The ordinal level of measurement refers to measurement in which the distances between observed values are irrelevant and only the order relations of $<$, $>$, and $=$ should be considered.

Consider the Likert-type item common in the social sciences. Typically, such an item consists of a statement that captures the essence of the construct being measured (e.g., depression), followed by adjectives or adjectival response phrases indicating degree of endorsement of the statement. Very often, the adjectival phrases are coded by increasing integer values, an example being 0 = *not at all*, 1 = *a little bit*, 2 = *moderately*, 3 = *a lot*, 4 = *quite a bit*. It is important to realize that considered in isolation (e.g., not in the context of a scaling model), the statements are inexact to the extent that they do not imply distances between them. Equidistant interpretations such as *quite a bit* – *a lot* = *moderately* – *a little bit*, characteristic of interval-level measurement, are not justified. On the other hand, ordinal interpretations such as *not at all* $<$ *quite a bit* are justified. Suppose there is no response error for an item and Respondent A selects *not at all* and Respondent B selects *quite a bit*. Then the empirical ordering with respect to endorsement is Respondent A $<$ Respondent B, which is represented by 0 $<$ 4. The empirical ordering of the respondents is accurately represented by the order relations of the observed values. The representation is limited to the relations

of $<$, $>$, and $=$, because $4 - 3 = 2 - 1$, for example, is not a valid representation for ordinal level of measurement.

An interesting characteristic of the ordinal level of measurement is invariance under any order-preserving transformation such as the natural log transformation. Suppose we obtain the following observed values from five people using our Likert-type item: 1, 2, 2, 3, 4. Ordinal level of measurement dictates that the values of the number are irrelevant and only their order is important. Thus, any other set of numbers with the same order will be an equally valid ordinal representation. For example, taking the natural log of the original values, we obtain 0, .6932, .6932, 1.0986, 1.3863. The log-transformed values look quite different from the original numbers but retain the same ordinal information.

Depending on an analyst's epistemology, the monotonic invariance property may proscribe certain statistical methods for ordinal-level data. Methods such as the Spearman rank correlation coefficient yield invariant results under any monotonic transformation whereas methods such as Pearson's correlation coefficient do not. When one is analyzing ordinal data, it may be desirable to use a statistical method that considers only ordinal relations so that test statistics and p values do not change under order-preserving transformations.

ORTHOGONAL PREDICTORS IN REGRESSION

In multiple regression, a single dependent variable (y , the criterion) is predicted from a number of

independent variables. If there were only a single independent variable (x_1), the regression coefficient b is simply a rescaling of the correlation coefficient r_{xy} (i.e., $b = r_{xy}$). Therefore, r_{xy} can be used to gauge the importance of the single predictor variable. With multiple predictor variables, the correlations among these predictors (i.e., multicollinearity), as well as the correlations of the predictors with the criterion, influence the regression weights. If one is interested only in optimizing the overall fit of the model (i.e., R^2), then the regression coefficients do not require much interpretation. However, understanding the effect of each individual variable is very difficult. It can also be the case that variables significantly correlated with the criterion do not enter the model because another variable is more strongly associated with the criterion and the additional variance explained is insufficient to achieve statistical significance.

One approach to this problem is to conduct a principal component analysis. All dimensions are independent but, unfortunately, hard to interpret with respect to the original variables. Alternatively, the predictor variables can be orthogonalized by means of a transformation so that all predictor variables are uncorrelated with each other, but simultaneously each transformed predictor variable is maximally correlated with the corresponding original variable. If the correlations of the transformed variables with the original predictor variables are high, the results of the orthogonal regression analysis are easy to interpret. The transformation provides variables that are pure in that no variable shares any common variance with any other in the explanatory set. The regression model with the orthogonal predictors is insensitive to the order in which the independent variables are entered into the equation. The explanatory power of each predictor is directly interpretable as the squared criterion correlation.

The transformation of the original variables is obtained from the matrix equation $Z^* = ZR - 1/2$ so that the correlation matrix (R^*) for the orthogonalized predictors in the columns of Z^* is $(Z^*)'Z^* / N = I$ the identity matrix (i.e., indicates orthogonality or 0 correlation), where Z is the 0 mean and standard

deviation of 1 (i.e., z score) matrix of original variables and $R^{-1/2}$ is the square root of the inverse of the correlation matrix R among the original variables. The correlation of the orthogonally transformed predictor variables with the original predictor variables is the square root of the correlation matrix R among the original predictor variables $R^{1/2}$.

The amount of predictable variance accounted for by each predictor variable in orthogonal regression is the correlation between the orthogonalized predictor and the criterion, and the overall fit of the model

(i.e., R^2) is simply the sum of the individual r^2 for each variable in the model.

PAGE'S L TEST

When comparing c populations in randomized complete block designs, researchers are often interested in examining ordered treatment effects among the c groups. The c levels of the treatment are either categorically ordered, as in the treatment condition “undergraduate class designation” with levels “freshman,” “sophomore,” “junior,” and “senior,” or the c levels are numerically ordered, as in the treatment condition “drug dosage” with levels “20mg,” “25mg,” “30mg,” and “35mg.” For situations where the researcher is interested in testing specifically for monotonically increasing or monotonically decreasing treatment effects, and either collects data only in ordinal form or collects data that are either interval- or ratio-scaled but does not desire to make the stringent assumptions necessary for employing a parametric procedure, the nonparametric L test devised by Ellis B. Page in 1963 may be selected.

Development

Let x_{ij} be the observed value under the j th treatment in the i th block (where $j = 1, 2, \dots, c$ and $i = 1, 2, \dots, n$).

In each of the n independent blocks, replace the c observations by their corresponding ranks such that a rank of 1 is given to the smallest observation in the block and a rank of c is given to the largest. Thus, R_{ij} is the rank (from 1 to c) associated with the j th treatment in the i th block.

The layout for the ranked responses from a sample of either n subjects or n blocks of matched subjects over c levels of a treatment condition are shown in Table 1.

Note that under the null hypothesis of no treatment effects, each ranking within a block is equally likely, so there are $c!$ possible rankings within a particular block and $(c!)^n$ possible arrangements of ranks over all n blocks. The sum of the ranks within each block is $c(c + 1)/2$, the sum of the ranks assigned to each of the c treatment levels. If the null hypothesis were perfectly true, the sum of the ranks for each of the c treatment levels would be $n(c + 1)/2$. On the other hand, if the alternative hypothesis is true and there is a perfect ordering in the c rankings among all n subjects, the sum of the ranks for each of the c treatment levels would respectively be $n, 2n, \dots, cn$ if the treatment effects were monotonically increasing, and $cn, (c - 1)n, \dots, n$ if the treatment effects were monotonically decreasing.

Table 1 Data Layout for the Page L Test

Block	Treatments				Totals
	1	2	...	c	
1	R_{11}	R_{12}	...	R_{1c}	$c(c + 1) / 2$
2	R_{21}	R_{22}	...	R_{2c}	$c(c + 1) / 2$
⋮	⋮	⋮	⋮	⋮	⋮
⋮	⋮	⋮	⋮	⋮	⋮
n	R_{n1}	R_{n2}	...	R_{nc}	$c(c + 1) / 2$
Totals	$R_{.1}$	$R_{.2}$...	$R_{.c}$	$nc(c + 1) / 2$

where
 c = the number of treatment levels (i.e., columns)
 n = the number of blocks (i.e., rows of subjects)
 R_{ij} = the rank assigned to the *j*th treatment in the *i*th block
 $R_{.j}$ = the sum of the ranks for treatment level *j*

To develop the Page test statistic *L*, the ranks assigned to each of the *c* treatment levels are totaled over all *n* blocks. That is, $R_{.j} = \sum_{i=1}^n R_{ij}$ is obtained for each of the treatments (where $j = 1, 2, \dots, c$). Page's test statistic *L* is

$$L = \sum_{j=1}^c j \cdot R_{.j}$$

where *j* is the hypothetical "ranking" (1 to smallest and *c* to largest) given to the *j*th treatment based on the alternative hypothesis of ordered treatment levels. Page shows that the test statistic *L* is approximately normally distributed with mean

$$\mu_L = \frac{nc(c + 1)^2}{4}$$

and standard deviation $\sigma_L = \sqrt{\frac{nc^2(c^2 - 1)(c + 1)}{144}}$.

For a nonparametric analysis, M_j represents some location parameter, typically the median of level *j* (where $j = 1, 2, \dots, c$). The Page *L* procedure may be used to test the null hypothesis of no treatment effect

$$H_0 : M_{.1} = M_{.2} = \dots = M_{.c}$$

against either the ordered alternative that a monotonically increasing treatment effect is present

$$H_1 : M_{.1} \leq M_{.2} \leq \dots \leq M_{.c}$$

(with at least one inequality strict)

or against the ordered alternative that a monotonically decreasing treatment effect is present

$$H_1 : M_{.1} \geq M_{.2} \geq \dots \geq M_{.c}$$

(with at least one inequality strict)

Note that the monotonic effects expressed by these two ordered alternative hypotheses are built into the calculation of the Page test statistic *L*, which correlates the hypothesized monotonic ordering of the *c* treatment levels with the sum of the ranks given by the *n* subjects in the *c* treatment levels. Thus, the Page *L* test statistic is related to Spearman's coefficient of rank correlation ρ .

To test the null hypothesis of no differences among the *c* treatment levels against the ordered alternative that differences among treatment levels are monotonically increasing, the decision rule is to reject the null hypothesis at an α level of significance if

$$Z \cong \frac{L - \mu_L}{\sigma_L} = \frac{L - \frac{nc(c + 1)^2}{4}}{\sqrt{\frac{nc^2(c^2 - 1)(c + 1)}{144}}} > Z_{1-\alpha},$$

where $Z_{1-\alpha}$ is the upper-tailed critical value from the standardized normal distribution. On the other hand, to test against monotonically decreasing treatment effects, the decision rule is to reject the null hypothesis at an α level of significance if $Z < Z_\alpha$ where Z_α is the lower-tailed critical value from the standardized normal distribution.

Applying Page's L Test

The following hypothetical example is based on a behavioral investigation of visual pattern recognition. The practical ramifications of the actual physiological research are in advertising and communications theory.

Suppose 10 subjects placed in front of a monitor are each presented with a single numerical digit (0–9) for a variable on-time of 10, 14, 18, or 22 milliseconds, immediately followed by the presentation of a randomly selected masking noise field that, for one-half second, may confound what digits the subjects had been shown. A computer program randomly generates the order in which the numerical digits appear as well as the particular on-time treatment level until 20 trials of each combination of digit and on-time level are observed by each subject. Based on this randomization process, each subject is given different sequences of digit and on-time level combinations until he or she completes the experiment.

To investigate the effects of different on-time levels on the percentage of correct responses, a randomized complete block design with but one observation per cell is used. The observation in each cell, x_{ij} , corresponds to the percentage of correct responses out of 200 trials under the j th on-time treatment level by the i th subject (where $j = 1, 2, \dots, c = 4$ and $i = 1, 2, \dots, n = 10$).

Given these different numerical on-time levels, it may be of primary interest for the researcher to test for ordered treatment effects. Transforming each subject's percentage of correct responses across the four treatment levels into ranks, the Page *L* test can be employed.

The original data values x_{ij} along with the transformed ranks R_{ij} are displayed in Table 2.

To test the null hypothesis of no treatment effect (that is, each of the four on-time levels results in similar pattern recognition abilities across subjects, and any observed differences are due to chance),

$$H_0 : M_{.1} = M_{.2} = M_{.3} = M_{.4}$$

against the ordered alternative that a monotonically increasing treatment effect is present

$$H_1 : M_{.1} \leq M_{.2} \leq M_{.3} \leq M_{.4}$$

(with at least one inequality strict)

the Page *L* procedure may be used. From the rank sums over the j treatment levels in Table 2, the Page *L* statistic is computed as follows:

$$L = \sum_{j=1}^c j \cdot R_{.j}$$

$$= (1)(20) + (2)(21) + (3)(25) + (4)(34)$$

$$= 273.$$

Moreover,

$$\mu_L = \frac{nc(c+1)^2}{4} = \frac{(10)(4)(5^2)}{4} = 250$$

and

$$\sigma_L = \sqrt{\frac{nc^2(c^2-1)(c+1)}{144}}$$

$$= \sqrt{\frac{(10)(4^2)(4^2-1)(5)}{144}}$$

$$= 9.129.$$

To perform the Page *L* test,

$$Z \cong \frac{L - \mu_L}{\sigma_L} = \frac{273 - 250}{9.129} = 2.52.$$

Using a .05 level of significance, given that $Z = 2.52 > Z_{.95} = 1.645$, the upper-tail critical value from the standardized normal distribution, the null hypothesis is rejected. A significant ordered treatment effect is present. The p value for Page's *L* test is 0.0059.

Discussion

In order to examine a set of c ordinal responses pertaining to the levels of some treatment condition provided either by a sample of subjects used as their own controls to make these assessments or by a sample of c matched subjects randomly assigned to each treatment level as members of a block, in 1937 the economist Milton Friedman developed a non-parametric competitor of the two-way randomized block *F* test. This test should be useful for testing against general alternatives when the data collected are only ordinal or when the researcher does not desire to make the more stringent assumptions underlying the classical parametric ANOVA procedure.

When employing the Friedman test, a rejection of the null hypothesis of no differences in the c treatment levels leads to the generalized conclusion that a treatment effect is present. This implies that at least one of the groups is different from another group or from all other groups. Owing to the general nature of the conclusions that would be drawn, it becomes imperative for the researcher to employ a posteriori an appropriate multiple comparisons procedure in order to determine where the actual significant differences in the treatment levels are.

The Page *L* test is, in a sense, a nonparametric extension of the more general Friedman test. If interest centers on global or generalized findings, the Friedman should be selected. However, if the treatment levels are ordered and interest is in monotonic effects, the Page *L* test is much preferred.

Comment: The Impact of Testing for Ordered Alternatives

It is essential to a good data analysis that the appropriate statistical procedure be applied to a specific situation. If the Friedman test were used on the data

displayed in Table 2, the null hypothesis of no differences in treatment effects

$$H_0 : M_{.1} = M_{.2} = \dots = M_{.c}$$

would be tested against the more general alternative

$$H_1 : \text{Not all } M_j \text{ are equal (where } j = 1, 2, \dots, c).$$

From Table 2, it is observed that $n = 10$, $c = 4$, and the rank sums for the four treatment levels are 20, 21, 25, and 34, respectively.

For these data, the Friedman test statistic $T = 7.32 < \chi^2_{0.05, (c-1=3)} = 7.815$, the upper-tailed critical value under the chi-square distribution with 3 degrees of freedom. Thus, it is important to note that in using a .05 level of significance, the null hypothesis is not rejected. The Friedman test fails to detect a significant treatment effect, and no a posteriori analysis on the $c = 4$ levels can be undertaken. The p value for the Friedman test is 0.0624.

Conclusions

The Page *L* test is quick and easy to perform. The only assumptions are that either the n subjects providing the repeated measurements (i.e., the ranks) across the c treatment levels are independently and randomly selected, or the n blocks of homogeneous subjects examining the c treatment levels are independently and randomly selected.

When evaluating the worth of a statistical procedure, statistician John Tukey defined "practical power" as the product of statistical power and the utility of the statistical technique. Based on this, the Page *L* test enjoys a very high level of practical power under many useful circumstances. Although some competing tests may provide slightly more statistical power than the Page *L* test, no other test of this type can match its distinct simplicity and computational ease.

PAIRED SAMPLES *t* TEST (DEPENDENT SAMPLES *t* TEST)

Paired samples *t* test, also known as dependent samples *t* test, is used when there are two groups to compare, wherein the scores in one group are linked or paired with scores in the other group. In this situation, the assumption of independence has been violated, so an independent *t* test cannot be used.

An example of when to use a paired samples *t* test is a study examining happiness of twins (based on a survey with a composite score ranging from 1 to 100), with both twins involved in the study. Because the scores are paired or dependent (each twin's score is related to the other twin's score), these data would be analyzed using a paired samples *t* test. This is the best choice of statistic to use because the scores from one twin are linked, or might be similar, to the scores from the other twin.

Another example of when it would be appropriate to use the paired samples *t* test is with repeated measures. For example, to understand if a teaching method is effective, a pretest could be given on the first day of class and then again on the last day of class. The scores from these tests (the data) would be considered linked for each student. Therefore, in the case of repeated measures with two sets of scores, the paired samples *t* test would be an appropriate choice for a statistic.

Table 1 shows an example of data that would be appropriate on which to use the paired samples *t* test. The first variable is “twin 1 happiness scores” and the

second variable is “twin 2 happiness scores.” Happiness is measured on a scale of 1 to 100, where 1 is very unhappy and 100 is extremely happy.

Assumption of the Paired Samples *t* Test

There is one important assumption or condition for the paired samples *t* test: The variables should be normally distributed. This can be tested with a computer program such as SPSS with the skewness and kurtosis values with the Explore command. A graphical representation of the normal distribution can be obtained through the Q-Q plot.

If the assumption of normality is not met, the Signed Rank Test should be computed instead.

Research Hypothesis

The null hypothesis analyzed with the paired samples *t* test is similar to the hypothesis used with the independent samples *t* test:

$$H_0 : \mu_1 = \mu_2$$

This hypothesis is testing that the means are equal. The alternative hypothesis would be that the means are not equal:

$$H_a : \mu_1 \neq \mu_2.$$

Computing the Value for the Paired Samples *t* Test

The formula for the paired samples *t* test is as follows:

$$t = \frac{\bar{X} - \bar{Y}}{s_{\bar{D}}}$$

where \bar{X} is the mean for the first variable and \bar{Y} is the mean for the second variable. The denominator, $s_{\bar{D}}$ is the standard error of the difference between the means. It is calculated with the following formula:

$$s_{\bar{D}} = \frac{s_D}{\sqrt{N}}, \text{ where } s_D = \sqrt{\frac{\sum D^2 - \frac{(\sum D)^2}{N}}{N - 1}}$$

The $s_{\bar{D}}$ is the standard error of the difference between the means. The s_D is the standard deviation of the difference between the means, the D is the difference between each paired score ($X - Y$), and N is the number of paired scores.

Using the Computer to Compute the Value

The data used in the above example were entered into SPSS. To check whether the data for each variable are normally distributed, the skewness values can be computed through the Explore command and the Q-Q plot can be generated in the computer program SPSS. The output is in Figures 1 and 2.

Next, the paired samples *t* test is computed with the Paired Samples *t* Test command found under Compare Means. The output is in Figure 3. As shown in the last table of the output, there is a statistically significant difference between the twins' happiness scores, $t(9) = -2.44, p = .037, d = .77$. By examining the means in the first table, we see that Twin 2 has a higher

mean happiness score ($M = 69.70$) than Twin 1 ($M = 66.60$). The effect size is calculated by $d = \frac{Mean}{SD}$, where the *Mean* is the paired differences mean and *SD* is the paired differences standard deviation. Thus, for this example, $d = \frac{3.1}{4.012} = .77$.

There are advantages to using dependent samples. Dependent samples tend to reduce the effects of variability between the elements in a sample that can confound the results. For example, suppose the sample obtained is an independent sample of students, one group of students who took a course and one group who did not. One of the students who did not take the course has an extremely high score. If we examine the sample means of the scores for each group, this student's score might distort the results, thus making the sample mean for the students who have not taken the course unrealistically high. Dependent samples

would create a different situation. In this example, the data would include a “before the course” and “after the course” score for each student. If one student in the study scores high, this should appear in both samples and therefore will not distort just one of the samples. In other words, things would balance out. Thus, the effects of variability among the participants in the sample will be reduced.

Whereas some studies involve using the same group of individuals with measurements recorded before and after some intervening treatment, some other studies use naturally occurring pairs by matching on factors with an effect that might otherwise obscure differences (or the lack of them) between the two populations of interest. Paired samples often provide more information than would independent samples because extraneous effects are ruled out. It is important to remember that the matching needs to be

PAIRWISE COMPARISONS

For psychological variables, the operations of addition and multiplication—and therefore most elementary statistics—cannot be applied to scales that are constructed from pairwise comparison data. Pairwise comparisons may be used to construct ordinal scales, but because the operations of addition and multiplication are not applicable to ordinal data, the construction of scales from ordinal data is problematic, especially in the multicriteria and multiple decision makers cases. In those cases where the construction of ordinal scales is possible, the operations of addition and multiplication are not applicable to scale values.

Operations on Scale Values

The application of elementary statistics—such as standard deviation—to scale values requires the availability of the operations of addition and multiplication as well as order and the limit operation of calculus. Psychological variables to which addition, multiplication, order, and the limit operation are applicable must be modeled in the same manner—and for the same mathematical reasons—as such familiar physical

variables as *time*, *position* of points on a straight line, *potential energy*, and *temperature* on the Fahrenheit or Celsius (but not Kelvin) scales.

Reference Objects

The building blocks for such scales require three or four rather than two objects. Consider, for example, the statement that the temperature of a certain object is 100 degrees on the Fahrenheit scale. As can be seen in Figure 1, this statement involves three empirical objects, three mathematical objects, and three correspondences: The empirical objects are freezing water, boiling water, and the object under measurement; the mathematical objects are the numbers 32, 100, and 212; and the correspondences are the assignments of the temperatures—{freezing water, 32}, {object under measurement, 100}, and {boiling water, 212}. It should be noted that this statement requires two empirical reference objects (freezing water and boiling water) and two corresponding mathematical reference objects (the numbers 32 and 212).

Removing one of these empirical reference objects and its corresponding mathematical reference object results in an ordinal pairwise comparison where neither differences nor ratios are defined. If both empirical reference objects are removed and the numerical ones are not, the statement “on a scale of 32 to 212, an object scores 100” is obtained. Statements of this form, such as the common phrase “on a scale of 1 to 10, an object scores 7,” have no mathematical meaning. No mathematical operations or statistics are applicable to numbers produced from such statements.

Figure 1 Example of Scale Values and Reference Objects

Ratios

Ratios of the type T_1/T_2 have become defined for *temperature* only after it has been established that temperature has an absolute zero. Conversely, for variables where the existence of an absolute zero has not been established, such ratios are undefined. For example, for *time*, the ratio t_1/t_2 where t_1 and t_2 are two points in time is undefined, whereas the ratio of two *time differences*, (i.e., time periods or time intervals) $(\Delta t)_1/(\Delta t)_2$, is well-defined. It follows that the ratio v_1/v_2 is undefined for any psychological variable because the existence of an absolute zero has not been established for such variables. In particular, decision methodologies such as the Analytic Hierarchy Process that depend on data in the form of ratios of preferences are not valid methodologies. In general, a ratio of differences depends on four points, but this ratio may depend on three variables rather than four when two of the four points are identical. Although the number of variables in this expression can be reduced from four to three, it cannot be further reduced to a pairwise comparison.

Ordinal Comparisons

Pairwise comparisons are applicable to ordinal data, but the operations of addition and multiplication and the concepts of cancellation and trade-off do not apply to ordinal scales. For example, ordinal methodologies ignore the question “By how much is Object A preferred to B?” because the concepts of *difference*, *slight difference*, *large difference*, or “*twice as preferable*” are inapplicable in the ordinal case.

Mathematical Structure

In technical terms, in the case of physical or mathematical variables, for addition, multiplication, order, and limits to be applicable, the measured objects must correspond to scalars in the ordered complete field of real numbers, to vectors in a one-dimensional vector space over this field, or to points in a one-dimensional affine space over the real numbers. The zero vector in a vector space is an absolute zero because it is a fixed point of the automorphisms of the space. For psychological variables where the existence of an absolute zero is not established, the only possibility for addition,

multiplication, order, and limits to be applicable is the model where the measured objects correspond to points in a one-dimensional affine space over the ordered real numbers. In such a space, the ratio of two points is undefined, whereas their difference is a vector and the ratio of two vectors is a scalar.

PARALLEL COORDINATE PLOTS

Parallel coordinate plots were first introduced by Inselberg and by Wegman. The main idea of parallel coordinate plots is to switch from Cartesian coordinates, where points are plotted along orthogonal axes,

Note: Left line translates to the common intersection point on the right.

to a projective geometry, where axes are plotted side by side.

Figures 1 and 2 show this principle for three data points in two and three dimensions. On the left-hand side of Figure 1, the scatterplot shows the three points (2, 8), (7, 7), and (8, 2) plotted as +, x, and o, respectively. The same data points are plotted on the right-hand side: The first observation (2,8) is shown by first putting a “+” at the 2 of the x-axis, then a “+” at the value 8 of the y-axis. Both of these markers are then connected by a line. This way, each observation corresponds to a single line.

The advantage of this approach becomes visible in Figure 2. Measurements in a third variable are added to our previous example. Although we would need interactive tools, such as rotation, to be able to see the

relationship between the three points in the three-dimensional scatterplot on the left, the parallel coordinate plot on the right is extended naturally to three dimensions by putting another axis alongside the other two, drawing markers for each of the measurements and connecting them by lines to the corresponding values of the neighboring axis.

Obviously, this principle is applicable far beyond the (usually up to three) dimensions of Cartesian displays.

The disadvantage of parallel coordinate plots is that we lose our familiar coordinate system. Because the two systems show the same information, it is a matter of a little practice to get used to the new coordinate system.

Properties

The basic properties of a principal coordinate plot are based on the duality between projective and Euclidean geometry: Points in one system correspond to lines in the other. The scatterplot on the left-hand side of Figure 3 shows 10 data points on a straight line. The same points are shown in the parallel coordinate plot on the right. All 10 lines meet in the same point, indicating the linear relationship.

Example

Parallel coordinate plots are used mostly to find and explore high-dimensional clusters in data. Figure 4

Figure 5 Two Different Classes of Forgeries

Note: The two classes of forgeries (marked in dark grey and black, respectively) are visible in the Swiss bank note data set. Marked in white is another bill. From its measurements it fits very well into the smaller group of forged bills. It was classified as genuine by the bank, however.

shows a parallel coordinate plot of the Swiss bank note data set by Flury and Riedwyl. Measurements of 100 genuine and 100 forged Swiss bank notes were taken, with the goal of identifying forgeries. Six different measurements are available to us: the horizontal length of a bill at the top (Length), left and right vertical width (Lwidth, Rwidth), vertical width of the margin at center bottom (Bmargin) and center top (Tmargin), as well as the diagonal length of the image on the bill. Marked in grey are genuine bills. From the parallel coordinate plot, we can see that the forged bills tended to have larger margins at the bottom and top, and the diagonal length of the image seemed to be smaller than those measurements of genuine bills.

Among the forgeries, we can find a “knot” between the axes BMargin and Tmargin, indicating a negative linear relationship between bottom and top margin. What is strange, though, is a very tiny second knot among the forgeries between the same axes a little bit further down closer to the genuine bills. The smaller knot is marked in black in Figure 5. The two knots clearly identify two different types of forged bills. Marked by the unfilled circle on the left and the white line on the right of Figure 5 is another bill, classified as genuine; from its overall measurements, it seems to fit into the second class of forgeries very well.

PARALLEL FORMS RELIABILITY

All observations and all measurements contain error. The focus of much work in measurement is to minimize and estimate the amount of error in any given measurement. In classical test theory, X is an observed score that is composed of T , the true score, and E , the error score: $X = T + E$. The true score is never known, but can be thought of as the long-range average of scores from a single instrument administered to an individual an infinite number of times (the expected value or expected score). The error score is random and may have many sources, including testing conditions, individual characteristics that fluctuate from administration to administration, differences in forms, or instability of an individual's ability or trait over time.

This random error score is quite different from systematic sources of error, like testwiseness, which may systematically increase an individual's score on each administration. Because testwiseness is systematic or constant, it finds its way into the true score and creates problems regarding validity, in that the trait being measured inadvertently may be influenced by testwiseness. Random error, because it varies randomly, influences the consistency of scores, but not the expected value of a score (the true score), and thus influences reliability, not validity.

Theoretically, we can estimate the amount of error if we know how much of a given score is due to errors of measurement. If we were able to test a single person repeatedly without the effects of recall and fatigue, variation in his or her scores would be considered measurement error. If there was no measurement error, he or she would get the same score on each administration. Because it is not possible to test individuals repeatedly without the interference of recall and fatigue, we employ groups to estimate measurement error variance. This allows us to estimate the standard error of measurement, the typical amount of measurement error in a set of scores.

If we take the classical test theory model of scores and consider groups of scores and their variances, we see that the variance of the observed scores equals the sum of the variance of true scores and the variance of error scores: $S_X^2 = S_T^2 + S_E^2$ (in sample notation).

This is the long way of introducing the need for reliability; reliability is a tool used to estimate the standard error of measurement, but it also has some intrinsic benefits in and of itself. Theoretically, reliability is considered the correlation between scores on two parallel forms of a test. The idea is that if there is no measurement error at work, scores from two parallel forms administered to the same group of individuals should be perfectly correlated—each individual should obtain the same score. It can be shown that the correlation between two parallel forms of a test is equal to the ratio of true score variance to observed score variance—the proportion of variance in observed scores that is due to true individual differences: $r_{tt} = \frac{S_T^2}{S_X^2}$. This reliability coefficient then can be used in estimation of the standard error of measurement, because it tells us the proportion of observed variance that is true variance; the standard error of measurement is a function of the proportion of observed variance that is true variance.

Estimating Reliability

Based on the classical test theory conception of reliability, scores are reliable to the extent that individuals' scores remain constant on repeated measurements. One way to estimate the degree of consistency of scores is to employ parallel forms—two or more forms of a measurement instrument that are built to the same specifications in terms of the content domain or construct definition. Each form provides a separate sample from the domain.

This form of reliability is best estimated when the actual measurement procedure employs multiple forms, because if scores vary between forms for a single individual, we are likely to attribute this to differences in content—error results from item or content sampling error. This is typically done by administering two forms to each individual during the same administration time. To avoid order effects, subjects can be randomly assigned one form first and the other

second. The scores resulting from the two forms are then correlated; this correlation is the parallel forms reliability coefficient.

Formal Conditions for Parallel Forms Reliability

Parallel forms reliability is estimated from the administration of two forms simultaneously. This is appropriate when the measurement procedure includes multiple forms or when the inference from scores is based on the ability to generalize in terms of the items selected for a given form. Knowledge of parallel form reliability allows one to generalize from one sample of items to a larger domain of items. To be a coefficient of reliability, the parallel forms should be built to the same content specifications and have equal means, variances, and item intercorrelations.

This form of reliability is also called alternate forms reliability or the coefficient of equivalence. This form of reliability can be estimated from forms that are parallel or equivalent, where equivalent forms are similar in content but not statistical quality. Note that if scores are uniformly different between two forms by a constant (perhaps because one test is more difficult than the other), the correlation between two scores is potentially perfect (1.0). This does not mean that the measures are exchangeable in any practical sense; such tests are often equated to adjust for differences in difficulty. In this context, the parallel conditions of the forms have not been met (form means are not equal), and the reliability coefficient or resulting correlation is more difficult to interpret.

General Issues Regarding Reliability

Because the parallel forms estimate of reliability is based on a correlation, it is not simply a characteristic of the measurement instrument itself. Score variability directly influences correlations, such that all else being equal, the more score variance present, the higher the correlation and thus the higher the reliability. Correlational forms of reliability are sample specific and thus not necessarily generalizable to other samples. They do, however, provide an estimate of score consistency for the scores at hand.

In any estimate of reliability, conditions present during the specific administration of the measurement instrument can affect performance and scores in random ways, leading to lower consistency of scores and lower reliability. Each type of reliability estimate (e.g., parallel forms reliability) also captures a specific form of random error. The parallel forms reliability primarily captures measurement error due to sampling items from a domain, a form of sampling error. If this source of error is important to estimate given the measurement procedure (because multiple forms are used and we assume they are equivalent random samples of the domain), then it is an appropriate form of reliability. Technically speaking, an estimate of reliability should be obtained for each set of scores because any one estimate is sample specific, and the argument of generalizability across samples is difficult to make.

Finally, because sampling error is a function of sample size, all else being equal, longer forms will yield higher reliability coefficients. Better, larger samples of items from the domain will reduce the likelihood that two forms differ in their ability to cover the domain. There is a functional relation between form length and reliability that is represented by the Spearman-Brown prophecy formula.

PARAMETER

A parameter is a characteristic that describes the elements in a population. It represents a collective

measure that summarizes the data elements, which comprise the population. Such measures may indicate the central tendency, dispersion or variability, symmetry, or the degree of peakedness in the distribution of the data points in the population. Because a parameter is always associated with a population, it is vital to define the population first.

Population

A population is the set of all items possessing a characteristic of interest, as defined by the problem. Suppose the objective is to study the distribution of income of all working people in a given state. The population in this case is the set of all working people (with an income) in the chosen state.

Parameter Examples

In relation to the population of all working people in the selected state, a parameter that represents the central tendency of the income distribution could be the mean income or the median income. Typically, parameters are denoted by Greek letters. For example, the mean income of all working people in the chosen state could be \$40,000, which would be represented by μ .

Another example of a parameter that represents the variability in the income could be the range. The population range is defined as the difference between the maximum and minimum value, when all elements in the population are considered. Hence, the population range could be \$500,000, a measure that depicts the spread in the population values.

Note that in order to come up with the value of the parameter (i.e., population mean μ), one needs to take into consideration each and every data point in the population. Sometimes, this may be a time-consuming and costly process, as it may be accomplished only through a census. The population mean is calculated as follows:

$$\mu = \frac{\sum_{i=1}^N X_i}{N},$$

where

X_i denotes the value of the i th element in the population;

Σ , the Greek letter sigma, is the summation sign, which directs us to add the value of all the elements (1, 2, . . . , N) in the population;

N represents the total number of elements in the population, and is also known as the population size.

Differences Between Parameter and Statistic

Whereas a parameter represents a characteristic of a population, a statistic represents a characteristic of a sample chosen from the defined population. The value of a parameter remains constant, for a static problem, whereas the value of a statistic may change from sample to sample.

Consider the previously defined problem of income distribution of working people in a state for the month of September 2005. Suppose there were 5,000 working people during that month. The population mean, μ , would be the average income of all 5,000 people for that month, which would be a constant value. On the other hand, if a random sample of 500 people is selected from the population, and the average income of those in the sample is calculated, it would be a statistic. The sample mean, \bar{X} , a statistic, could be \$38,000, which necessarily may not equal the value of the corresponding parameter, μ . Furthermore, the value of the sample mean will usually change from sample to sample.

In practice, because a census is not always feasible, a sample statistic is used to estimate the value of a corresponding population parameter. Thus, the sample mean, \bar{X} , serves as an estimator of the population mean, μ .

PARAMETER INVARIANCE

According to *Webster's New Universal Unabridged Dictionary*, *invariant* simply means “constant,” and, in mathematics more specifically, “a quantity or expression that is constant throughout a certain range of conditions” (p. 1003). Furthermore, a *parameter* in a statistical model is an explicit component of a mathematical model that has a value in one or multiple populations of interest; its value is estimated with a certain estimation routine based on sample data to calibrate the model. Therefore, *parameter invariance* simply means that a certain parameter in a certain statistical model is constant across different measurement conditions such as examinee subgroups, time points, or contexts.

From a decision-making viewpoint, parameter invariance is a desirable characteristic of a statistical model, because it implies that identical statistical decisions can be made across different measurement conditions. In this sense, parameter invariance is one of the preconditions for the generalizability of inferences.

Four aspects of parameter invariance warrant a separate highlighting because they are easily overlooked by practitioners. First, parameter invariance is an abstract ideal state, because parameters are either invariant or not. If a parameter varies across measurement conditions, then a *lack of invariance* is present, which is a continuum of differing values. However, it is always open to debate and secondary assessment whether the difference between parameter values across conditions affects practical decision making. Second, parameter invariance is always tied to a specific statistical model that contains parameters as elements. Therefore, the issue of whether parameters are invariant cannot be answered abstractly without reference to a certain statistical model. Third, parameter invariance implies a comparison of parameter values

across measurement conditions, making discussions about invariance without a reference frame for what constitutes different conditions similarly irrelevant.

The Mathematical Formalization of Parameter Invariance

In the psychometric literature, particularly in the area of confirmatory factor analysis, parameter invariance has had a long tradition, and important groundwork was laid in the middle of the previous century. In the early 1990s, when models in Item Response Theory (IRT) became more popular and accessible, the work of Meredith and colleagues expanded the rich basis of work by Jöreskog and McDonald. At the end of the 1990s, procedures for assessing parameter invariance had become fully integrated into many software programs for latent variable models, such as BILOG-MG, Mplus, LISREL, or AMOS.

Today, parameter invariance has also become fully conceptually integrated into comprehensive and unifying treatments of modeling frameworks in the area of psychometrics and, sometimes, does not appear to have any particular importance for authors that merits a treatment in separate chapters or even books.

Methodological Approaches for Assessing Parameter Invariance

The following common approaches are organized by the type of comparison that is being done (i.e., across subgroups of items, persons, or time points). Moreover, this entry will focus on parameter invariance for psychometric assessment as it is investigated with both observed- and latent-variable models. Although the issue of what constitutes a latent variable is complex itself, for the purpose of this entry, latent variable models are defined as statistical models that contain continuous or discrete unobservable variables whose values are estimated with a specific algorithm.

Parameter Invariance Across Items

In classical test theory (CTT), the total test score is used to rank-order examinees or to make mastery

decisions about them, and its value typically gets supplemented with information about its precision at different score levels. Moreover, measurement models can be specified in terms of how the true scores of different items are related to each other and how error variances are related to one another (e.g., parallel items, τ -equivalent items, congeneric items). Within the framework of structural equation modeling (SEM), the assumptions that these different measurement models postulate about the true score relationship, error variances, and covariances can be estimated today. The added analytical power, however, comes at the price of requiring data structures that make the estimation of such models computationally feasible.

Parameter Invariance Across Examinee Subgroups

The most common setup for investigating parameter invariance is one where the properties of an assessment instrument are compared for different subgroups of examinees such as different ethnic or gender groups. It is important to highlight that the definition of these groups is by no means “natural” in any common sense of the term; rather, it is typically driven by either legislative or theoretical needs. Alternatively, one can view the problem of which groups to compare as an empirical one such that the grouping structure should be data driven. In this case, one works within the area of latent class models, where models such as a mixture Rasch model are employed. Of course, additional parameters such as group membership proportions get estimated along the way, but if the same measurement model is postulated across groups, the core of the model is concerned with parameter invariance.

If parameters for individual items are investigated for invariance, such research is more commonly known under the label *differential item functioning* (DIF); for sets of items (i.e., item bundles or testlets), such research is known under the labels *differential bundle functioning* (DBF) and *differential test functioning* (DTF), respectively. A wide range of techniques for assessing DIF have been proposed, some of

which condition on manifest variables such as the observed total score, whereas others condition on latent variables such as θ in an IRT model.

The first class of models includes procedures such as the traditional Mantel-Haenszel χ^2 statistic, loglinear models, logistic regression models, and discriminant function analysis models. The second class of models leads to a variety of approaches that compare, for example, the area between item response curves for dichotomous and polytomous scoring models or compute an adjusted weighted difference in proportions of examinees at different score levels, as in the SIBTEST, Poly-SIBTEST, and MULTISIB packages.

Common to all of the procedures is that a variety of decisions have to be made to implement them in practice. Specifically, examinees need to be matched on a criterion so that the performance of the different groups of interest can be conducted for people with identical characteristics on the construct that is to be measured. This matching criterion can be internal (e.g., observed total score or estimated latent variable score) or external (e.g., intelligence score, secondary test score). Furthermore, if it is internal, a decision has to be made about whether items that hold the potential for a lack of invariance should be included or excluded in the computation of the criterion because they may potentially contaminate its value; multiple procedures for purifying internal criteria exist.

An important distinction is made between bias and impact, uniform, nonuniform, and crossing lack of invariance, as well as item-, bundle-, and test-level lack of invariance. The first distinction between bias and impact allows one to distinguish between undesirable psychometric properties of the items (i.e., bias) and true average differences in abilities between the subgroups of interest (i.e., impact). This intuitively appealing and necessary distinction became more properly formalized in the research program of William Stout and colleagues, which is based on non-parametric IRT. The second distinction is best understood in the context of IRT or logistic regression analyses because smooth response curves can be considered. Here, uniform effects manifest themselves in parallel curves, nonuniform effects in curves that are

nonparallel but do not cross, and crossing effects in curves that do cross. The practical relevance of this is that, in the case of a set of curves that crosses, different groups are proportionally disadvantaged in different ranges of the score continuum, whereas otherwise, the effects always favor one or multiple groups over others. The third distinction between item- and test-level effects underscores that an item-level lack of invariance may be present that could either augment or vanish at higher levels, such as bundles or the test. This can result in the fact that effects of differing magnitudes are detected at the item level but may not affect practical decision making when sum scores are used if they cancel out; in practice, different levels of effects should be investigated.

Because of the multitude of methodological choices that are available to the practitioner, it can be difficult to synthesize results from various DIF studies. Moreover, the current literature has augmented the demands on researchers to go beyond empirically and rationally justifiable lack-of-invariance detection to provide potential explanations for its causes. In this respect, the use of variables that operationalize components of cognitive response processes to items may prove fruitful but are just beginning to be joined with lack-of-invariance analyses. Their use, along with the use of other noncognitive predictor variables, can be integrated eloquently into hierarchical logistic regression models.

If one integrates cognitive predictor variables into cognitive psychometric models, these parameters are also subject to an investigation of invariance. For some models, such as the DINA or the NIDA model, the linear logistic test model, as well as the rule-space methodology, these parameters are provided a priori by specialists so that the issue of parameter invariance can be resolved primarily theoretically. For other models, such as the reparameterized unified model, decisions about parameter inclusion and exclusion are made empirically so that the issue of parameter invariance should now be resolved through a synthesis of theoretical and empirical findings. How this can be accomplished in practice and whether a parameter invariance perspective is at all called for, is not yet agreed upon at this time.

Invariance Across Time Points

Less common, but equally important for large-scale testing companies in particular, is an investigation of parameter invariance over time. Due to the fact that a separate time point can be viewed abstractly as a mechanism that induces another grouping structure, many of the methods in the previous section for DIF, DBF, or DTF can be applied for this purpose with sometimes only minor modifications or, perhaps, even no modifications at all. However, the assessment of a lack of invariance in longitudinal models gets more complex when the models themselves get more complex. For example, in nonlinear growth models, some assumptions about a lack of invariance manifest themselves in very subtle parameter differences and, in some instances, may not be detectable with current software programs because of identification problems.

Conclusions

In conclusion, a lack of parameter invariance is somewhat of a paradox. It is simple to understand conceptually, but challenging to assess practically. Furthermore, even though methods for its assessment are either direct or slightly modified applications of existing statistical routines—with the exception of a few selected cases—understanding its nature, its directionality and the magnitude of its effects, and its potential causes is a challenging endeavor. But it is an indispensable endeavor to ascertain, from both empirical and rational perspectives, the validity of inferences about examinees and assessment instruments and the degree to which they are generalizable across measurement conditions.

PART AND PARTIAL CORRELATIONS

The semi-partial regression coefficient—also called part correlation—is used to express the specific portion of variance explained by a given independent variable in a multiple linear regression (MLR) analysis. It can be obtained as the correlation between the dependent variable and the residual of the prediction of one independent variable by the other ones. The semi-partial coefficient of correlation is used mainly in nonorthogonal multiple linear regression to assess the *specific* effect of each independent variable on the dependent variable.

The partial coefficient of correlation is designed to eliminate the effect of one variable on two other variables when assessing the correlation between these two variables. It can be computed as the correlation between the residuals of the prediction of these two variables by the first variable.

Multiple Regression Framework

In MLR, the goal is to predict, knowing the measurements collected on N subjects, a dependent variable Y from a set of K independent variables denoted

$$\{X_1, \dots, X_k, \dots, X_K\}. \quad (1)$$

We denote by \mathbf{X} the $N \times (K + 1)$ augmented matrix collecting the data for the independent variables (this matrix is called augmented because the first column is composed only of ones), and by \mathbf{y} the $N \times 1$ vector of observations for the dependent variable. These two matrices have the following structure:

$$\mathbf{X} = \begin{bmatrix} 1 & x_{1,1} & \cdots & x_{1,k} & \cdots & x_{1,K} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 1 & x_{n,1} & \cdots & x_{n,k} & \cdots & x_{n,K} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 1 & x_{N,1} & \cdots & x_{N,k} & \cdots & x_{N,K} \end{bmatrix} \text{ and } \mathbf{y} = \begin{bmatrix} y_1 \\ \vdots \\ y_n \\ \vdots \\ y_N \end{bmatrix}. \quad (2)$$

The predicted values of the dependent variable \hat{Y} are collected in a vector denoted $\hat{\mathbf{y}}$ and are obtained using MLR as

$$\mathbf{y} = \mathbf{X}\mathbf{b} \quad \text{with} \quad \mathbf{b} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y}. \quad (3)$$

The quality of the prediction is evaluated by computing the multiple coefficient of correlation, denoted $R^2_{Y,1,\dots,K}$. This coefficient is equal to the coefficient of correlation between the dependent variable (Y) and the predicted dependent variable (\hat{Y}).

Partial Regression Coefficient as Increment in Explained Variance

When the independent variables are pairwise orthogonal, the importance of each of them in the regression is assessed by computing the squared coefficient of

correlation between each of the independent variables and the dependent variable. The sum of these squared coefficients of correlation is equal to the squared multiple coefficient of correlation. When the independent variables are correlated, this strategy *overestimates* the contribution of each variable because the variance that they share is counted several times; and therefore, the sum of the squared coefficients of correlation is not equal to the multiple coefficient of correlation anymore. In order to assess the importance of a particular independent variable, the partial regression coefficient evaluates the *specific* proportion of variance explained by this independent variable. This is obtained by computing the increment in the multiple coefficient of correlation obtained when the independent variable is added to the other variables.

For example, consider the data given in Table 1, where the dependent variable is to be predicted from the independent variables X and T . The prediction equation (using Equation 3) is

$$\hat{Y} = 1.67 + X + 9.50T; \quad (4)$$

it gives a multiple coefficient of correlation of $R_{Y,XT}^2 = .9866$. The coefficient of correlation between X and T is equal to $r_{XT} = .7500$, between X and Y is equal to $r_{YX} = .8028$, and between T and Y is equal to $r_{YT} = .9890$. The squared partial regression coefficient between X and Y is computed as

$$r_{YX|T}^2 = R_{Y,XT}^2 - r_{YT}^2 = .9866 - .9890^2 = .0085; \quad (5)$$

this indicates that when X is entered *last* in the regression equation, it increases the multiple coefficient of

correlation by .0085. In other words, X contributes a correlation of .0085 over and above the other dependent variable. As this example shows, the difference between the correlation and the part correlation can be very large. For T , we find that

$$r_{YT|X}^2 = R_{Y,XT}^2 - r_{YX}^2 = .9866 - .8028^2 = .3421. \quad (6)$$

Partial Regression Coefficient as Prediction From a Residual

The partial regression coefficient can also be obtained by first computing for each independent variable the residual of its prediction from the other independent variables and then using this residual to predict the dependent variable. In order to do so, the first step is to isolate the specific part of each independent variable. This is done by first predicting a given independent variable from the other independent variables. The residual of the prediction is by definition uncorrelated with the predictors, hence, it represents the *specific* part of the independent variable under consideration.

We illustrate the procedure by showing how to compute the semi-partial coefficient between X and Y after the effect T has been partialled out. We denote by \hat{X}_T the prediction of X from T .

The equation for predicting X from T is given by

$$\hat{X}_T = a_{X,T} + b_{X,T}T, \quad (7)$$

where $a_{X,T}$ and $b_{X,T}$ denote the intercept and slope of the regression line of the prediction of X from T .

Table 2 gives the values of the sums of squares and sum of cross-products needed to compute the prediction of X from T .

We find the following values for predicting X from T :

$$b_{X,T} = \frac{SCP_{XT}}{SS_T} = \frac{18}{16} = 1.125; \quad (8)$$

$$a_{X,T} = M_X - b_{X,T} \times M_T = 7 - 1.125 \times 3 = 3.625. \quad (9)$$

So, the first step is to predict one independent variable from the other one. Then, by subtracting the predicted value of the independent variable from its actual value, we obtain the residual of the prediction of this

$$e_{x,T} = X - \hat{X}_T. \tag{10}$$

Table 3 gives the quantities needed to compute $r_{Y.X|T}^2$. It is obtained as

$$r_{Y.X|T}^2 = r_{Y.e_{x,T}}^2 = \frac{(SCP_{Ye_{x,T}})^2}{SS_Y SS_{e_{x,T}}}. \tag{11}$$

In our example, we find

$$r_{Y.X|T}^2 = \frac{15.75^2}{1,846.83 \times 15.75} = .0085.$$

F and t Tests for the Partial Regression Coefficient

The partial regression coefficient can be tested by using a standard F test with the following degrees of freedom $v_1 = 1$ and $v_2 = N - K - 1$ (with N being the number of observations and K being the number of predictors). Because v_1 is equal to 1, the square root of F gives a Student t test. The computation of F is best described with an example: The F for the variable X in our example is obtained as

$$\begin{aligned} F_{Y.X|T} &= \frac{r_{Y.X|T}^2}{1 - R_{Y.XT}^2} \times (N - 3) \\ &= \frac{.0085}{1 - .9866} \times 3 = 1.91. \end{aligned}$$

The relations between the partial regression coefficient and the different correlation coefficients are illustrated in Figure 1.

Alternative Formulas for the Semi-Partial Correlation Coefficients

The semi-partial coefficient of correlation can also be computed directly from the different coefficients of correlation of the independent variables and the dependent variable. Specifically, we find that the

semi-partial correlation between Y and X can be computed as

$$r_{Y.X|T}^2 = \frac{(r_{Y.X} - r_{Y.T}r_{X.T})^2}{1 - r_{X.T}^2} \tag{12}$$

For our example, taking into account that

$$\begin{aligned} r_{X.T} &= .7500, \\ r_{YX} &= .8028, \text{ and} \\ r_{YT} &= .9890, \end{aligned}$$

we find that

$$\begin{aligned} r_{Y.X|T}^2 &= \frac{(r_{Y.X} - r_{Y.T}r_{X.T})^2}{1 - r_{X.T}^2} \\ &= \frac{(.8028 - .9890 \times .7500)^2}{1 - .7500^2} \approx .0085. \end{aligned} \tag{13}$$

Partial Correlation

When dealing with a set of dependent variables, sometimes we want to evaluate the correlation between two dependent variables after the effect of a third dependent variable has been removed from *both* dependent variables. This can be obtained by computing the coefficient of correlation between the residuals of the prediction of each of the first two dependent variables by the third dependent variable (i.e., if you want to eliminate the effect of, say, variable Q from variables Y and W , you first predict Y from Q and W from Q , and then you compute the residuals and correlate them). This coefficient of correlation is called a *partial* coefficient of correlation. It can also be computed directly using a formula involving only the coefficients of correlation between pairs of variables. As an illustration, suppose that we want to compute the squared partial coefficient of correlation between Y and X after having eliminated the effect of T from both of them (this is done only for illustrative purposes because X and T are independent variables, not dependent variables). This coefficient is noted $r_{(Y.X)|T}^2$ (read “ r square of Y and X after T has been partialled out from Y and X ”), and it is computed as

$$r_{(Y.X)|T}^2 = \frac{(r_{Y.X} - r_{Y.T}r_{X.T})^2}{(1 - r_{Y.T}^2)(1 - r_{X.T}^2)} \tag{14}$$

For our example, taking into account that

$$\begin{aligned} r_{X.T} &= .7500, \\ r_{YX} &= .8028, \text{ and} \\ r_{YT} &= .9890, \end{aligned}$$

we find the following values for the partial correlation of Y and X :

$$\begin{aligned} r_{(Y.X)|T}^2 &= \frac{(r_{Y.X} - r_{Y.T}r_{X.T})^2}{(1 - r_{Y.T}^2)(1 - r_{X.T}^2)} \\ &= \frac{(.8028 - .9890 \times .7500)^2}{(1 - .9890^2)(1 - .7500^2)} \approx .3894. \end{aligned} \tag{15}$$

PARTIAL LEAST SQUARE REGRESSION

Partial least square (PLS) regression is a recent technique that generalizes and combines features from principal component analysis and multiple regression. Its goal is to predict or analyze a set of dependent variables from a set of independent variables or predictors. This prediction is achieved by extracting from the predictors a set of orthogonal factors called *latent variables*, which have the best predictive power.

PLS regression is particularly useful when we need to predict a set of dependent variables from a (very) large set of independent variables (i.e., predictors). It originated in the social sciences (specifically economics) with Herman Wold, but became popular first in chemometrics (i.e., computational chemistry), due in part to Herman's son Svante, and in sensory evaluation. But PLS regression is also becoming a tool of choice in the social sciences as a multivariate technique for nonexperimental and experimental data alike (e.g., neuroimaging). It was first presented as an algorithm akin to the power method (used for computing eigenvectors) but was rapidly interpreted in a statistical framework.

Prerequisite Notions and Notations

The I observations described by K dependent variables are stored in a $I \times K$ matrix denoted \mathbf{Y} , and the values of J predictors collected on these I observations are collected in the $I \times J$ matrix \mathbf{X} .

Goal

The goal of PLS regression is to predict \mathbf{Y} from \mathbf{X} and to describe their common structure. When \mathbf{Y} is a vector and \mathbf{X} is full rank, this goal could be accomplished using ordinary multiple regression. When the number

of predictors is large compared to the number of observations, \mathbf{X} is likely to be singular and the regression approach is no longer feasible (i.e., because of multicollinearity). Several approaches have been developed to cope with this problem. One approach is to eliminate some predictors (e.g., using stepwise methods); another one, called principal component regression, is to perform a principal component analysis (PCA) of the \mathbf{X} matrix and then use the principal components (i.e., eigenvectors) of \mathbf{X} as regressors on \mathbf{Y} . Technically, in PCA, \mathbf{X} is decomposed using its singular value decomposition as $\mathbf{X} = \mathbf{S}\mathbf{\Delta}\mathbf{V}^T$ with $\mathbf{S}^T\mathbf{S} = \mathbf{V}^T\mathbf{V} = \mathbf{I}$, and $\mathbf{\Delta}$ being a diagonal matrix with the singular values as diagonal elements. The singular vectors are ordered according to their corresponding singular values, which correspond to the square root of the variance of \mathbf{X} explained by each singular vector. The left singular vectors (i.e., the columns of \mathbf{S}) are then used to predict \mathbf{Y} using standard regression because the orthogonality of the singular vectors eliminates the multicollinearity problem. But the problem of choosing an *optimum* subset of predictors remains. A possible strategy is to keep only a few of the first components. But these components are chosen to explain \mathbf{X} rather than \mathbf{Y} , and so, nothing guarantees that the principal components, which "explain" \mathbf{X} , are relevant for \mathbf{Y} .

By contrast, PLS regression finds components from \mathbf{X} that are also relevant for \mathbf{Y} . Specifically, PLS regression searches for a set of components (called *latent vectors*) that performs a simultaneous decomposition of \mathbf{X} and \mathbf{Y} with the constraint that these components explain as much as possible of the *covariance* between \mathbf{X} and \mathbf{Y} . This step generalizes PCA. It is followed by a regression step where the decomposition of \mathbf{X} is used to predict \mathbf{Y} .

Simultaneous Decomposition of Predictors and Dependent Variables

PLS regression decomposes both \mathbf{X} and \mathbf{Y} as a product of a common set of orthogonal factors and a set of specific loadings. So, the independent variables are *decomposed* as $\mathbf{X} = \mathbf{T}\mathbf{P}^T$ with $\mathbf{T}^T\mathbf{T} = \mathbf{I}$, with \mathbf{I} being the identity matrix (some variations of the technique do

not require \mathbf{T} to have unit norms). By analogy, with PCA, \mathbf{T} is called the *score* matrix and \mathbf{P} the *loading* matrix (in PLS regression, the loadings are not orthogonal). Likewise, \mathbf{Y} is *estimated* as $\hat{\mathbf{Y}} = \mathbf{TBC}^T$, where \mathbf{B} is a diagonal matrix with the “regression weights” as diagonal elements and \mathbf{C} is weight matrices for the dependent variables (see below for more details on these two matrices). The columns of \mathbf{T} are the *latent vectors*. When their number is equal to the rank of \mathbf{X} , they perform an exact decomposition of \mathbf{X} . Note, however, that they only *estimate* \mathbf{Y} (i.e., in general, $\hat{\mathbf{Y}}$ is not equal to \mathbf{Y}).

PLS Regression and Covariance

The latent vectors could be chosen in a lot of different ways. In fact, in the previous formulation, any set of orthogonal vectors spanning the column space of \mathbf{X} could be used to play the role of \mathbf{T} . In order to specify \mathbf{T} , additional conditions are required. For PLS regression, this amounts to finding two sets of weights \mathbf{w} and \mathbf{c} in order to create (respectively) a linear combination of the columns of \mathbf{X} and \mathbf{Y} such that their covariance is maximum. Specifically, the goal is to obtain a first pair of vectors $\mathbf{t} = \mathbf{Xw}$ and $\mathbf{u} = \mathbf{Yc}$ with the constraints that $\mathbf{w}^T\mathbf{w} = 1$, $\mathbf{t}^T\mathbf{t} = 1$, and $\mathbf{t}^T\mathbf{u}$ is maximal. When the first latent vector is found, it is *subtracted* from both \mathbf{X} and \mathbf{Y} , and the procedure is reiterated until \mathbf{X} becomes a null matrix (see the algorithm section for more).

A PLS Regression Algorithm

The properties of PLS regression can be analyzed from a sketch of the original algorithm. The first step is to create two matrices: $\mathbf{E} = \mathbf{X}$ and $\mathbf{F} = \mathbf{Y}$. These matrices are then column centered and normalized (i.e., transformed into z scores). The sum of squares of these matrices are denoted SS_X and SS_Y . Before starting the iteration process, the vector \mathbf{u} is initialized with random values (in what follows, the symbol \propto means “to normalize the result of the operation”).

Step 1. $\mathbf{w} \propto \mathbf{E}^T\mathbf{u}$ (estimate \mathbf{X} weights)

Step 2. $\mathbf{t} \propto \mathbf{Ew}$ (estimate \mathbf{X} factor scores)

Step 3. $\mathbf{c} \propto \mathbf{F}^T\mathbf{t}$ (estimate \mathbf{Y} weights)

Step 4. $\mathbf{u} = \mathbf{Fc}$ (estimate \mathbf{Y} scores)

If \mathbf{t} has not converged, then go to Step 1; if \mathbf{t} has converged, then compute the value of b , which is used to predict \mathbf{Y} from \mathbf{t} as $b = \mathbf{t}^T\mathbf{u}$, and compute the factor loadings for \mathbf{X} as $\mathbf{p} = \mathbf{E}^T\mathbf{t}$. Now subtract (i.e., partial out) the effect of \mathbf{t} from both \mathbf{E} and \mathbf{F} as follows: $\mathbf{E} = \mathbf{E} - \mathbf{tp}^T$ and $\mathbf{F} = \mathbf{F} - \mathbf{btc}^T$. The vectors \mathbf{t} , \mathbf{u} , \mathbf{w} , \mathbf{c} , and \mathbf{p} are then stored in the corresponding matrices, and the scalar b is stored as a diagonal element of \mathbf{B} . The sum of squares of \mathbf{X} (respectively, \mathbf{Y}) explained by the latent vector is computed as $\mathbf{p}^T\mathbf{p}$ (respectively, b^2), and the proportion of variance explained is obtained by dividing the explained sum of squares by the corresponding total sum of squares (i.e., SS_X and SS_Y).

If \mathbf{E} is a null matrix, then the whole set of latent vectors has been found; otherwise, the procedure can be reiterated from Step 1 on.

PLS Regression and the Singular Value Decomposition

The iterative algorithm presented above is similar to the power method, which finds eigenvectors. So PLS regression is likely to be closely related to the eigen and singular value decompositions, and this is indeed the case. For example, if we start from Step 1, which computes $\mathbf{w} \propto \mathbf{E}^T\mathbf{u}$, and substitute the rightmost term iteratively, we find the following series of equations: $\mathbf{w} \propto \mathbf{E}^T\mathbf{u} \propto \mathbf{E}^T\mathbf{Fc} \propto \mathbf{E}^T\mathbf{FF}^T\mathbf{t} \propto \mathbf{E}^T\mathbf{FF}^T\mathbf{Ew}$. This shows that the first weight vector \mathbf{w} is the first right singular vector of the matrix $\mathbf{X}^T\mathbf{Y}$. Similarly, the first weight vector \mathbf{c} is the left singular vector of $\mathbf{X}^T\mathbf{Y}$. The same argument shows that the first vectors \mathbf{t} and \mathbf{u} are the first eigenvectors of $\mathbf{XX}^T\mathbf{YY}^T$ and $\mathbf{YY}^T\mathbf{XX}^T$.

Prediction of the Dependent Variables

The dependent variables are predicted using the multivariate regression formula as $\hat{\mathbf{Y}} = \mathbf{TBC}^T = \mathbf{XB}_{\text{PLS}}$ with $\mathbf{B}_{\text{PLS}} = (\mathbf{P}^{T+})\mathbf{BC}^T$ (where \mathbf{P}^{T+} is the Moore-Penrose pseudo-inverse of \mathbf{P}^T). If all the latent variables of \mathbf{X} are used, this regression is equivalent to principal

component regression. When only a subset of the latent variables is used, the prediction of \mathbf{Y} is optimal for this number of predictors.

An obvious question is to find the number of latent variables needed to obtain the best generalization for the prediction of *new* observations. This is, in general, achieved by cross-validation techniques such as bootstrapping.

The interpretation of the latent variables is often helped by examining graphs akin to PCA graphs (e.g., by plotting observations in a $t_1 \times t_2$ space; see Figure 1).

A Small Example

We want to predict the subjective evaluation of a set of five wines. The dependent variables that we want to predict for each wine are its likeability and how well it goes with meat or dessert (as rated by a panel of experts) (see Table 1). The predictors are the price and the sugar, alcohol, and acidity content of each wine (see Table 2).

The different matrices created by PLS regression are given in Tables 3 to 11. From Table 11, one can

find that two latent vectors explain 98% of the variance of \mathbf{X} and 85% of \mathbf{Y} . This suggests keeping these two dimensions for the final solution. The examination of the two-dimensional regression coefficients

(i.e., \mathbf{B}_{PLS} , see Table 8) shows that sugar is mainly responsible for choosing a dessert wine, and that price is negatively correlated with the perceived quality of the wine, whereas alcohol is positively correlated with it (at least in this example). Looking at the latent vectors shows that \mathbf{t}_1 expresses price and \mathbf{t}_2 reflects sugar content. This interpretation is confirmed and illustrated in Figure 1a, which displays the projections on the latent vectors of the wines (matrix \mathbf{T}) and the predictors (matrix \mathbf{W}), and in Figure 1b, which displays the correlation between the original dependent variables and the projection of the wines on the latent vectors.

Relationship With Other Techniques

PLS regression is obviously related to canonical correlation, STATIS, and to multiple factor analysis. The main originality of PLS regression is to preserve the asymmetry of the relationship between predictors and dependent variables, whereas these other techniques treat them symmetrically.

Software

PLS regression necessitates sophisticated computations, and therefore, its application depends on the availability of software. For chemistry, two main programs are used: the first one, called SIMCA-P, was developed originally by Wold; the second one, called the Unscrambler, was first developed by Martens, who was another pioneer in the field. For brain imaging, SPM, which is one of the most widely used programs in this field, has recently integrated a PLS regression module. Outside these domains, SAS PROC PLS is probably the most easily available program. In addition, interested readers can download a set of MATLAB programs from the author's home page (www.utdal.las.edu/~herve). Also, a public domain set of MATLAB programs is available from the home page of the *N*-Way project (www.models.kvl.dk/source/nwaytoolbox/), along with tutorials and examples. From brain imaging, a special toolbox written in MATLAB is freely available from www.rotman-baycrest.on.ca. And finally, a commercial MATLAB toolbox has also been developed by Eigenresearch.

PASCAL, BLAISE (1623–1662)

Pascal was born at Clermont-Ferrand in France on June 19, 1623. His mother died when he was 3 years old. He was an obviously bright child, and his father initially forbade his study of mathematics, preferring that he become fluent in the classics instead. Of course, this

merely spurred Pascal's curiosity, and he swiftly began solving geometric problems for himself. By the age of 17, he had published a paper (on conic sections), and at 18, he invented his first calculator. This was the first of several adding machines, some of which cleverly worked to different bases (e.g. both 12 and 20).

From mathematics, Pascal turned to physics, observing that the atmospheric pressure was lower at the top of the mountain than at the bottom. This observation had followed a visit by Descartes, in which the two had discussed whether a vacuum could exist. Apparently, Descartes left, remarking that Pascal "had too much vacuum in his head."

When Pascal's father injured his leg, religious brothers cared for Pascal, and this marked the beginnings of Pascal's religious conversion. In 1650, he took a break from science to consider religion, but following the death of his father in 1653, he returned to scientific and mathematical studies. At this time, he introduced the numerical configuration now called Pascal's triangle. His correspondence with Fermat laid the foundations for the modern treatment of probability.

Once again, however, fate took a hand. In 1654, he had a traffic accident: his carriage veered off the road, and he escaped death only because the harness straps broke. Shortly afterwards, Pascal had a vision: He wrote an account of this vision that he kept on his person for the rest of his life. He then began writing philosophical and theological pieces. The last and best known of these was entitled *Pensées* (Thoughts), which was unfinished at the time of his premature death in Paris on August 19, 1662. It is in the *Pensées* that Pascal argued that it is always a better "bet" to believe in God than not to believe in God. This is because the expected value to be gained from believing in God must be greater than the expected value for nonbelievers!

PATH ANALYSIS

Path analysis is a method of describing and quantifying the relationship of a dependent variable Y to a set of other variables. Each of the variables may have a direct effect on Y , as well as indirect effects via other variables. It is difficult to infer causation without an experiment, but by describing a system of interrelationships, path analysis can take a step to support cause-and-effect inference.

Path analysis was originally developed by Sewall Wright for the field of genetics. It has since been adopted by virtually all the behavioral sciences and applied to a variety of research questions. Properly applied, it can be an aid to scientific, business, governmental, and educational policy decisions.

Examples

One well-known example relates income to occupation, education, father's education, father's occupation, and number of siblings. In another example, a professor wants to relate students' scores on the final exam to those on the two exams during the term. Exam 1 can be related to the final exam score either directly or indirectly via Exam 2. What are the sizes of these effects of Exam 1? If both are small, then the professor might give only a midterm and a final next semester. In a third example, Profit can be studied as a function of Sales and Assets. Assets support Sales, and hence indirectly contribute to Profit. But Assets can also contribute directly to Profit, via interest and rents. What are the relative sizes of these effects? (See Table 1.)

In considering the relationship between Profit, Sales, and Assets, it becomes apparent that Assets, by supporting Sales, contribute indirectly to Profit. Assets also contribute directly to Profit via dividends on investments, interest on savings, and rents on property. The prediction equation for Profit based on Sales and Assets, estimated by the statistical technique of multiple linear regression, is

$$\text{predicted Profit} = 1464 + 0.010348 \text{ Sales} \\ + 0.010069 \text{ Assets } (\$M).$$

Table 1 Sales, Profits, and Assets of the 10 Largest U.S. Industrial Corporations (in millions of dollars)

The fitting of such a relationship is called *regressing* Profit on Sales and Assets. The interpretation of the coefficient (multiplier) of Assets is that if Assets increase by one unit (1 \$M) and Sales remain the same, Profit is predicted to increase by 0.010069. But if Assets increase by one unit, what are Sales expected to do? Would not higher Assets possibly mean higher Sales? We need also to regress Sales on Assets. This gives

$$\text{predicted Sales} = 21097 + 0.507 \text{ Assets } (\$M).$$

So, in view of our understanding of Assets as contributing both directly and indirectly to Profit, we really need this system of two regression equations, one for Sales on Assets, the other for Profit on Sales and Assets. Now we can see that if Assets increase by 1 unit, Sales are expected to increase by 0.507, and the expected change in Profit is

$$0.010348(0.507) + 0.010069(1) = 0.015315 (\$M).$$

The system can be described by the paths

$$\text{Assets} \rightarrow \text{Sales} \rightarrow \text{Profit}, \text{Assets} \rightarrow \text{Profit};$$

The variable Assets has a direct connection to Profit and also an indirect connection via Sales.

Regression

In more general terms, path analysis employs a system of *regression* equations. Regression is a method of studying the dependence of a variable Y on several explanatory variables X_1, X_2, \dots, X_p . The data set is of the form

$$\{(x_{1i}, x_{2i}, \dots, x_{pi}, y_i), i = 1, 2, \dots, n \text{ cases}\}.$$

A prediction equation of the form

$$Y' = a + b_1X_1 + b_2X_2 + \dots + b_pX_p,$$

where Y' is the predicted value of Y , is obtained. The coefficients a, b_1, \dots, b_p are obtained from the data set by a method such as least squares. Values of the X s for a new individual can be substituted into the equation to predict the value of Y for that individual. But regression usually raises more questions than it answers. It does not deal explicitly with relationships among the X s. The coefficient of an X gives the predicted change in Y corresponding to a unit change in that X , given that the other X s remain constant. But usually if the value of one X changes, some of the other X s, correlated with it, will change too.

A System of Relationships

In path analysis, variables explained in terms of others are called *endogenous* and denoted by Y s; variables not predicted by others are called *exogenous* and denoted by X s. Causation can be illustrated by paths. Even in a system of one dependent variable and two other variables, there are several possibilities, including the following:

$$X \rightarrow Y_1 \rightarrow Y_2$$

This path indicates that X affects Y_1 , and Y_1 affects Y_2 . An alternative model is the following system of two paths:

$$X \rightarrow Y_1 \rightarrow Y_2, X \rightarrow Y_2$$

This indicates that X affects Y_1 , and Y_1 affects Y_2 , but also X has a direct effect of its own on Y_2 .

From a postulated model, specifying relationships among the variables, one can derive estimates of the *path coefficients*, the weights on the arcs of the paths. These are obtained by estimating the system of equations corresponding to the paths. Each endogenous variable is regressed on all the variables pointing directly to it in paths.

For the model consisting of a single path, there would be two simultaneous equations, one showing dependence of Y_2 on Y_1 ; the other, that of Y_1 on X :

$$[1]: Y_2' = a + bY_1$$

$$[2]: Y_1' = c + dX$$

For the model consisting of two paths, in which X has both a direct and an indirect effect on Y_2 , there would again be two equations, but now one shows dependence of Y_2 on both Y_1 and X :

$$[1]: Y_2' = a + bX + cY_1$$

$$[2]: Y_1' = d + eX$$

The input for path analysis can be the set of correlations between the pairs of variables. Use of correlations is equivalent to standardizing the data to z scores at the outset. The z score is the raw score, minus the mean for the variable, divided by the standard deviation for the variable.

Assumptions Underlying Path Analysis

The sample size needs to be adequate; guidelines for the minimum range from at least 5 cases per variable to at least 10 cases per variable. (The sample size in the Assets-Sales-Profit example is purposefully small.) The usual assumptions of linearity and constant variance (variance not dependent upon the values of the explanatory variables) underlying the use of multiple linear regression apply to each of the regressions in the model. For use of the t distribution for hypothesis tests, the errors should be at least

approximately normally distributed. Path analysis is not without its detractors, at least in part because of the difficulty of checking these assumptions for a whole set of equations.

Related Techniques

The variables in path analysis are observable (*manifest*). Structural equation modeling (SEM) includes models with hidden (*latent*) variables. In SEM, concepts (*constructs*) are linked via the structural model. Each construct is entered via its measurement model, involving a factor analysis of several indicators, which are observable variables that relate to it. The factor analysis produces a combination of the indicators for that construct.

Example

Sears, Roebuck & Co. used SEM in a new employee-customer-profit corporate model developed in the early 1990s. The constructs were employee satisfaction, customer satisfaction, and profit. Each construct was measured by several indicators; for example, profit was measured by the customary accounting variables. The indicators for each construct are combined by factor analysis into an index of that construct. Profit in each fiscal quarter was predicted from customer satisfaction in the preceding quarter, which in turn was related to employee satisfaction in the quarter before that.

Path Diagrams

The paths for a larger model, such as the first example given above, look like this.

Let FE be father's education, FO be father's occupation, S be number of siblings, E be education, O be occupation, and I be income. These paths might be those considered.

$$FE \rightarrow FO \rightarrow S \rightarrow E \rightarrow O \rightarrow I$$

$$FE \rightarrow FO \rightarrow S \rightarrow E \rightarrow O$$

$$FE \rightarrow FO \rightarrow S$$

A *path diagram* is a way of drawing the system. The diagram, made up of paths like the ones above, is constructed as follows:

1. A straight arrow is drawn to each endogenous variable from each of its sources.
2. A straight arrow is drawn to each dependent variable from its residual. Each endogenous variable has a residual because it is the dependent variable in a regression.
3. A curved, double-headed arrow is drawn between each pair of exogenous variables thought to have nonzero correlation.

Conditions for Estimability

To estimate the path coefficients, equations are set up between the path coefficients and the variances and covariances of the p endogenous and q exogenous variables. The complexity of the model considered is limited by the number of variables in the data set. It is necessary that the number t of path-model parameters be no more than the number $(p + q)(p + q + 1)/2$ of variances and covariances of the $p + q$ variables. If this condition is satisfied, then, by a process analogous to checking whether a system of linear equations consists of independent equations, it is determined whether the system is solvable.

Comparing Alternative Models

Note that path analysis and SEM are mainly concerned with estimating the sizes of effects in an already postulated model. However, sometimes, there is a search among a number of models. Members of a research team may propose competing models. Path diagrams provide a way of brainstorming to organize a research project into the exploration of competing models. Then there is the problem of choosing among them.

Model-selection criteria are figures of merit for scoring alternative models. Prominent among these are criteria equal to a measure of lack of fit of the model (analogous to residual sum of squares in

regression), plus a multiple of the number of parameters used to achieve that fit. The smaller the score on such a criterion, the better the model.

Using the Computer

Although there was path analysis software before graphical user interfaces, these can be used now to draw and modify diagrams. Given the diagram, the software checks estimability of the model and then fits the model. Then, the diagram can be displayed with the path coefficients on it. Software for path analysis and SEM includes AMOS, EQS, and LISREL.

PEABODY PICTURE VOCABULARY TEST

The Peabody Picture Vocabulary Test, now in its third edition (PPVT-III), is an individually administered, untimed, norm-referenced, wide-range test of listening comprehension for the spoken word in standard English. The test serves as both an achievement test of receptive vocabulary attainment for standard English

and a screening test of verbal ability, but only when English is the language of the examinee's home, community, and school. The test is designed for use with persons aged 2½ through 90+ years, and the average administration time is 10–15 minutes. Two types of normative scores are provided. Deviation-type norms tell you how far the individual's performance deviates from the average person of the same age group on whom the test was standardized. Developmental-type norms tell you how the individual's performance compares to others on a growth or development curve.

Two forms are available, Form IIIA and Form IIIB, that allow for reliable testing and retesting. Each form contains four training items and 204 test items. Items are grouped into 17 sets of 12 items, arranged in order of increasing difficulty. Each item contains four black-and-white illustrations arranged on a page. The examinee selects the picture that best represents the meaning of a stimulus word presented orally by the examiner. A sample item for the stimulus word *carpenter* could contain a picture of a carpenter with three distracter pictures of various workers such as a doctor, a chef, and a farmer.

The PPVT-III is useful with diverse populations. Reading or writing are not required from the examinee; therefore, it is useful with nonreaders and people with written-language problems. The examinee can respond orally, by pointing, or by signaling “yes” or “no” as the examiner points to each choice in turn. Because an oral, written, or point response is not required from the examinee, the test may be used with people with language impairments, and disabilities such as autism or cerebral palsy. The test can aid in the detection of language impairments, such as aphasia. The PPVT-III can be useful as a screening measure for both giftedness and mental retardation for people with English-language backgrounds. When English is a second language, the test can provide a measure of English-language proficiency. The ease of administration and high reliability at young ages makes the test useful in testing preschool children's vocabulary acquisition. The extensive adult norms make the test useful in testing adults'

listening comprehension and possible vocabulary deterioration.

PEARSON, KARL (1857–1936)

Karl Pearson was judged by his contemporaries to be among the most influential university teachers of his time. The modern statistician sees him as a founding father of what are now considered to be elementary statistical methods.

Pearson, the son of a barrister, was born in London, on March 27, 1857. In 1875, he gained a scholarship to study mathematics at King's College, Cambridge. A somewhat rebellious student, Pearson spent much of his time studying other subjects. His wide range of interests was further extended when he spent time studying physics, metaphysics, and German literature at the Universities of Heidelberg and Berlin. It was in Germany that he changed his first name from Carl to Karl, retaining that spelling thereafter.

Returning to England, Pearson rejected the offer of a post in the German Department at Cambridge University, opting instead to study law. He was called to the Bar in 1882, but never practiced law. Instead, in 1885, he was appointed Goldsmid Professor in the

Applied Mathematics Department at University College, London.

In 1890, Pearson's career changed direction once again, with the appointment of Raphael Weldon as Professor of Zoology. Pearson's interaction with Weldon was stimulated by the publication of Francis Galton's *Natural Inheritance*. By the time of his first statistical publication (*The Chances of Death and Other Studies in Evolution*), he already had 100 publications to his name (including many on German history and folklore). However, between 1893 and 1912, Pearson wrote 18 papers under the general title of *Mathematical Contributions to the Theory of Evolution*. These papers resulted in the introduction of such familiar concepts as standard deviation, regression, correlation, and the chi-square goodness-of-fit test.

In 1901, Pearson was a co-founder (with Weldon and Galton) of the journal *Biometrika*. The intention was to provide a vehicle for the mathematical treatment of biological problems. Pearson remained the journal's editor until his death more than 30 years later. In 1911, Pearson, remaining at University College, became its first Galton Professor of Eugenics.

A feature of statistics in the early 20th century was the long-running disagreements between Pearson and his distinguished younger contemporary, Ronald Fisher, in their approaches to data analysis. Pearson favored the use of large data sets, whereas Fisher was prepared to look for causation through small data sets.

As early as 1919, Fisher turned down a job opportunity so as to avoid working with Pearson. However, when Pearson retired in 1933, it was Fisher who succeeded him as head of the Department of Eugenics. In a Solomon-like judgment, Egon Pearson (Karl's son) was simultaneously appointed head of the Department of Statistics.

Pearson was elected a Fellow of the Royal Society in 1896 and a Fellow of the Royal Society of Edinburgh in 1934. He died on April 27, 1936, in Coldharbour, Surrey, England.

PEARSON PRODUCT-MOMENT CORRELATION COEFFICIENT

Among his many accomplishments, Sir Francis Galton first introduced the concept of correlation in a book titled *Natural Inheritance*, which was published in 1889. However, Karl Pearson is credited for extending the concept of correlation and for developing the product-moment correlation coefficient. Pearson's product-moment correlation coefficient is by far the most common index of the relationship between two variables, or bivariate relationship.

Pearson's product-moment correlation coefficient measures the degree to which the points in the scatterplot tend to cluster about a straight line. In other words, the product-moment correlation coefficient *measures the degree of linear relationship between two variables*. If we label the two variables of interest as x and y , then Pearson's product-moment correlation coefficient, denoted by r , is given by the following formula:

$$r = \frac{\Sigma(x - \bar{x})(y - \bar{y})}{\sqrt{\Sigma(x - \bar{x})^2} \sqrt{\Sigma(y - \bar{y})^2}} = \frac{\text{Cov}(xy)}{\sqrt{\text{Var}(x)\text{Var}(y)}} \quad (1)$$

$$= \frac{\Sigma xy - n\bar{x}\bar{y}}{\sqrt{\Sigma x^2 - n\bar{x}^2} \sqrt{\Sigma y^2 - n\bar{y}^2}},$$

where

$$\bar{x} = \frac{\Sigma x}{n} \quad \text{and} \quad \bar{y} = \frac{\Sigma y}{n}. \quad (2)$$

The first element of Equation 1 indicates that Pearson r is the ratio of the covariance between variables X and Y to the square root of the product of the x and y variances. Interestingly, only the numerators

of the variance and covariance equation appear in the latter part of Equation 1 because the denominators cancel each other out. Furthermore, Equation 2 could be used to rewrite the Pearson r formula as

$$r = \frac{n \Sigma xy - (\Sigma x)(\Sigma y)}{\sqrt{n \Sigma x^2 - (\Sigma x)^2} \sqrt{n \Sigma y^2 - (\Sigma y)^2}}. \quad (3)$$

However, an even more interpretable way of expressing Pearson r is as follows:

$$r = \frac{\Sigma Z_x Z_y}{n - 1}, \quad (4)$$

where

$$Z_x = \frac{x - \bar{x}}{S_x} \quad \text{and} \quad Z_y = \frac{y - \bar{y}}{S_y}$$

and $S_x = \sqrt{\frac{\Sigma(x - \bar{x})^2}{n - 1}}$ and $S_y = \sqrt{\frac{\Sigma(y - \bar{y})^2}{n - 1}}$.

That is, S_x and S_y are the standard deviations of the two variables. Thus, Equation 4 indicates that Pearson r is the average cross-product of the standardized x and y variable scores. The fact that Pearson r can be expressed as a product of two variables measured in standard units means that we can express the relationship between two variables even if they are measured on different scales. For example, x can be measured in inches and y can be measured in acres, or in pounds, or in dollars. Provided that both variables are converted to standard units, r can measure their association.

If only the numerator in Equation 4 was used to compute Pearson r , then r would increase as the number of observations in the data set increased, regardless of the true relationship between the two variables. Therefore, $n - 1$ is needed in the denominator of Equation 4 to provide a statistic that is independent of the sample size. This denominator guarantees that r always lies between -1 and $+1$, inclusive.

Pearson's correlation coefficient helps to determine both the magnitude and direction of pairwise variable relationships. The sign of the coefficient tells us whether the relationship is positive or negative.

A positive correlation means that as the values of one variable increases, so do the values of the second variable. Conversely, a negative relationship indicates that an increase in one variable is associated with a decrease in the other variable. The numerical part of the correlation coefficient indicates the magnitude of the relationship. A value of zero indicates no linear relationship between the two variables, whereas the closer the correlation coefficient is to 1 or -1 , the greater the relationship between the variables.

A key assumption pertaining to Pearson r is that the relationship between the two underlying variables is linear. An effective way of assessing the linearity of relationships is via bivariate scatterplots.

Pearson r as a Descriptive Statistic

When Pearson r is needed solely for the purpose of describing a relationship between two variables, then other than the linearity assumption, three other assumptions should be checked before deciding whether the use of Pearson's correlation coefficient is appropriate. These assumptions are as follows:

1. At least one of the variables should represent a continuous variable.
2. Each observation of the dependent variable (Y) must be statistically independent of every other observation.
3. The variability in scores for one variable is approximately the same at all values of the other variable (i.e., the homoscedasticity assumption).

Example With Real Data

Any of the formulae in Equation 1, Equation 3, or Equation 4 can be used to compute Pearson r . Onwuegbuzie was interested in determining a relationship between the total number of points scored (x) by all 30 professional National Football League (NFL) teams and their winning percentages (y) during the 1997–1998 football season. (Both variables are continuous.) These data are presented in Table 1. Also, the scatterplot is displayed in Figure 1.

It can be seen from this plot that the relationship is linear, and that homoscedasticity is present. Table 1 presents the summary statistics. From this table, we can use Equation 1 to compute Pearson r , as follows:

$$\begin{aligned}
 r &= \frac{\Sigma xy - n\bar{x}\bar{y}}{\sqrt{\Sigma x^2 - n\bar{x}^2}\sqrt{\Sigma y^2 - n\bar{y}^2}} \\
 &= \frac{555100 - 30(340.50)(50.00)}{\sqrt{3675819.00 - (30)(340.50)^2}\sqrt{88281.25 - (30)(50.00)^2}} \\
 &= \frac{555100 - 510750.00}{\sqrt{3675819.00 - 3478207.50}\sqrt{88281 - 75000.00}} \\
 &= \frac{44350.00}{\sqrt{197611.50}\sqrt{13281.00}} \\
 &= \frac{44350.00}{(444.54)(115.24)} \\
 &= \frac{44350.00}{51228.79} \\
 &= 0.87
 \end{aligned}$$

Figure 1 Scatterplot of Number of Points Scored Against Winning Percentage

Thus, $r = .87$ indicates a positive linear relationship between the total number of points scored by NFL teams and their winning percentage, which is consistent with the scatterplot in Figure 1. A useful feature of Pearson r is that if we square it, we obtain r^2 , the coefficient of determination, which indicates that 75.69% (i.e., $.87^2$) of the variance in winning

percentage is explained by the total number of points scored by teams. Although the correlation coefficient is extremely large, we cannot use terms such as *statistically significant relationship* because, as yet, we have not conducted a null hypothesis significance test (NHST) for this correlation coefficient.

Pearson r as an Inferential Statistic

When a researcher's goal is to use the observed Pearson r to make inferences, then a further assumption is needed than for when Pearson r is used for descriptive purposes only—namely, that the dependent variable is normally distributed. The normality assumption should be assessed by both graphical and statistical means. With regard to the former, frequency histograms could be used. In addition to graphical checks of normality, the skewness and kurtosis can be assessed for direction and magnitude. Scores with large positive or negative skewness coefficients and/or large positive (i.e., leptokurtic distribution) or negative (i.e., platykurtic distribution) kurtosis coefficients indicate violations to the normality assumption. It should be noted that large

skewness and kurtosis coefficients affect Type I and Type II error rates.

If the normality assumption holds, the researcher is ready to use Pearson r to determine whether a relationship between two variables is statistically significant—that is, whether the derived Pearson r represents a finding that is sufficiently different from zero to reject the null hypothesis. The NHST concerning a population correlation coefficient (ρ) takes the general form:

$$\rho = \frac{\text{Proportion of variance explained}}{\text{Proportion of variance unexplained}}$$

Using the fact that R^2 is the proportion of variance explained, and $1 - R^2$ is the proportion of variance unexplained, the test statistic (t) for Pearson r generalizes to

$$t = \frac{\sqrt{\frac{R^2}{1 - R^2}}}{\sqrt{\frac{n - 2}{n - 2}}} = \frac{r}{\sqrt{\frac{1 - r^2}{n - 2}}} = \frac{r\sqrt{n - 2}}{\sqrt{1 - r^2}} \quad (5)$$

The test statistic in Equation 5 is then compared to the associated t critical value based on $n - 2$ degrees of freedom and is determined by the desired level of statistical significance α . The three possible types (two one-tailed and one two-tailed) of NHSTs involving the correlation coefficient and the decision rules for determining whether the null hypothesis is rejected (and a statistically significant relationship inferred) are presented in Table 2.

A close examination of the numerator of the right-hand side of Equation 5 indicates that, holding the correlation constant, as the sample size (n) increases so does the t value, and, consequently, the probability of rejecting the null hypothesis. This probability is

Table 2 Decision Rules for Determining Whether the Null Hypothesis Is Rejected

Alternative Hypothesis	Rejection Region
$H_a: \rho > \text{hypothesized value}$	Reject H_0 if $t > t$ critical value (upper-tail test)
$H_a: \rho < \text{hypothesized value}$	Reject H_0 if $t < -t$ critical value (lower-tail test)
$H_a: \rho \neq \text{hypothesized value}$	Reject H_0 if either $t > t$ critical value or $t < -t$ critical value (two-tailed test)

commonly known as the p value. Conveniently, virtually all statistical software automatically computes this p value, thereby making the use of t tables obsolete. As can be seen from the output generated by SPSS in Figure 2, for the NFL football data set, the p value is less than .0001, which is less than .05 (the typical nominal value). Thus, the null hypothesis that the population correlation is zero is rejected, and we conclude that there is a statistically significant relationship between the total number of points scored by a NFL team and the team’s winning percentage.

Effect Size for Pearson r

Because of the influence that the sample size has on p values associated with tests of bivariate correlations, as well as on all other NHSTs, it is not sufficient to

report the r value and p value corresponding to each relationship tested. The magnitude of the r value also should be interpreted. By interpreting the r value, this statistic also serves as an effect size value, resulting in the delineation of the practical significance of the findings. The r value can be interpreted by using Cohen's criteria of .1 for a small correlation, .3 for a moderate correlation, and .5 for a large correlation. Using Cohen's criteria, the relationship found for the NFL data set (i.e., $r = .87$) is extremely large.

PERCENTILE AND PERCENTILE RANK

The terms *percentile* and *percentile rank* are considered by some people to mean the same thing. However, these two terms are different in conceptual meaning and should not be used interchangeably.

Percentile Rank

A percentile rank describes the standing, or position, of an earned score in comparison to a reference group. The percentile rank for that earned score indicates the percentage of scores in the reference group that are

lower than the earned score. Thus, an examinee whose test performance earns him or her a percentile rank of 72 would have scored higher than 72 percent of those in the reference group who took the same test.

Percentile ranks are reported in terms of whole numbers between 1 and 99 (inclusive). No decimals are used, and percentile ranks never assume the values of 0 or 100. These extreme values are not used because the percentile rank for any earned score considers that earned score to be *in* the reference group. Considered in that way, it is logically impossible for an earned score to be higher than no scores or all of the scores.

It is important to note that a percentile rank indicates relative (not absolute) standing. Thus, knowing the nature of the reference group is exceedingly important if one is to properly interpret an examinee's percentile. An examinee's percentile rank might be 92 when the reference group is a nationwide group of test takers, 81 when the reference group is defined as those in the examinee's state, but only 47 if the reference group is test takers in the examinee's school.

Percentile

A percentile is a point along the score continuum that divides the reference group's distribution of earned scores into two parts such that a desired percentage of the group's scores lie below that point. For example, if we are dealing with a normal distribution of IQ scores (with a mean of 100 and a standard deviation of 15), then 75% of the IQ scores would fall below 110.1. Thus, that score value (110.1) would be the 75th percentile.

In computing percentiles, we state a percentage (such as 75% in the above example) and then examine the distribution of scores in the reference group to determine what particular value of the score continuum has that particular percentage of scores below it. This sequence of steps is different from that used in determining a percentile rank, for in the latter case, we begin with a given earned score and then determine what percentage of the reference group's scores are below that earned score. Because of this difference,

a percentile can assume a value that's not the same as any earned score. For example, if the earned scores of six examinees on a 20-item quiz in which quiz scores are determined simply as "number correct" are 19, 17, 16, 14, 13, and 12, the 50th percentile would be equal to 15, a score no one earned. (The value of 15 comes from taking the arithmetic average of the two middle scores, 16 and 14.) Pretend that the two lowest-scoring examinees are not part of the group, and in this situation, the 50th percentile for the remaining four scores is 16.5, a score that not only was not earned but also was not earnable!

The primary difference between percentile ranks and percentiles can be conceptualized as a "figure-ground" difference. In both cases, the "ground" is the reference group. The figure, however, is different. With percentile ranks, the figure is an earned score. In contrast, the figure for a percentile is a point on the score continuum.

For any group of scores, there are 99 percentile points. These percentiles divide the scores in the reference group into 100 parts, each containing 1% of the total. Because of this definitional feature of percentiles, certain percentiles are equivalent to other concepts in statistics and measurement. For example, the 50th percentile is equal to the median. Also, the 25th, 50th, and 75th percentiles are equal to the lower, middle, and upper quartile points (Q_1 , Q_2 , and Q_3), respectively. Terciles are the two points that divide the reference group's scores into three equal parts.

Comments

It is important to keep three things in mind when dealing with percentile ranks and percentiles. If these "warnings" are overlooked, it is easy to misinterpret and misuse these concepts.

First, percentile ranks are not the same thing as ranks, even though both involve whole numbers. A rank indicates a person's relative position in a group, with the rank of 1 given to the person who did the best, a 2 given to the person who did second-best, and so on. Thus, a low rank (e.g., 2) indicates that a person has a very high standing in the reference

group. With percentile ranks, high rather than low numbers indicate a high standing.

Second, percentile ranks and percentiles are ordinal in nature and lack the "equal interval" characteristic that's embodied in interval measurement scales. To illustrate this point, suppose four examinees in a larger group of test takers are A, B, C, and D, and further suppose that their percentile ranks on an ability test are 45, 55, 85, and 95, respectively. Because percentile ranks are ordinal, it would be improper to state (or to think) that the difference in ability between Examinees A and B is the same as the ability difference between Examinees C and D. If the reference group's ability scores are normally distributed, the earned test scores from Examinees A and B would be much closer together (along the scale of earnable raw scores) than the earned test scores from Examinees C and D.

Finally, those who interpret test scores need to remember that percentile ranks indicate relative, not absolute, positioning in a group. If an examinee's test performance leads to a percentile rank of 97, for example, that does *not* indicate that he or she correctly answered 97% of the test questions or has very little more to learn. Likewise, a very low percentile rank should *not* be interpreted to mean that an examinee has no knowledge or skill.

Percentiles and percentile ranks are very popular in educational systems. With them, educators can compare different students who take the same test in different backgrounds with their percentiles or percentile ranks in a more reasonable manner. Also, in a large-scale standardized test, students can take past results of the overall data about the relation between raw scores and percentiles or percentile ranks as references to predict their testing achievements.

PERFORMANCE IQ

Performance IQ is a measure of intelligence that does not require the use of words or language and is associated with the Wechsler Intelligence Scales. When David Wechsler developed his IQ test in 1939, he divided it into two components: tasks that required mainly verbal abilities and tasks that required mainly perceptual-manipulative skills. The Performance IQ can be considered mainly a measure of visual-spatial processing, novel problem solving, attentiveness to visual detail, and visual-motor integration and speed. Recent editions of the Wechsler scales have broken down the Performance IQ into a perceptual organization component and a processing speed component. The perceptual organization scale most closely represents what has been traditionally thought of as Performance IQ.

Another way of thinking about Performance IQ is that it is that aspect of intelligence that does not depend upon experience and learning, sometimes referred to as fluid intelligence. Because experience is not heavily weighted, Performance IQ is considered to be relatively free of cultural bias. For this reason, the Performance IQ is sometimes used in place of the Full Scale IQ with minorities and individuals whose first language is not English as the overall indicator of intelligence. Although the research is far from definitive, there is some indication that skills measured by Performance IQ tend to decline with age, whereas those measured by Verbal IQ tend to stay the same or actually increase. Attempts to tie Performance IQ to the right hemisphere of the brain and Verbal IQ to the left hemisphere generally have not been successful.

PERFORMANCE-BASED ASSESSMENT

Tests come in many forms, and in a real sense, the act of completing any test items, regardless of their format, constitutes a performance of some type. However, the term *performance-based assessment* (also, *performance assessment* or sometimes *authentic assessment*) has come to possess a specific meaning in the context of measuring cognitive abilities. Although Linn and others have noted that performance tasks are sometimes described relative to what they are *not* (as in, not selected-response, and not norm-referenced), performance-based tests can be characterized fundamentally by extended-length, highly interactive tasks that call for answers or products to be uniquely generated by the test taker. These tasks are often open-ended in nature and, to the extent possible, are framed in contexts approximating real-life applications of knowledge, skills, and abilities. Furthermore, performance-based assessments often involve complex, multistep problems requiring different types of performance, and, depending on the context for testing, may be intended to be completed by individuals working independently or in small groups.

Performance-Based Assessment Methods: Processes and Tasks

Many kinds of activities are commonly considered to be performance-based tasks. A (nonexhaustive) list of performance-based assessment activities includes presentations, research projects, role-plays, Web pages, experiments, portfolios, extended written responses, performance demonstrations, exhibitions, and working through case studies. Although the precise nature of the activity and the format of a performance-based assessment will vary widely by testing program and testing purpose, it is clear that the listed assortment of performance tasks gives test takers the opportunity—within whatever parameters might be defined by the assessment's developer—to produce rather than select. This range can reflect the individuality of test takers and their unique engagement with the specific nature of the assessment task.

Of course, the actual evaluation products could take any of a variety of actual forms, such as something written (here, think of formats such as short or extended-length essays and also reports, brochures, articles, transcripts of conversations, or letters); a live presentation (that may or may not be recorded for multimedia storage and later re-viewing); or the creation of other objects to be assessed according to specific criteria. For example, the creation of a Web site, the production of a working computer program, and the fabrication of a model or prototype object are items to be evaluated that likewise might be generated in response to a performance task. Furthermore, in addition to this range of products that may be generated, some applications of performance-based testing consider the process by which the intended product or answer is created to be on equal footing with the product or answer itself.

Indeed, in some cases, performance-based assessment might be described more accurately as *performance-and-product assessment*. Recognizing that process sometimes is and sometimes is not part of what is evaluated through performance-based assessments, Messick identified three kinds of performance tasks: (a) those in which the performance and product are essentially the same thing (i.e., a dance recital), (b) those where the end product is what mainly counts (i.e., an essay), and (c) those in which the performance and the product are distinctly separate but equally important elements to be evaluated (i.e., a science experiment).

There is one other attribute of performance-based assessment often regarded as a critical aspect of these formats: across applications, performance task users strive to incorporate a high degree of fidelity to realism. Performance tasks tend to be constructed so as to couch questions and activities within situations where the skills, knowledge, and abilities being tested would be commonly used. Think here of the road test for a driver's license: In many states, to make a pass-fail decision about granting the license, examiners ride in cars driven by candidates, on local streets, where other motorists are going about their business. The assessment task in this example provides the scorer with a direct observation of the

underlying skill of interest in a naturalistic setting. Although it could be said that the circumstance of performing for the purpose of being evaluated makes the performance by its very nature artificial, performance-based tasks are intended to inject realism back into the assessment process by setting the performance conditions in a context approximating typical use of the skill to the extent possible.

Although performance-based tasks have long been used by test developers in selected testing contexts such as professional certification and licensure, interest in including performance tasks across test uses has increased over recent years. Indeed, performance-based testing tasks can be appropriately created and adapted for many standardized and classroom testing purposes, from diagnosis and remediation to certification, selection, and accountability. Boodoo and Miller and Linn characterized this broadening use of performance-based assessments as concerted efforts to enhance the depth of measurement information, because performance tasks offer test users the possibility of capturing an array of examinee knowledge and skill in a richer, more realistic context than could be done ordinarily with traditional, selected-response approaches. This is not to say that multiple-choice and other such selected-response formats cannot be used for assessing complex cognitions, but performance tasks are typically characterized by elaborate, multi-step activities that entail considerable investment of time and involvement with the task.

Validity and Reliability Considerations for Performance-Based Assessment

Although substantial realism in measuring the skill or ability of interest and a high level of engagement with the task are among the valued qualities that contribute to making performance-based assessments appealing to many, there are likewise several psychometric issues that users should keep in mind with respect to the development, scoring, and use of such tasks. Performance-based assessments are unique enough that there are specific considerations that users need to take into account when they implement such tests

for most large-scale testing purposes, and many classroom applications as well.

Validity concerns specific to performance-based assessment have been the focus of many researchers. Although integrating a high degree of realism is an important part of performance-based assessment, the appearance of fidelity to real-life contexts (i.e., face validity) is not enough. The expectation is that performance tasks have meaning, require complex cognitions applicable to real-life problems, minimize the extent to which they draw on ancillary skills, and are rated according to explicit standards. Linn, Baker, and Dunbar describe several potential sources of validity-related evidence supporting the proposed uses of performance tasks, including consequences, fairness, transfer and generalizability, cognitive complexity, content quality, content coverage, meaningfulness, and cost and efficiency.

Another measurement issue for performance-based assessment concerns generalizability across tasks and topics and task specificity. As mentioned above, administrative limitations on testing time often result in performance-based tests that consist of just one or a very small number of tasks. This, in turn, offers a limited sample of behaviors to generalize to the larger domain of knowledge being tested, and it calls into question how broadly or narrowly the larger domain is defined and the extent to which the submitted performance is representative of (or generalizes to) tasks in that larger domain. Similarly, the limited number of tasks included in many performance assessments raises the potential for examinee by task interactions: Because examinees interact with most tasks in some depth for an extended length of time, care must be taken to ensure that tasks are general enough so that the performances are not affected negatively by an unfairly constrained context. For example, on a writing assessment where the skill of interest is descriptive writing, rather than insisting that all test takers expound about highly individual interest-specific topics such as ice hockey or favorite Montana resort towns, tasks should be defined more broadly to ensure that each test taker can reasonably draw from personal experience to complete the task (such as writing about hobbies enjoyed or vacations taken). These concerns

of generalizability and task specificity can be viewed as potential sources of invalidity because they can limit the extent to which inferences about individuals' proficiency in particular content areas can be made.

Another important consideration for performance-based assessment is reliability. Reliability concerns the consistency of test scores across both the administration of testing tasks and the scoring of test takers' responses. In terms of reliability, many performance-based tests are often composed of just one or a small number of highly involved tasks, and although examinees may engage in those tasks in great depth for an extended length of time, in terms of actual measurement opportunities, the yield may be minimal. For this reason, performance-based assessments may not appear to measure up favorably to other assessment formats in terms of traditional reliability expectations, because statistical approaches to reliability (such as computing internal consistency and split-halves) try to estimate how much variability in scores is due to random and systematic error, and how much is due to true ability. These indices benefit from lots of observations: When low reliability estimates are observed on tests composed of multiple-choice items or other such selected-response formats, one common solution is to increase the number of items administered. But because performance tasks are often elaborate in terms of both time and resources, adding tasks may not be feasible in some performance-based testing contexts for practical reasons. In this way, the validity challenge for test developers is to balance traditional expectations about efficiency, reliability, and comparability with other desired assessment qualities advanced by the use of performance-based assessments (e.g., fidelity, complexity, and response freedom).

Whether the performances submitted for evaluation are to be scored using holistic or analytical scoring rubrics, test developers must work to standardize the scoring process as much as possible to ensure that scorers apply the standards for judging performance in a consistent way, and to reduce the opportunities where subjectivity may enter into the scoring process. Procedures should be in place to train individual scorers and thoroughly familiarize them with the rubric being used (including what it does and does not

include), focusing on how to apply it uniformly across all of the performances they rate. Scorers should be monitored throughout for systematic and random deviations from the rubric, and spiraling in previously scored anchor responses can be helpful in this regard for monitoring purposes. Where necessary, remediation should be provided to realign scorers with the rubric. It should be explicit in the rubric what factors of the performance are to be reflected in the score and which are defined as extraneous. For example, is spelling or neatness explicitly defined as a part of the construct being assessed and therefore given weight in scoring? Cost permitting, each performance should be considered by more than one scorer, and another aspect of consistency for test developers to monitor is the extent to which scorers provide ratings of the performances that are consistent with one another. By putting these kinds of measures in place, comparability in scoring across different test takers' performances and across scorers can be maximized to the extent possible.

Conclusions

Ultimately, when performance-based assessments are constructed carefully, administered appropriately, and interpreted properly, they can provide a distinctive, in-depth window into how individuals apply knowledge, skills, and abilities in realistic ways. The possibilities for what can be evaluated encompass a wide range of products and processes, positioning performance-based assessment at the least-constrained end of the continuum of assessment methods ranging from most constrained (multiple-choice and other selected-response formats) to least constrained. Of course, as assessments, performance tasks must aspire to high standards of test quality, but by balancing methodological rigor with construct-driven task development, performance-based assessments permit test takers to engage more thoroughly in many respects with assessment tasks than most tests generally permit, and thus offer test users perspectives on proficiency informed by such engagement, to the benefit of test takers and users alike.

PERITZ PROCEDURE

The Peritz procedure can be applied after a significant overall F test in a one-way ANOVA. A series of additional F tests can be used to determine the significance of the difference between each of the possible pairs of means. Among k means, there will be $k(k - 1)/2$ pairs of means. If the usual assumptions of an ANOVA are satisfied, then the probability of one or more Type I errors is limited to the nominal level, α , of the overall F test. This will be true when each mean is based on the same sample size, N , and when sample sizes differ no matter how large the difference

in sample sizes may be. For a wide variety of conditions, the Peritz procedure is more powerful than any other procedure for pairwise testing of means.

The application of the Peritz procedure can be accomplished by testing all partitions of the k means into subsets. For a particular pair of means to be found significantly different, it must be the case that a significant F test is found for every partition of the k means in which the two means in question are included in the same subset. However, progressively smaller subsets must be tested at more stringent levels. For example, if five means are partitioned into two subsets of the first three means and the last two means, a separate F test would be applied to the two subsets. The first subset would be tested at level $(3/5)\alpha$ and the second subset at level $(2/5)\alpha$. That is, the first subset of three means includes three of the five means. It is tested at $3/5$ times α . The second subset of two means includes two of the five means. It is tested at $2/5$ times α .

If either of these tests is significant at the designated level, then the partition is rejected. Nonsignificance of the partition requires that a number of pairs cannot be significantly different. For example, there are three pairs among the means in the first subset (1, 2), (1, 3), and (2, 3). There is also the single pair in the second subset, (4, 5). All four pairs must fail to differ significantly if both F tests for this partition fail to be significant. Of course, all other partitions must be tested as well.

If the five means are partitioned into three subsets of the first two means, the third and fourth means, and the single fifth mean, then the first two means would be tested at level $(2/4)\alpha$ and the second subset at $(2/4)\alpha$. The denominator of each fraction is taken as the number of means included in subsets of at least two means.

Slightly greater power can be obtained for the Peritz procedure by using slightly less stringent levels in each subset of the partition. For example, consider the case of five means partitioned into two subsets of the first three means and the last two means. Instead of testing the first subset of three means at level $(3/5)\alpha$, it is possible to test that subset at level $1 - (1 - \alpha)^{3/5}$. Similarly, instead of testing the second subset at level $(2/5)\alpha$, it would be tested at level $1 - (1 - \alpha)^{2/5}$. Again, the

partition would be rejected if and only if at least one of the F tests is significant at the designated level.

Consider the data in Table 1, in which four treatment groups are being compared to each other and to a control. Lower scores indicate better performance.

The MS_{WG} for these data is 3.0326 with $df_{WG} = 179$. The ANOVA for these data would give $F = 5.75 > 2.42 = F_{.95}(4,179) = CV$. Therefore, we reject the full null hypothesis at the .05 level and proceed to pairwise testing. Suppose we consider the requirements for finding means 3.18 and 2.24 to be significantly different.

A total of 15 possible partitions must be tested and found significant in order for the difference between these two means to be significant. The first partition is the one in which all five means are together and the full null is tested. In the present case, the second partition has means 1, 2, and 3 together, and means 4 and 5 form a second subset. As shown in Table 2, the second subset of two means also produces a significant F at the appropriate level.

The differences between ordered means are in Table 3. The largest difference is 1.81 between Treatment 4 and the control. The individuals in Treatment 4 have significantly lower average scores than does the control. The second largest difference is 1.28. Those in Treatment 4 are significantly lower than those in Treatment 1.

The difference of .94 between Treatment 4 and Treatment 3 is significant, as demonstrated by the 15 partitions shown above. The original Newman-Keuls procedure cannot be applied because it does not provide accurate control of Type I errors. This difference of .94 would not be found significant when the Shaffer-Welsch modification is applied to the Newman-Keuls using the harmonic mean of sample sizes. The Peritz procedure is shown to be more

PERSONAL PROJECTS ANALYSIS

Personal projects are extended sets of personally relevant action with important implications for human well-being and adaptation. Personal projects analysis (PPA) is a methodology that allows researchers and practitioners to assess the content, appraisal, hierarchical nature, and impact of personal projects. Developed by Brian R. Little in the late 1970s, PPA has been widely adopted as the standard for assessing personal action and goal constructs in diverse fields of study. It is not a test, but an integrated set of flexible assessment modules. PPA is based upon a set of 12 foundational criteria that are prescribed as important to meet before orthodox psychometric criteria such as reliability and validity are addressed. Eight of these are discussed here as being particularly relevant to quantitative assessment methodology.

By way of brief overview, PPA provides a set of modules for (a) eliciting an individual's personal projects, (b) appraising these projects on a set of dimensions that has been selected for both theoretical relevance and applied utility, and (c) assessing additional features of project systems such as their hierarchical structure and impact. We will first discuss the foundational assumptions of the methodology, then describe two of the modules, and conclude with brief comments on the significance of the methodology for contemporary basic and applied research.

Eight Foundational Criteria for PPA

Personal Saliency

The personal saliency criterion requires that the units be personally significant to the individual being assessed and that these units be expressed in their own idiosyncratic language. In contrast with standard

inventories, PPA does not supply instances of the unit of analysis, but elicits them. The personal saliency criterion ensures that individuals can generate examples of the plans and actions they deem important to know if we are to understand their lives.

Ecological Representativeness

Projects are not just personal constructions, they are contextually embedded actions. This criterion requires that an assessment procedure afford an understanding of the person's everyday social ecology. Whereas the personal saliency criterion highlights the subjective importance of personal projects, this criterion illuminates the contextual factors that frustrate or facilitate project pursuit.

Social Indicator Potential

Besides providing information relevant to individuals, we believe that assessment can also provide information relevant to the social ecologies (e.g., workplace, rural area) within which individuals carry out their projects. In short, data derived from PPA have the potential to contribute to the development of social indicators—such as which projects are difficult for elderly people living in rural areas, or which are most enjoyable for inner-city youth. This criterion ensures that the data we gather on individuals and their pursuits are relevant to policy makers who design the contexts within which these pursuits take place.

Temporal Extension

Many assessment devices use units that take “snapshots” of human characteristics; PPA allows the temporally extended nature of daily lives to come into focus. Personal projects typically proceed through stages of inception, planning, action, and termination, although there are individual differences in the extent to which these stages are negotiated. Although much of the research on personal projects is cross-sectional, there is increasing use of longitudinal designs using hierarchical analysis in which we can examine projects embedded within persons, who in turn are embedded in different ecologies.

Joint Idiographic and Normative Measurement

PPA was based on the assumption that both individual-level and aggregate-level information are important aspects of measurement. When projects are rated on appraisal dimensions such as stress and enjoyment, we can measure the relationship between these variables within the single case (measuring across the individual's projects) or between cases (using the mean of the ratings on each dimension per individual). Unnecessarily divisive debates have characterized assessment methodology in terms of whether the appropriate measurement focus ought to be on idiographic or normative concerns. PPA assumes that each approach provides distinctive information of value to the basic researcher and applied analyst.

Systemic Measurement

In their daily lives, people are typically engaged in multiple projects, and these projects form systems. This criterion requires that the measurement device provide ways in which these systemic features of our unit of analysis can be accessed. PPA modules allow us to explore the conflicts and synergies that characterize complex human lives. Although projects are the equivalent of test items in conventional measurement, it is not meaningful to consider the systemic relations among test items in the same way as one does with projects. The latter have a reality status that is discernibly different from that of items.

Modularity

The modularity criterion requires a method to be flexible enough that it can be adapted readily to research situations. For example, unlike conventional testing, where items and scales are fixed, the dimensions upon which individuals appraise their projects can be selected from a standard set of approximately 20 that have broad theoretical utility, or create ad hoc dimensions specially chosen to reflect the particular person and social ecological context being assessed. The appraisal matrix therefore serves as a kind of

system board into which standard or special dimensions can be plugged for appropriate use. Among ad hoc dimensions used in PPA have been “age you feel when engaged in this project” in a study of mid-life transitions and “extent of benefit to others” in studies of volunteering.

Integrative Units

Assessment of cognitive, affective, and conative aspects of human conduct is typically carried out with different instruments, each with its own unit of analysis. In contrast, personal projects provide a natural base for integrating these interrelated features of daily life. In this respect, we think of personal projects as carrier units—a given project carries information about construed action, experienced affect, and challenges to volitional capacity. Similarly, projects carry information about both the individual and the context and can be regarded as transactional units of analysis. The integrative criterion is central to the project analytic endeavor because one of the central problems in contemporary social research is the difficulty of conjoining information derived from different specialty areas. By its modular, systemic, and integrative features, personal projects analysis offers direction for synthesis in diverse fields.

Assessment Modules in PPA

There are four major assessment modules used in PPA, two of which are particularly relevant to measurement issues—the project elicitation and project appraisal modules.

Project Elicitation Module

This requires respondents to generate a list of their personal projects. These can range from “taking out the trash” to “trashing a political opponent.” The content of projects listed is informative and can be examined through traditional procedures of content analysis. The most frequently elicited personal projects are interpersonal projects and either academic or work projects.

Project Appraisal Matrix

In this module, the participant rates each personal project on a set of standard as well as any desired ad hoc dimensions.

More formally, a $j \times k$ matrix is completed by the participant, in which j personal projects are rated on an 11-point Likert scale that ranges from 0 to 10, across k features or dimensions (such as Importance, Difficulty, Challenge, Stress, etc.). Both j and k are variable, with j typically being between 8 and 12, and k between 17 and 24, although these constraints can be varied to suit the particular research question. The data can be analyzed at the single-case level or normatively, the latter approach involving the derivation of k total scores (often taken as the mean of each of the k features across the j projects).

PPA dimension mean scores are often used as predictor variables with diverse measures of well-being, flourishing, and competency as outcome measures. Five theoretically relevant factors emerged from early factor-analytic studies of the correlations among project dimensions: project meaning, structure, community, efficacy, and stress. In meta-analyses of studies using these factors as predictors of well-being and depression, project efficacy and (absence of) project stress were the most reliable predictors. In recent years, in response to the interest in affective processes and project pursuit, we have augmented the appraisal matrix with a larger number of positive and negative affect dimensions. Factor analyses of these matrices have reliably produced dimensions of project meaning, manageability, support, positive affect, and negative affect.

The use of PPA at both idiographic and normative levels raises some important psychometric issues. Until the late 1990s, the studies of PPA that used factor analysis had primarily examined mean-level data within the same study, and so the extent to which between-study differences at the project-system level exist had not been mapped out. Some project-level data had been so analyzed, but results were viewed as possibly biased because of the violation of the assumption of independence of observations. Little pointed out the possibilities inherent in the ipsative

analysis of PPA features and noted that individual correlations within a matrix do not necessarily follow the pattern that obtains normatively. This problem is known more generally as Simpson's paradox, wherein generalizations made on the basis of data analyzed at one level of aggregation may be invalid at different levels of aggregation. For continuous data, correlations computed at the normative level do not logically imply that such correlations must obtain at the individual level. The magnitude, and even the sign, of the correlations can theoretically change when the data are disaggregated, and the mapping is an empirical, rather than a logical, issue. Travis Gee, in a detailed psychometric analysis of the properties of what he termed "project space," demonstrated that there is, in fact, a high degree of isomorphism between the relationship among dimensions analyzed normatively and those analyzed at the individual level. Indeed, in the rare cases where there is a lack of fit with the normative project space, one might be detecting a case of clinical interest.

Implications for Contemporary Basic and Applied Research and Practice

PPA has generated a number of related techniques for the assessment of life tasks, personal strivings, and personal goal pursuit. These have been generally referred to as personal action construct (PAC) units and are a legitimate alternative to more conventional units of analysis, such as traits. PAC units are, in some respects, closely related to some of the social cognitive learning units of analysis that are flourishing both as theoretical constructs and as aids to clinical assessment. Personal projects and other PAC units, however, are pitched at a somewhat higher level of molarity. A priority for both theoretical and applied research is the integration of middle-level units and more molecular cognitive social learning units.

At the applied level, researchers have adopted or adapted PPA to explore problems in areas as diverse as environmental planning, developmental transitions, and moral philosophy. Among the most active adopters of PPA methodology have been researchers

and practitioners in rehabilitation and occupational therapy, where personal projects have been adopted to explore the factors that lead to therapeutic compliance and coping with illness. Notable too, at the other end of the spectrum of human well-being, is that human flourishing can be understood as the sustainable pursuit of core projects. In short, personal projects analysis is a flexible suite of methodological tools designed for the integrative study of human lives in the worst of times and the best.

PERSONALITY ASSESSMENT INVENTORY

The Personality Assessment Inventory (published by Psychology Assessment Resources) is a self-administered, objective measure of adult personality and psychopathology designed to aid in the identification of critical client variables in therapeutic settings. The PAI consists of 344 items and four sets of scales: four validity scales (Inconsistency, Infrequency, Negative Impression, and Positive Impression);

11 clinical scales covering the major categories of pathology corresponding to the *DSM* nosology (i.e., Somatic Complaints, Anxiety, Anxiety-Related Disorders, Depression, Mania, Paranoia, Schizophrenia, Borderline Features, Antisocial Features, Alcohol Problems, and Drug Problems); five treatment scales measuring constructs related to treatment and case management (i.e., Aggression, Suicidal Ideation, Stress, Nonsupport, and Treatment Rejection); and two interpersonal scales (i.e., Dominance and Warmth). Respondents are asked to read each item and decide the self-accuracy of the statements on a 4-point Likert-type scale (i.e., False–Not at All True, Slightly True, Mainly True, or Very True). The PAI generally takes respondents 45–50 minutes to complete.

Unlike similar objective measures of personality and psychopathology (e.g., Minnesota Multiphasic Personality Inventory-2), all of the PAI scales are independent, with no item overlap. Among the combined normative sample, test-retest reliability of PAI clinical scales over an average of 24 days ranged from .79 to .92. This reflects the fact that the instrument taps relatively enduring patient characteristics rather than current clinical state alone. Validity studies have generally found the PAI scales to represent the domains of interest, sufficiently discriminate among clinical symptoms, and correlate with alternate existent measures of personality and psychopathology. Comparative norms exist for general adults, adult psychiatric inpatients, and college students (ages 18 and older).

Although a relatively new assessment instrument, the PAI has gained wide support from researchers, professional trainers, and practitioners. Since its introduction in 1991, the PAI has been included in more than 300 published studies. In addition, the PAI ranks fourth among personality tests employed by graduate training programs and predoctoral internships accredited by the American Psychological Association. With regard to practice applications, and in addition to traditional psychotherapeutic settings, the PAI is widely used in forensic settings and in legal cases involving emotional injury.

PERSONALITY RESEARCH FORM

The Personality Research Form (published by Sigma Assessment Systems) was developed by Douglas N. Jackson to assess Murray's comprehensive system of human needs. The PRF can be viewed as tapping fundamental features of motivation with broad relevance to human behavior across diverse contexts.

Various forms of the PRF are available. A and B are parallel forms and shorter, with only 15 scales. Forms AA and BB are also parallel forms and, like E, contain an additional 7 scales. Form G is the same as Form E but does not contain the Infrequency scale. The scales for forms A, B, AA, and BB contain 20 items each, whereas the scales of E and G contain 16 items each. Forms E and G are by far the most commonly used. The PRF-E contains 20 content scales for assessing human needs and two validity scales (Infrequency and Desirability). Infrequency was designed to assess random or careless responding or invalidity due to poor language comprehension. The Infrequency items are unlikely but not impossible. A score of 4 out of 16 indicates invalidity. Desirability is a measure of the evaluative good-bad dimension in which low scores can indicate an insensitivity to evaluation and high scores represent a propensity to appear favorable. The Desirability scale was also used for item selection. There is no item overlap between any of the 22 scales, and, with the exception of Infrequency, items were selected that correlated more highly with their own scale than any other scale.

The 22 scales of Form E contain 8 items true keyed and 8 items false keyed. Items are ordered to foster local independence by presenting one item from each of the 22 scales, and then this block of 22 items repeats in the same sequence with alternative keying. The 20 bipolar content scales of Form E can be categorized into the following: (a) impulse expression and control (Impulsivity and Change vs. Harm Avoidance), (b) work and play (Achievement and Endurance vs. Play), (c) direction from other people (Succorance vs. Autonomy), (d) intellectual and aesthetic pursuits (Understanding and Sentience), (e) ascendance (Dominance vs. Abasement), and (f) interpersonal relationships (Affiliation, Nurturance, Exhibition, and Social Recognition vs. Aggression and Defence).

The PRF can be administered in paper-and-pencil format with reusable question booklets to individuals or to groups and takes about 35 minutes. In addition to hand scoring, mail-in scoring, and Internet scoring, computerized administration with automated scoring and reporting is also available. Software reports are either clinical with some interpretation or ASCII (text) data file reports for research. The PRF is available in English, French, and Spanish. The reading level is between Grades 5 and 6. Normative data stratified by gender are available separately for juveniles and adults.

PERSONALITY TESTS

The term *personality* is conventionally defined in broad terms to reflect the enduring internal and manifested

features of one's character that influence behavior across different situations and settings. In measuring these internal and manifested features, personality tests are used to assess one's affective, motivational, interpersonal, and attitudinal characteristics, as opposed to one's abilities or achievements. Personality tests can be categorized by the method in which data are obtained (e.g., self-report vs. projective methods) as well as by the type of personality information one wishes to assess (e.g., psychopathological personality assessment vs. nonpathological or normal personality assessment). This entry will provide a brief overview of the issues pertinent to both methods and types of personality tests.

Self-Report Personality Tests

Personality is most commonly assessed by asking respondents to endorse, rank, or otherwise acknowledge that they possess certain characteristics, hold certain attitudes and beliefs, or exhibit certain behaviors by administering one or more self-report personality inventories. Self-report measures provide specific stimulus materials, usually in terms of questions, statements, and descriptor lists. For example, one of the earliest self-report personality tests is the Adjective Checklist. This test consists of a list of more than 300 adjectives or personality descriptors in which the respondent is asked to "check" the ones that are generally accurate descriptions of themselves (examples of adjectives are *happy*, *sad*, *anxious*, *depressed*, *friendly*, etc.). Over the years, self-report inventories expanded beyond simple descriptors to include questions and statements about beliefs, attitudes, and behaviors, including broad measures of personality (e.g., the Minnesota Multiphasic Personality Inventory, the 16 Personality Factors Questionnaire, California Personality Inventory, etc.) as well as more narrowly focused personality measures (e.g., Beck Depression Inventory, State-Trait Anxiety Inventory, State-Trait Anger Expression Inventory).

Development of self-report measures generally involves some combination of rational (or theoretical) empiricism. Items for self-report tests are generated

because they fit what one rationally (or theoretically) believes represents the domain of interest. For example, if one is interested in developing a self-report measure of extraversion, one would begin by constructing items that rationally describe what it means to be extraverted (e.g., I enjoy interacting with a large group of people; I am a very sociable person). Other instruments are designed to measure a specific theory of personality. For example, items on the Millon Clinical Multiaxial Inventory reflect Theodore Millon's theory of personality. Once items are conceptualized (rationally or theoretically), they are then empirically examined within the population. Items are included on the final version of the test because they discriminate consistently and significantly between people who possess or represent the domain of interest (e.g., extraverts) and those who do not possess or represent the domain of interest (e.g., introverts). Thus, self-report personality tests rely heavily on psychometric properties (i.e., reliability, content and construct validity).

One of the most critical issues regarding self-report personality testing is unfair test bias. Test bias is defined as the statistical difference found on test results among groups (e.g., difference found between women and men, difference found among racial or ethnic groups). Bias becomes unfair when the differences in test results among groups are not due to actual difference in the domain of interest, but rather due to some extraneous factor. For example, if the domain of interest is competitiveness, and the test item states, "I like to race in regattas," only people who have knowledge of and had opportunities to engage in yacht racing would endorse this item. Respondents without such knowledge of and opportunities to participate in regattas would not endorse this item, but very well may be as competitive as those who do endorse this item. In this case, the bias may be unfair on the basis of socioeconomic status, and possibly race, ethnicity, gender, and geographic origin. That is not to say that the item does not measure the domain of interest, but rather that the item has differential validity based on various social, cultural, and demographic variables. Thus, when selecting a self-report personality test, it is crucial to inquire about the standardization sample on which the

test was normed, as well as which populations the test has been found to appropriately represent. In addition, self-report inventories are not always appropriate for groups of people who may have difficulty understanding or responding to test material (e.g., children, the elderly, or people with below-average cognitive functioning). In these cases, alternative means of assessment may include interviews, behavioral assessments, or other-report inventories (from teacher, parents, partner, peer).

Projective Techniques

Another method of assessing personality avoids the potential pitfall of having test material that may be more or less familiar to certain groups—projective techniques. Projective personality tests involve presenting respondents with ambiguous stimuli (e.g., inkblots, pictures) and having them provide (or project) meaning or interpretation for the stimuli. The underlying assumption of this method is that the way in which the respondent perceives and interprets the ambiguous stimuli reflects one's personality. Thus, the respondent is free to project any thoughts, feelings, attitudes, or beliefs onto the stimuli and is not limited to responding to a specific set of questions or statements.

Projective techniques evolved out of the psychoanalytic tradition. One of the defense mechanisms for anxiety identified by Sigmund Freud was projection, which is described as placing (or projecting) anxiety-arousing impulses onto other objects (in Freud's theory, these objects were other people). For example, if one is frightened by seeing a snake while walking in the woods with a friend, one may react by saying, "We need to leave because you are scared." Projective techniques operate in a similar manner. For example, on the Thematic Apperception Test, pictures of people in ambiguous situations are presented, and respondents are to tell a story about what is happening in the picture. It is believed that the respondents will project their own feelings, attitudes, and beliefs onto the characters in the pictures.

Although many projective techniques are not scored numerically, as with self-report measures, psychometric

properties remain relevant. Interpretations of one's responses to projective materials need to be consistent across test administrators (i.e., interrater reliability is crucial). With regard to validity, projective stimuli rarely (if ever) have content validity because they are designed to be ambiguous. The type of validity that is most crucial in projective testing is criterion-related validity (i.e., concurrent and predictive). Results of projective testing should yield correspondence to other evidence associated with the domain of interest and should also be predictive of future behavior. Potential test bias is also a critical issue; however, the nature of test bias in projective testing differs from self-report inventories. For projective techniques, bias does not exist with the item or stimulus object, but rather in the interpretation of responses. In interpreting responses to projective material, consideration of cultural, social, and other salient factors must be included. The lack of agreement among professionals about how to interpret projective techniques remains one of the biggest problems with this method of personality testing.

Testing for Psychopathology

In clinical contexts, personality testing is typically used to assess for the presence of psychopathology as well as issues of emotional adjustment. The most widely used measure of personality and psychopathology is the Minnesota Multiphasic Personality Inventory (MMPI; now in its second edition—MMPI-2; also available in an adolescent version—MMPI-A). This is a self-report test designed to assess a broad array of psychological symptoms and is primarily employed as a diagnostic aid (it should be noted that no single test or assessment technique should be the only criterion for assigning psychiatric or psychological diagnoses). Other commonly used broad self-report measures of personality and psychopathology are the Personality Assessment Inventory (PAI); the Personality Diagnostic Questionnaire (PDQ; now in its fourth edition—PDQ-4); the Personality Inventory for Children (PIC; now in its second edition—PIC-2; this inventory is completed by the child's parent or guardian); and the Millon Clinical Multiaxial Inventory

(MCMI, now in its third edition—MCMI-III; this measure has a strong focus on assessing personality disorders). In addition to broad measures of personal pathology and psychopathology, many self-report measures have been developed to assess for specific psychopathological symptoms and disorders. Some of the most common self-report measures used to assess narrow personality constructs are the Beck Depression Inventory (BDI; now in its second edition—BDI-II); the State-Trait Anxiety Inventory (STAI); the State-Trait Anger Expression Inventory (STAXI; now in its second edition—STAXI-2); and the Hamilton Depression Rating Scale (HAMD).

Several projective techniques are also commonly used to assess personality and psychopathology. Projective techniques may be preferable to self-report measures with clients who may have a tendency to misrepresent themselves (regardless of intention). Because projective techniques lack face validity, it is difficult for respondents to fake the "correct" answer. Also, the content of projective responses is generally less important than the themes or patterns of responses. The two most popular projective techniques used to assess for psychopathology are the Rorschach Inkblot Method (RIM) and the Thematic Apperception Test (TAT). Other common projective techniques include sentence completion tests, graphic techniques, and assessments of early memories.

Nonpathological Personality Testing

Personality tests are not always used to assess psychopathology or what is "wrong" with one's personality. Many tests have been developed to assess one's "normal" personality or how one generally interacts with his or her environment. This type of nonpathological, or normal, personality testing arose out of the work of trait theorists, such as Gordon Allport, Raymond Cattell, and others. The underlying philosophy of trait theory is that all people are born with distinguishing personal characteristics and qualities called traits. These traits interact with one's environment, resulting in a variety of outcomes (e.g., satisfying or unsatisfying). The current state of the field generally endorses a five-factor model of personality

(referred to as the “Big Five”): Neuroticism (also referred to by its inverse, Emotional Stability); Extraversion; Openness; Agreeableness; and Conscientiousness. Some of the most popular tests for assessing one’s normal personality traits include the NEO Personality Inventory (NEO-PI, now revised—NEO-PI-R), the 16 Personality Factor Questionnaire (16PF), and the Myers-Briggs Type Indicator (MBTI). In addition to trait-based tests of normal personality, other tests have also been designed to measure salient psychological issues in normal populations. The most prominent of these measures is the California Personality Inventory (CPI). One context in which these types of personality tests have been very popular is in educational and vocational counseling.

PIE CHART

Pie charts are used to illustrate proportions for categorical variables (nominal or ordinal data). An entire pie represents 100% of the measured variable. The sectors of a pie are proportional to the total number. Negative numbers and percentages over 100 are not presented in a pie chart. These charts are sometimes labeled as 100%, cake, circle, or percentage charts.

Figure 1 is a pie chart created with Microsoft PowerPoint that illustrates the percentage of time day cares devote to various activities during a 9-hour day.

The following are options that can be considered when creating a pie chart:

1. Each pie sector has a color and/or pattern that distinguishes it from other pie sectors.
2. The smallest pie sectors must be distinguishable.

Figure 1 Percentage of Activities Pursued in Day Care

3. The largest pie sector starts at the 12 o’clock position.
4. A legend is provided to the right of the pie chart.
5. The percentages can be included either inside or outside each pie sector. They may be placed outside if the small sectors are not large enough to accommodate their size.

PIERS-HARRIS CHILDREN’S SELF-CONCEPT SCALE

The Piers-Harris Children’s Self-Concept Scale (PHSCS), published by Psychological Assessment Resources, is also titled “The Way I Feel About Myself.” It is a self-reported instrument that was designed to be used in research as well as in clinical and educational settings. Thus, the purpose of the PHSCS is to measure conscious self-perceptions in children rather than drawing inferences from perceptions of other people

or behavioral observations. The PHCSCS is an important contribution to the field of self-concept's measuring instruments, because its items portray global as well as particular areas of self-concept prior to the current focal point of multidimensionality.

The test was conceived as a unidimensional measurement device of children's self-concept in connection with six areas of their everyday functioning: Behavior (BEH), Intellectual and School Status (INT), Physical Appearance and Attributes (PHY), Anxiety (ANX), Popularity (POP), and Happiness and Satisfaction (HAP). However, the multidimensional status of the scale has been pointed out in the most recent research. The PHCSCS includes two additional scales, the Inconsistency Index and the Response Bias Index.

The original scale contained 80 items, but a second edition consists of 60 items. Both are answered by a dichotomous "yes" or "no" response (e.g., "I am a happy person . . . yes no"). All the domains of the scale have the same names in both editions, except for two: Behavior has changed to Behavioral Adjustment (BEH), and Anxiety has changed to Freedom from Anxiety (FRE).

The theoretical rationale of its construction is based on the notion that the self-concept expresses both an overall aspect of self and special perceptions that are formed through interaction with other people. More specifically, the reasoning is derived from the following assumptions: (a) The self-concept has a phenomenological nature, (b) the self-concept has global and social elements, (c) the self-concept is relatively stable, (d) the self-concept has appraisable and descriptive elements, (e) the self-concept is affected by developmental considerations, and (f) the self-concept is organized and plays a leading part in motivation.

The PHCSCS measures the self-concept of children ages 8–18 years (Grades 4 through 12), and the test taker will need 30 minutes to complete it. The test can be administered individually or in groups. The scale yields a total score and separate scale scores, both of which are converted to stanines, percentile ranks, and *T* scores.

The PHCSCS has adequate internal consistency reliability, although its test-retest reliability is low and its construct validity is modest.

The instrument is useful for screening purposes in clinical, educational, and research settings.

POISSON, SIMÉON DENIS (1781–1840)

Siméon Denis Poisson was born in Pithiviers, France. In 1825, he was awarded the title Baron, and in 1837, Peer of France.

The story is told that when Poisson was a child, his nanny once suspended him from a nail to protect him from animals prior to leaving him to conduct household errands. In swinging back and forth to release himself, he became interested in the properties of the pendulum, which he later studied extensively.

His mathematical talents were first noticed by Adrien-Marie Legendre (1752–1833) when Poisson was only 17. With Legendre's support, Poisson published a paper on finite differences in *Recueil de Savants Étranges* when he was only 18.

Poisson graduated from École Polytechnique. His teachers were Joseph Louis Lagrange (1736–1813) and Pierre Simon Laplace (1749–1827). He accepted a position at Polytechnique and rose through the ranks as Lecturer (Deputy Professor) in 1802, Professor (1806), and Examiner (1816). In 1808, he gained an appointment as Astronomer at Bureau des Longitudes, and he obtained a joint appointment as Chairman of Mechanics at the Faculté des Sciences in 1809. He was elected to the physics section of the Institut National des Sciences et des Arts (Académie des Sciences) in 1812. He became an Examiner for the École Militaire in 1815.

He published about 400 works, most of which appeared in *Journal de l'École Polytechnique*, *Mémoires*

de l'Académie, and *Connaissance des Temps*. Poisson published in applied subjects, such as heat, celestial mechanics, and magnetism. His name is associated with the Poisson integral (potential theory), Poisson ratio (elasticity), and Poisson constant (electricity). Among his most important works are the *Traité de Mécanique*, with Volume 1 published in 1811 and Volume 2 published in 1833. This masterpiece is remarkable considering Poisson was never involved in conducting experiments.

He also published extensively in pure mathematics. His name is associated with Poisson brackets (differential equations). His major work in probability theory was *Recherches sur la Probabilité de Jugements*, published in 1837, in which he coined the phrase “law of large numbers,” derived from the work of Bernoulli. The major implication is that the binomial distribution tends toward the normal distribution as the number of trials increases, but as the number of successes decreases, the limit becomes the Poisson distribution.

Poisson was a gifted mathematician and teacher. His students included Michel Chasles (1793–1880), Gustav Peter Lejeune Dirichlet (1805–1859), and Joseph Liouville (1808–1882), who led the next generation’s mathematicians.

POISSON DISTRIBUTION

A genesis of Poisson distribution with a misnomer is interesting and intriguing. It was first introduced by de Moivre (1718) rather than French

probabilist Siméon D. Poisson (1837), although the distribution is named Poisson. The Poisson distribution has been frequently employed to explain uncertainty in count data such as radioactive decay, traffic congestion, molecular motions, and so on, as long as it is about rarity. For an example, the number of incorrect answers in a series of questions in item response theory is considered to follow a Poisson distribution by psychologists.

For a chance mechanism to be governed and explained by a Poisson distribution, three assumptions should be validated: (a) The chance of an event occurring is proportional to the size of the time interval, which is usually infinitely small; (b) the chance of two or more events occurring together in that smaller time interval is slim; and (c) what happens in one time interval is stochastically independent of what happens in any other time interval. The probability mass function of Poisson distribution is

$$p(y) = e^{-\lambda} \lambda^y / y!,$$

where $y = 0, 1, 2, \dots$, a collection of observables in the sample space $0 < \lambda < \infty$ constitutes parametric space. The factorial moments $E[Y(Y-1)\dots(Y-k+1)]$ of order k are simply λ^k . Both Poisson events $Y = Y_{mode}$ and $Y = Y_{mode} - 1$ are equally probable when the parameter λ is an integer and equal to Y_{mode} . Otherwise, only the event Y_{mode} is the most probable event.

The Poisson distribution is a member of the linear exponential family. The Poisson probability model for counts data is popularly used to describe rare events, arrival patterns in queuing systems, particle physics, number of cancerous cells, reliability theory, risk, insurance, toxicology, bacteriology, number of accidents, number of epileptic seizures, and number of cholera cases in an epidemic, among others.

A unique property of Poisson distribution is the equality of mean and variance. That is, $\text{var}(Y) = \lambda = E(Y)$. In reality, this unique Poisson property is falsified by Poisson-like data. To match such an anomaly, several extensions of Poisson distribution have been

suggested and used. One such extension is incidence rate restricted Poisson distribution, which was introduced by Shanmugam. However, a square root transformation \sqrt{Y} stabilizes the Poisson variability. When the Poisson parameter, λ , in repeated studies is noticed to be stochastically fluctuating and following a gamma probability density curve, the Poisson random variable, Y , is convoluted with a gamma density curve, and it yields an unconditional probability distribution called an inverse binomial distribution. The zero truncated inverse binomial distribution, with its scale parameter becoming negligible, approaches what is called *logarithmic series distribution*. Ecologists, including the well-known R. A. Fisher, applied logarithmic series distribution to illustrate the diversity of species on earth.

The sum $Y_1 + Y_2 + \dots + Y_n$ of two or more ($n \geq 2$) independent Poisson random variables follows a Poisson distribution with parameter equal to the sum of the parameters, $\sum_{i=1}^n \lambda_i$. Also, the conditional distribution of any one $Y_i = y_i$, given the sum $\sum_{i=1}^n Y_i = t$ of Poisson observations, follows a binomial distribution

$$p(y_i|t, n) = \binom{t}{y_i} \left(\frac{\lambda_i}{\sum_{i=1}^n \lambda_i} \right)^{y_i} \left(1 - \frac{\lambda_i}{\sum_{i=1}^n \lambda_i} \right)^{t-y_i},$$

where $y_i = 0, 1, 2, \dots, t$. Using this property, Shanmugam devised a simple and powerful test statistic to verify whether collected observations have come from an intended Poisson population or a size-biased Poisson population. Actually sampled population sometimes differs from the intended population. In a random sampling, every unit in the population should have an equal chance of being observed. Instead, the unit with a larger value has a greater chance of being observed in the sample, and such imbalanced importance of observing is recognized as size-biased sampling. The size-biased data are realizations of a not intended but actually sampled population.

Whether the Poisson parameters are equal (that is, $\lambda_1 = \lambda_2 = \dots = \lambda_n$) is tested using what is known as *dispersion test statistic* $D = \sum_{i=1}^n (y_i - \bar{y})^2 / \bar{y}$, which follows a chi-squared distribution with $n - 1$ degrees

of freedom. The maximum likelihood (also, moment) estimator of the Poisson parameter is $\bar{\lambda} = \bar{y}$. When $\lambda_1 = \lambda_2 = \dots = \lambda_n$ is true, the sum $\sum_{i=1}^n Y_i = t$ is called *complete sufficient statistic* because the conditional (binomial) distribution $p(y_i|t, n)$ is free of parameter.

Suppose that Poisson distributed counts Y_{11}, Y_{12}, Y_{21} , and Y_{22} with their parameters $\lambda_{11}, \lambda_{12}, \lambda_{21}$, and λ_{22} constitute entries in a 2×2 categorical table in case-control studies. Then, the random variable Y_{11} for given sums $Y_{i1} + Y_{i2} = r_i$ and $Y_{1j} + Y_{2j} = c_j$ follows a noncentral, hypergeometric distribution with noncentral parameter $\delta = \lambda_{11}\lambda_{12}\lambda_{21}\lambda_{22}$.

The mean and variance are equal only in Poisson distribution. Using this property, several characterizations of Poisson distribution within a specified class of distributions have been done. This property is also used as a baseline value to identify and explain the occurrence of a phenomenon called *overdispersion* in data.

Poisson is an extreme case of a binomial chance mechanism under extremely large sample size when the chance of an event is slim in each case. In a random sample of n persons from a neighborhood, the number (Y) of persons among them might have a specific disease if the chance of contracting the disease is $0 < p < 1$. That is, the binomial distribution

$$\Pr[Y = y|n, p] = \binom{n}{y} p^y (1 - p)^{n-y},$$

$$y = 0, 1, 2, \dots, n,$$

converges to Poisson probability mass function as shown below.

$$\begin{aligned} \lim_{\substack{n \rightarrow \infty \\ p \rightarrow 0 \\ np = \lambda}} \frac{n!}{y!(n-y)!} p^y (1-p)^{n-y} \\ &= \frac{\lambda^y}{y!} \left[\lim_{n \rightarrow \infty} \left(1 - \frac{\lambda}{n} \right) \right]^n \left[\lim_{n \rightarrow \infty} \left(1 - \frac{\lambda}{n} \right) \right]^y \\ &\quad \left[\lim_{n \rightarrow \infty} \left(1 - \frac{1}{n} \right) \dots \left(1 - \frac{y-1}{n} \right) \right] \\ &= \frac{e^{-\lambda} \lambda^y}{y!} \end{aligned}$$

Likewise, the inverse binomial distribution

$$\Pr[Y = y|k, p] = \binom{k + y - 1}{y} p^k (1 - p)^y,$$

$$y = 0, 1, 2, \dots, \infty,$$

converges to Poisson distribution when the so-called convolution parameter k is large. In a health screening, suppose a clinical researcher is engaged in searching for persons in a general population until a collection of k persons with a specified illness is identified.

The coefficient of variation (CV) is the ratio σ/μ of the standard deviation to the mean. The CV is scale free and illustrates the variability in the data as a percentage of its mean value. Applied scientists are fond of CV to compare several populations. For examples, CV portrays the effect of a gene in molecular studies, financial risk in stock market studies, income inequality in economics, and ecological improvement in aquatic systems. In Poisson distribution, the CV is $\lambda^{-1/2}$. Poisson and inverse binomial distributions are alternatively used to fit count data, but a comparison of their performances in terms of CV becomes difficult because their domain of possibilities is different in the scale. The CV of inverse binomial and Poisson distributions are respectively $(0, 1)$ and $(0, \infty)$. For the sake of comparing the performances of Poisson and inverse binomial distributions, Shanmugam and Singh introduced a new way of defining CV, and it is $e^{-\lambda}(1 - e^{-\lambda})$ for the Poisson distribution. The CV for the inverse binomial distribution is $(1 - p)^{-k}[1 - (1 - p)^{k+1}]$. Notice that the domain of Shanmugam and Singh's CV for Poisson and inverse binomial distributions are $(0, 1)$, making the comparison easier and meaningful.

For the collected Poisson distributed data on Y and predictor variables x , a Poisson regression or so-called log linear regression can be built with the relation $\lambda = \exp(\beta_0 + \beta_1 x)$, which is called *link function*. An interpretation of this link function is that when the predictor x increases by one unit, the count on Y is expected to increase by an amount e^{β_1} .

When the expected value of Poisson observation, $Y(t)$, in time interval of length t is a time-varying rate $\lambda(t)$, then it is called *nonhomogeneous Poisson*

process, and $\lambda(\tau) = \int_0^{g(\tau)} \lambda(t) dt$ is called *Poisson intensity function*. Suppose for the i th sampling unit, there is a relation like $\lambda_i(t) = \lambda_0 \exp(\sum_{j=1}^k \beta_j x_j)$ with covariates x_1, x_2, \dots, x_k , then λ_0 is called the *baseline value* and the corresponding $\lambda_0[g(\tau)]$ is the *baseline intensity function*. Special cases include *exponential*, *Weibull*, or *extreme-value intensity functions* if $h(\tau) = \tau, \tau^l, e^{\alpha\tau}$, respectively.

Like in several discrete distributions of the mean exponential family, the standardized Poisson variate

$$Z = \frac{Y - E(Y)}{\sqrt{\text{var}(Y)}} = \frac{Y - \lambda}{\sqrt{\lambda}}$$

also approaches the standard Gaussian distribution. The cumulative distribution function $\Pr[Y \leq c]$ is simply the chi-squared survival function $\Pr[\chi_{2(c+1)df}^2 > 2\lambda]$ with $2(c + 1)$ degrees of freedom. Based on the property

$$\ln(y! \Pr[Y = y]) = -\lambda + y \ln \lambda,$$

D. C. Hoaglin and his colleagues devised a graphical technique to verify whether collected data are from a Poisson population. The data are from a Poisson population if the plot of

$$\ln\left(y! \frac{\# \text{ observations} = y}{\text{SampleSize}}\right)$$

versus y is a linear line with intercept and slope equal to $-\lambda$ and $\ln \lambda$. The so-called *damage model* establishes that unless the damaged part D and the undamaged part $Y - D$ follow independently a Poisson distribution with parameters λp and $\lambda(1 - p)$ respectively, the complete observation $Y = D + \text{undamaged}$ follows a Poisson distribution with parameter λ where p denotes the chance for an observation to be damaged. For an example, note that Y and D might be the number of cancerous and successfully eliminated cancerous cells in a laser therapy.

In spite of being the natural choice for data on rare events, the Poisson distribution has failed many times. Shanmugam stated that there is only a 4% chance that the chance mechanism regarding the

number of accidents per day in a location near Virginia State will be a Poisson. With respect to the number of chromatid aberrations in gene mutation analysis, the performance of Poisson distribution has been reported to be worse, even though the data are about rareness. Where does the fallacy occur? Is it due to the lack of equality of mean and variance? To combat such mistrust, what is commonly done in the Bayesian approach is that the Poisson parameter is assumed to follow a probability distribution. This approach results in an inverse binomial distribution, but we part company with Poissonness. Instead, Shanmugam recommends using what is known as *incidence rate restricted Poisson distribution* with a probability mass function

$$\Pr[Y = y|\lambda, \beta] = \left(1 + \frac{y}{\beta}\right)^{y-1} (\lambda e^{-\lambda/\beta})^y / y! e^\lambda,$$

where the incidence parameter λ is restricted by β on the upper side and $y = 0, 1, 2, \dots$. The moment estimate of mean and variance of the incidence rate restricted Poisson are respectively $\hat{\lambda} = \bar{y}^{3/2}/s$ and $\hat{\beta} = \hat{\lambda}/(1-(\bar{y}/s^2)^{1/2})$ where \bar{y} and s^2 are sample mean and variance, respectively. When $\hat{\beta} = \infty$, or, equivalently, $s^2 = \bar{y}$, the above probability mass function of the incidence rate restricted Poisson distribution simplifies to Poisson distribution. This implies that the usual Poisson distribution is appropriate when the incidence parameter is unrestricted. The size-biased incidence rate restricted Poisson distribution with probability mass function

$$\begin{aligned} \Pr[Y = y|\lambda, \beta] &= \frac{y \Pr[Y = y|\lambda, \beta]}{E(Y)} \\ &= (1 - \lambda/\beta) e^{-\lambda(1+\lambda/\beta)} [\lambda e^{-\lambda/\beta} (1 + y/\beta)]^{y-1} / (y - 1)! \end{aligned}$$

was found to fit well with international terrorism data by Shanmugam, where $y = 0, 1, 2, \dots$.

When both the probability mass and the mean functions can be expressed in an exponential format, it has been defined by Shanmugam to be *mean exponential family* (MEF) distributions. A Poisson distribution is a member of the MEF. Using a characterization of MEF, Shanmugam devised a

goodness-of-fit test for an unbiased and a size-biased Poisson sample. That is, a nonnegative random sample y_1, y_2, \dots, y_n of size n could be considered to have come from an intended (or size-biased) Poisson population with $100(1 - \alpha)\%$ confidence level if the standardized score

$$\begin{aligned} z &= \left| \left[\sum_{i=1}^n y_i^2 - n\bar{y}(\bar{y} + 1) \right] / \bar{y} \sqrt{2(n-1)} \right| \text{ or,} \\ z &= \left| \left[\sum_{i=1}^{n^*} y_i^2 - n^*(\bar{y}^2 + 1) \right] / (1 + \bar{y}^*) \sqrt{\bar{y}^*(n^* - 1)} \right| \end{aligned}$$

is less than or equal to $z_{\alpha/2}$, respectively, where $n^* = n - \# \text{ zero observations}$ and $\bar{y}^* = \# \text{ nonzero observations over } n^*$.

PORTFOLIO ASSESSMENT

A portfolio is a systematic, purposeful, and ongoing collection of students' work that exhibits their efforts and achievements in one or more skill domains. The content of a portfolio is created in response to specific instructional objectives and evaluated in relation to those objectives. Although teacher guidance and support are provided, portfolio development is primarily the responsibility of the learner. Portfolio assessment is not a single assessment method, but rather a process of collecting, compiling, and maintaining information from multiple sources to evaluate students' learning and development. This type of assessment places an emphasis on what the learner can do, not on identifying deficits or comparing performance and work products with those of other students. Portfolio assessment is also an effective communication system for conveying information to students, other teachers, and parents about students' progress and unique accomplishments.

Although approaches to portfolio development and assessment may vary, all share several key characteristics. Portfolios reflect explicit learner outcomes, identified in the curriculum and/or by teachers, that students are expected to achieve; they focus on students' performance-based learning experiences as well as their acquisition of knowledge and skills; they contain samples of work that range over an entire grading period, rather than a single point in time (e.g., a single test score); and they include a variety of different types and formats of evidence (e.g., written, oral, graphic, media-based).

Benefits of Portfolio Assessment

Portfolio assessment is an alternative to the use of traditional grading systems and standardized

testing procedures, which may not provide teachers with a clear understanding of students' accomplishments and, often, are not directly linked to instruction. The development of portfolio assessment resulted from concerns surrounding traditional assessment procedures and addressed the need for an assessment method capable of demonstrating what individual students know and what they can accomplish. Traditional assessment practices measure students' ability at one point in time, are usually conducted outside the context of classroom instruction, and may not capture the full range of students' abilities. In contrast, portfolio assessment measures students' ability over time, is embedded within instructional activities, and captures multiple facets of students' performance across diverse skill areas.

There are multiple advantages to portfolio assessment, especially for instructional planning and student progress monitoring. First, portfolio assessment links assessment information directly to teaching and instructional outcomes. Portfolio artifacts are authentic examples of classroom work, not divorced from instructional activities as some test items can be. Portfolio assessment is viewed as *embedded assessment*, that is, assessment in which the assessment tasks are actually part of instruction. As such, portfolio assessment is an effective method to bring assessment in line with instructional goals and provides teachers with valuable information on which to base their instructional decisions.

Second, because the products and evidence are collected over time, portfolios serve as a record of students' growth and progress. Portfolio assessment is longitudinal and continuous, providing both formative (ongoing) and summative (culminating) opportunities for monitoring students' progress toward achieving essential learning outcomes. It provides a comprehensive body of student work that is used to evaluate performance over time.

Third, using portfolio assessment enables teachers to broaden their curriculum to include areas they traditionally could not assess with standardized testing or classroom exams. Portfolio assessment complements teachers' use of innovative instructional

strategies centered around the use of teamwork, group projects, and applied learning. Portfolio assessment is also compatible with individualized instruction and teaching strategies that focus on unique learning styles. Rather than teaching “to the test” and gearing instruction toward achieving high test scores, portfolio assessment encourages teaching and learning to help students acquire and apply new knowledge.

Fourth, a portfolio is a form of assessment that students complete together with teachers. An important dimension of portfolio assessment is that it encourages teacher-student collaboration and actively involves students in the process of assessment. Students are involved in choosing and justifying the portfolio pieces to be included. Portfolio assessment enables teachers to get to know students and promotes joint goal setting and negotiation of grades. It affords opportunities for students and teachers to discuss learning goals and progress toward these goals through both structured and informal conferences.

Fifth, a portfolio enables students to demonstrate their highest quality work, without the pressure of high-stakes testing or time constraints. Portfolios are multidimensional and include many different types of artifacts that demonstrate various aspects of students’ learning and a range of skills. Students can include work at their own level and related to their personal interests; portfolios accommodate different learning styles and allow for demonstration of individual learner strengths. Furthermore, students are empowered to select and justify their portfolio entries, monitor their own progress, and establish learning goals. The empowerment of students to demonstrate their achievements and personal accomplishments through portfolio assessment has been shown to enhance student motivation. Few traditional assessment practices afford students the opportunity to assume an integral role in their own learning and evaluation. Students feel a pride of ownership of their portfolio work, and they see the personal and academic relevance of the work they have completed. Most importantly, students value themselves as learners as they proceed through the

portfolio process of selecting work and reflecting on each piece.

Implementation of Portfolio Assessment

Implementation of portfolio assessment involves two basic components, portfolio development and portfolio evaluation. The development of a portfolio occurs across three distinct phases. During Phase 1, Organization and Planning, students and teachers collaborate to organize and plan the development of a student’s portfolio. Questions for students to address during this planning phase include the following: How do I select work samples to reflect what I am learning? How do I organize and present the work I have collected? How will I maintain and store my portfolio? Phase 2, Collection, involves the collection and compilation of work products that reflect the student’s accomplishments and attainment of educational goals. Portfolios may consist of a variety of written, oral, graphic, or media content that demonstrate progress over time, including notes, videotapes of presentations, photographs, logs, written summaries, and samples of work. Students may also be evaluated on projects or assignments completed in pairs or small groups of students. Phase 3, Reflection, is a critical feature of portfolio development. During this phase, students engage in self-reflection on the learning process and their developing knowledge and skills. Students are required to evaluate their own progress and the quality of their work in relation to targeted goals or competencies. By reflecting on their own learning, students begin to identify their strengths and weaknesses. Identified weaknesses become goals for improvement and future learning. Student reflections may take the form of learning logs, reflective journals, or self-ratings. When possible, teacher and parent reflections on the student’s products and learning are also included in a portfolio.

For effective evaluation of a portfolio to occur, teachers must have scoring criteria in place that are clearly communicated and understood by students. The criteria for assessment of the portfolio contents is articulated at the outset of the process. Portfolio

evaluation is based on multiple criteria, such as the student's growth and development in relationship to curriculum expectations and goals; his or her understanding of key concepts; the comprehensiveness, accuracy, and relevance of work products; diversity of entries; and thoughtfulness of self-reflections and justification of the selected artifacts. Scoring keys, rules, or rubrics are designed for portfolios and shared with students prior to evaluation. Letter grades, combined with evaluative feedback, may be assigned to portfolios based on the scoring rubric. Finally, a form of oral interview or discussion between the teacher and student is often included as part of the portfolio evaluation process.

Conclusion

Portfolio assessment fits well with the growing trend in education toward monitoring and promoting all students' progress toward achievement of targeted outcomes. Portfolio assessment improves upon traditional student testing practices by revealing a range of skills and understandings. Portfolio assessment supports instructional goals, reflects students' progress and growth over a period of time, and encourages students' self-assessment and self-directed learning.

POST HOC COMPARISONS

Post hoc comparisons among sample means from three or more groups are generally performed only after obtaining a significant omnibus F when we use an ANOVA. After we find the various means are not all equal, the second step is using post hoc comparisons to find out exactly which means are significantly different from which other ones. In contrast to a priori comparisons, which are chosen before the data are collected, post hoc comparisons are tested after the researcher has collected the data.

Post hoc comparisons include pairwise comparisons and nonpairwise comparisons. Pairwise comparisons compare two sample means at a time, whereas nonpairwise comparisons compare more than two sample means at a time.

The main post hoc comparison procedures include Scheffé procedure and Tukey HSD (honestly significant difference) procedure. The Scheffé procedure allows for a comparison of all possible paired comparisons and complex comparisons between combined means.

The formula for the Scheffé test is as follows:

$$F_c = \frac{(\sum C_j \bar{X}_j)^2}{(MS_W) \left(\sum \frac{C_j^2}{n_j} \right)},$$

where

Σ , the Greek letter sigma, is the summation sign;

C_j is the coefficient used for any group;

\bar{X}_j is the mean of the corresponding group;

MS_w is the mean square within from the analysis of variance.

The Tukey HSD procedure only allows for a comparison of the possible pairs of means. The formula for the Tukey HSD test is as follows:

$$HSD = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{(MS_w/2)(1/n_1 + 1/n_2)}}$$

where

\bar{X}_1 and \bar{X}_2 are two sample means that are needed for comparison,

MS_w is the mean square within from the analysis of variance,

n_1 is the number of scores of Group 1,

n_2 is the number of scores of Group 2.

For example, the data set in Table 1 consists of 10 cases with two variables, Group and Test Score.

To produce the post hoc comparison, follow these steps:

1. Compute the sample mean for each group.

	<i>Group 1</i>	<i>Group 2</i>	<i>Group 3</i>	<i>Group 4</i>
Mean	9.70	10.70	9.80	7.10

2. Check the assumption of equal variance.

<i>Levene Statistic</i>	<i>df1</i>	<i>df2</i>	<i>Sig.</i>
1.429	3	36	.250

To test the null hypothesis that groups come from populations with the same variance, the Levene test is produced. The observed significance level is larger than .05. The null hypothesis is not rejected. Four groups come from populations with the same variance.

3. Produce ANOVA to get the omnibus *F* test.

The null hypothesis of the *F* test is that all the population means are the same.

According to the results of the *F* test, $F(3,36) = 5.382, p = .004, p < .05$, so we reject the null hypothesis, and the four population means are not all equal.

4. Use post hoc comparison to determine which means are significantly different from each other.

The results of the Scheffé procedure show that only Group 2 and Group 4 are significantly different from

each other, whereas the results of the Tukey HSD procedure show that Group 4 is significantly different from Group 1, Group 2, and Group 3. The reason is that the Scheffé test is more considerate than the Tukey HSD test in holding Type I error low.

The SPSS output is shown in Tables 2 and 3.

POSTERIOR DISTRIBUTION

The term *posterior distribution* refers to a probability density function for an unobserved or latent variable, θ , based on the observed data, x , used in Bayesian statistical analysis. In Bayesian data analysis, inferences are made on the basis of the posterior distributions of parameters. Bayes’ theorem is generally phrased in terms of distributions of observed and unobserved variables:

$$f(\theta | x) = \frac{f(x | \theta)f(\theta)}{f(x)}$$

By using this formulation of Bayes’ theorem, statisticians are able to make inferences about some parameter of interest, θ , given the observed data, x . Therefore, under the framework of a Bayesian data analysis, statistical inferences are based on a quantity that is of direct interest to the analyst (i.e., θ), not some proxy for that quantity of interest (i.e., the data, x).

In order to estimate the posterior distribution and make inferences about it, three pieces of information are required: (a) estimation of the function, $f(x | \theta)$, often termed the “likelihood function,” which represents a statistical model that has been fit to the distribution of observed data, x , given the underlying parameter, θ ; (b) estimation of $f(\theta)$, referred to as the “prior distribution,” which represents either the empirical or expected distribution of the parameter, θ , in the population, and (c) estimation of $f(x)$, which represents the empirical distribution of the observed data, x .

Inferences from the posterior distribution are typically made by determining point estimates for θ , either by finding the mean of the posterior distribution (referred to as an “expected a posteriori” estimate) or by determining the mode of the posterior distribution

(referred to as a “modal a posteriori” estimate). The standard error of θ is determined by estimating the standard deviation of the posterior distribution.

PREDICTIVE VALIDITY

There are several different types of validity, all of which are used to establish a test’s “truthfulness,” or whether the test does what it is supposed to do (the main claim of validity). Among the many different kinds of criterion validity, a subset is concurrent and predictive validity.

Predictive validity allows the measurement specialist to judge how well a test predicts future performance. The interest is in whether the instrument can predict what it theoretically should be able to predict.

For example, the following outcomes would characterize test and measurement tools that have predictive validity.

- A math test predicts future performance in an occupation where sophisticated mathematical skills are essential, such as engineering or computer science.
- A test of spatial skills predicts future performance in an occupation where the ability to visualize in more than two dimensions is essential, such as mechanically oriented tasks and professions.
- A test of personality predicts the configuration of personal skills that might be needed to succeed in a particular profession, such as hotel management.

What these three hypothetical statements have in common is that each of the tests that is developed is predictive of a later outcome (which is the criterion) and hence, if they do their job, they have predictive validity.

Predictive validity is most often established through the simple Pearson product-moment correlation

computed between the test itself and the criterion. To then establish the predictive validity of the mathematics test mentioned above, test scores would be collected and then correlated with some criterion used to evaluate engineering skills a certain number of years later. That simple zero-order correlation indicates the strength of the association between the test and the criterion and, hence, the predictive validity of the test.

PRESCHOOL LANGUAGE ASSESSMENT INSTRUMENT

The Preschool Language Assessment Instrument (PLAI-2), published by PRO-ED (www.proedinc.com), is a nationally standardized tool for assessing children's discourse abilities. It consists of 70 items that are classified in terms of four levels of abstraction (matching, selective analysis, reordering, and reasoning) and two modes of responding (receptive and expressive). Items from each category are interspersed to simulate the demands of classroom discourse. The test, which takes about 30 minutes to administer, is intended for children between 3 years, 0 months to 5 years, 11 months. Scoring procedures classify responses according to the levels of abstraction and modes of responses yielding scores for six subtests for 4- to 5-year-olds. Reordering and reasoning are combined for the 3-year-olds, resulting in five subtests. The inclusion of normative data permits evaluation of whether children's classroom discourse skills are developing normally. The test also permits identification

of strengths and weaknesses and documentation of change over time.

The four levels of abstraction represent increasing levels of difficulty encountered in classroom discourse. Receptive and expressive items are included in each level. Matching, the lowest level of abstraction, involves naming items (e.g., "What is this?"), pointing to named items (e.g., "Find me a cup"), following directions, or imitating. Some items require visual matching and visual memory. Selective Analysis, the next level of abstraction, requires selective attention to visual detail. The receptive items require understanding descriptions (e.g., given a picture, "show me what we use for cleaning dishes" or "find something we could eat with"), following multistep directions, and identifying differences. The expressive items involve answering a variety of *Wh* questions (e.g., *who*, *what*, *where*, *how*, *which*, and *what is happening*) in response to pictures or a brief narrative. Auditory memory, integration, and classification are required for successful responses at this level. The third level of abstraction, Reordering, requires overriding perceptual clues while selecting or identifying multiple features in a picture (e.g., "If I wanted to paint a picture, show me all the things I don't need"). This level also requires identifying similarities, defining words (e.g., "Tell me what a fork is") or solving class inclusion problems. The highest level of abstraction, Reasoning, requires predicting events under specified conditions (e.g., "Given a stack of blocks, select the picture that shows what will happen if the bottom block is removed"). The responses at this highest level specify predictions, logical justifications, and causal relations.

Raw scores for each subtest are converted into scaled standard scores, percentile ranks, descriptive ratings, and age-equivalent scores. Scaled scores for the receptive and expressive subtests are converted into an overall Discourse Ability Score. The expressive responses are also scored in terms of four levels of adequacy and six types of interfering behaviors. The authors describe these latter types of scores as measures of pragmatic aspects of communication.

An original 165-item version and a more practical 60-item experimental edition of the test were

developed in 1978. The original versions and the current revised test are based on a model of classroom discourse in which a child is required to respond to varying levels of abstraction. At the lowest level, language is connected to concrete perceptions, whereas at the highest level, language is used to reflect upon perceptions. The PLAI-2 has expanded the number of items from 60 to 70. It has added normative data representative of the 2000 U.S. population, full-color illustrations, new reliability and validity data, as well as two additional scales related to adequacy of responses and interfering behaviors. Reported data indicate that the overall Discourse Ability Score meets current minimum standards for test-retest reliability.

At the present time, published literature on the test refers to the original versions. A positive feature of the test is the focus on assessing classroom discourse skills. Issues regarding validity are discussed in Skarakis-Doyle, Miller, and Reichheld.

The manual for the PLAI-2 addresses some of the issues raised in the review.

PRINCIPAL COMPONENT ANALYSIS

Principal component analysis (PCA) is a multivariate analysis technique whose goal is to reduce the dimensionality of a large number of interrelated variables. It belongs to the class of projection methods and achieves its objective by calculating one or more linear combinations of the original set of maximum variance. This criterion implies that the directions of maximum variability in the data are those of interest. PCA is a fairly old technique, because its basic formulation can be traced back to the work of Pearson, whereas its usual algebraic derivation is found in the work of Hotelling. Moreover, for time series data, it corresponds to the Karhunen-Loeve decomposition of Watanabe. In its basic formulation, PCA is most suitable for numerical data; however, extensions to categorical data have been proposed in the literature, together with some generalizations suitable for data exhibiting nonlinearities. PCA has been proven to be a very successful dimension reduction technique, widely used in many scientific fields.

PCA Formulation

Data on K variables have been collected for N objects. The data are organized in an $N \times K$ matrix \mathbf{X} . We will denote the variables by $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_K$ that correspond to the columns of the data matrix \mathbf{x} . It is customary to work with *standardized* versions of the variables—that is, $\text{Mean}(\mathbf{X}_k) = 0$ and $\text{Var}(\mathbf{X}_k) = 1$, $k = 1, \dots, K$, the reason being to avoid the scale (range) of the variables to affect the results.

PCA constructs linear combinations of the original variables $\mathbf{y}_j = \mathbf{X}\mathbf{w}_j$, $j = 1, \dots, K$ that have maximum variance. Collecting the \mathbf{y}_j variables in a matrix $\mathbf{Y} = \mathbf{X}\mathbf{W}$, the PCA problem can be written as

$$\max_{\mathbf{W}} \text{Cov}(\mathbf{Y}) = \max_{\mathbf{W}} (\mathbf{W}^T \mathbf{R} \mathbf{W}), \quad (1)$$

where \mathbf{R} denotes the correlation matrix of the data matrix \mathbf{X} . It is further required that $\mathbf{W}^T \mathbf{W} = \mathbf{I}$, in order to identify a unique solution. An application of the Rayleigh-Ritz theorem shows that by performing an eigenvalue decomposition of $\mathbf{R} = \mathbf{U}\mathbf{A}\mathbf{U}^T$

and setting $\mathbf{W} = \mathbf{U}$, the optimal weight matrix \mathbf{W} is obtained. Hence, the j th column of \mathbf{W} corresponds to the eigenvector of \mathbf{R} associated with the j th largest eigenvalue.

The y_j variables are called the principal components. Some of their properties useful for understanding and interpreting PCA are outlined next.

- The principal components have mean zero and are uncorrelated.
- The variance of the j th principal component is given by the corresponding eigenvalue; that is, $\text{Var}(\mathbf{y}_j) = \lambda_j$.
- The correlation of the j th principal component with original variables is given by $\text{Corr}(\mathbf{y}_j, \mathbf{x}_i) = \sqrt{\lambda_j} w_{i,j}$. The latter quantity is called the *factor loading*.
- The proportion of total variance explained by each principal component is given by $\lambda_j / \sum_{j=1}^p \lambda_j$.

Remark: The above presentation took a data centric point of view. An alternative derivation could have been based on a population point, with \mathbf{R} corresponding to a known population correlation matrix.

Remark: Over the years, a considerable amount of work has been devoted to deriving the probability distribution of sample principal components and their variances. The results are mostly asymptotic, and they are often based on the assumption that the original set of variables follows a multivariate normal distribution.

Remark: The derivation of PCA was based on the sample correlation matrix. However, if one decided not to standardize the data, then the optimal weights \mathbf{W} correspond to the eigenvectors of the sample covariance matrix. Unfortunately, there is no straightforward mathematical relationship that links the two analyses, namely, that based on the correlation matrix and that based on the covariance matrix.

PCA is illustrated next using a data set that gives crime rates per 100,000 people for the 72 largest U.S. cities in 1994. The variables correspond to the following seven crimes: murder, rape, robbery, assault, burglary, larceny, and motor vehicle thefts (MVTs). Because of the disparity in the scale of the variables, PCA was based on the correlation matrix of the data. The first two eigenvalues accounted for 54% and 17% of the total variance, respectively.

The optimal weights \mathbf{W} of the crime variables for the first two principal components are given in Table 1.

A projection of the 72 cities on the space spanned by the first two principal components is shown in Figure 1.

Looking at the weights of the first two principal components, it can be seen that the first one can be interpreted as an overall measure of crime activity. With this interpretation in mind, the cities on the right side of the plot, such as St. Louis, Atlanta, Tampa Bay, Newark, Detroit, and Miami, can be characterized as high-crime cities, whereas cities appearing on the left side, such as Virginia Beach, San Jose, Colorado, and Honolulu, can be characterized as low-crime cities. On the other hand, the second principal component distinguishes between cities with high rape and larceny incidents (and to some degree, burglaries) and cities with high murder, robbery, and MVT incidents. So, on the bottom of the picture, we find cities such as Newark; Jersey City; Philadelphia; Santa Ana; Detroit; Washington, DC; New York City; Chicago; and Long Beach characterized by relatively more murder, robbery, and MVT crimes, whereas in Oklahoma City, Corpus Christi, Tucson, and Minneapolis, rapes and larcenies are more frequent. However, one should be careful regarding how far to proceed with this interpretation. For example, it is appropriate to make such statements for Newark and Detroit, which score high on the first component as well. On the other hand, the situation is not that clear for cities like Santa Ana, whose score is fairly low on the first component. Nevertheless, the second component allows one to distinguish between Corpus Christi and Santa Ana, which score similarly on the first component. Therefore, the

Generalizations of PCA

A variation of PCA is suitable for performing dimension reduction to categorical data. The corresponding version of the technique is known as *multiple correspondence analysis*.

Other generalizations try to deal with the presence of nonlinearities in the data. Some of these approaches are principal curves, local PCA, and kernel PCA.

Hastie and Stuetzle proposed the concept of a principal curve, where the data are mapped to the closest point on the curve, or, alternatively, every point on the curve is the average of all the data points that are projected onto it (a different implementation of a centroid-like principle). The regular PCA solution produces the only straight lines possessing the above property.

Local PCA attempts to preserve the conceptual simplicity and algorithmic simplicity of PCA in the presence of nonlinearities. One implementation first uses cluster analysis to group the data and subsequently applies different principal component analyses to the various clusters.

Finally, the main idea behind kernel PCA is that nonlinearities in the original data essentially disappear if the data are projected onto some higher dimensional space, at which point regular PCA becomes an effective solution. Although this idea is contrary to the spirit of PCA as a dimension reduction technique, it has nevertheless enjoyed some success in application areas such as handwritten digit recognition. In order to make this idea computationally tractable, kernels (to some extent, they can be thought of as generalizations of a covariance function) are used, which essentially calculate inner products of the original variables. It should be noted that kernels are at the heart of support vector machines, a very popular and successful classification technique.

PRIOR DISTRIBUTION

The term *prior distribution* refers to an empirical or expected probability density function used in

Bayesian statistical analysis, which represents an analyst's belief about the distribution of an unobserved parameter, θ , in the population. In Bayesian data analysis, inferences are made on the basis of estimated probability distributions for unobserved or “latent” variables based on observed data. Bayes' theorem is generally phrased in terms of distributions of observed and unobserved variables:

$$f(\theta | x) = \frac{f(x | \theta)f(\theta)}{f(x)}.$$

By using this formulation of Bayes' theorem, statisticians are able to make inferences about some parameter of interest, θ , given the observed data, x . This density function, $f(\theta | x)$, is referred to as the *posterior distribution* of θ , and it represents a probability density function for the latent variable, θ , based on the observed data, x . In this formulation, $f(x | \theta)$ is the “likelihood function,” which represents a statistical model that has been fit to the distribution of observed data, x , given the underlying parameter, θ . $f(x)$ is the empirical distribution of the observed data, x , and $f(\theta)$ is the prior distribution for the unobserved parameter, θ .

Whereas $f(x | \theta)$ and $f(x)$ are quantities estimated using observed data, the prior distribution, $f(\theta)$, is typically unobserved and therefore must be selected by the analyst based on a belief about how the parameter θ is distributed in the population. Selection of an appropriate value for a prior distribution is therefore critical to the accuracy of results from a Bayesian statistical analysis.

Bayesian procedures incorporate information from the prior distribution in order to make inferences. Generally speaking, the prior distribution for θ is an unobserved probability density function that must be estimated somehow by the analyst. Often, this can be done by making some reasonable assumptions about the distribution of θ in the population, or by collecting data and empirically estimating this function. Because the statistician can never be sure that the particular choice of a prior distribution is accurate, one criticism of Bayesian statistics is that one cannot be sure how well the posterior distribution represents the distribution of θ given x . The impact of the prior distribution on the final results of the analysis (i.e., the posterior

distribution) will vary depending on the statistician's choice for the distribution. Prior distributions that have significant influence on the posterior distribution are referred to as relatively "informative," whereas prior distributions with relatively little influence are called "non-informative" priors. For this reason, analysts tend to choose relatively non-informative prior distributions in situations where they are less confident about the distribution of θ in the population.

PROBABILITY SAMPLING

Probability sampling is the term used to describe sampling where the probability of a population unit being selected in the sample is known. In nonprobability sampling, this probability is not known. When probability sampling is used to survey a population, population parameters can be inferred from the sample. Examples of probability sampling are simple random sampling, stratified sampling, and cluster sampling. In all of these examples, the probability that an individual unit is selected in the sample can be calculated.

For simple random sampling (without replacement), the probability that a unit appears in the sample is the same for every unit and is n/N . Consider a population of size five, say, five children. A simple random sample of size three is selected. This could be done by writing the children's names on five separate balls and putting the balls in an urn. The balls are mixed well and three balls are drawn out. The balls are all equal in size, shape, and weight, and so each ball will have an equal chance of being selected. The number of possible samples that could be selected is

$$\binom{N}{n} = \binom{5}{3} = 10.$$

The probability that an individual unit i is selected in the sample is

$$\frac{\binom{N-1}{n-1}}{\binom{N}{n}} = \frac{6}{10} = \frac{3}{5},$$

where

π_i = number of samples that include the unit,

i = number of possible samples.

The numerator in this equation uses $N - 1$ and $n - 1$. If the sample includes unit i , then there are $N - 1$ units left in the population from which to choose the remaining sample of size $n - 1$. In the sample of children, after choosing the first ball out of five, there are only four balls left to choose the second ball and three balls left to choose the third ball in the sample. With probability sampling, sampling theory then can be used to estimate the sample mean, and the variance of the sample mean to infer the population mean.

Nonprobability sampling is called *haphazard sampling*, *convenience sampling*, and *judgment sampling*, among other terms. Examples of nonprobability sampling would be to stand on a street corner and interview pedestrians who walk by when the population of interest is all citizens who live in the city, running survey lines in a forest adjacent to roads when the population of interest is all the forest, and surveying only those businesses that appear to be representative. The samples could, in fact, give informative and reliable results. Pedestrians who walk may be representative of all the citizens, the forest adjacent to the road may be representative of the entire forest, and the judgment of what are representative businesses may be correct. However, without using probability sampling, sampling theory cannot be used, and there is no way of knowing if the resultant samples are informative and reliable. It is not possible to estimate how accurate the samples are or how precise they are.

PROFILE ANALYSIS

In psychological research, there are many instances in which the goal is to classify people as belonging to certain groups. Personality researchers often search for evidence of personality types, some intelligence researchers search for evidence that people exhibit different types of intelligences, and so on. The term *profile analysis* is used to represent a variety of techniques that share the common goal of empirically classifying individual observations into distinguishable groups based on common characteristics measured by observed variables. Strictly speaking, it is not a statistical technique because no inferences are being made to population parameters. Rather, profile analysis is a data reduction technique. It is conceptually similar to factor analysis, but the difference is that the focus in profile analysis is on grouping people (or observations) on the basis of common traits measured by observed variables.

The two major approaches to profile analysis are quite different from one another conceptually, but they share the same goal of grouping cases based on observed variables. The first approach is based on correlation methods, such as Pearson's r or Spearman's ρ . The goal under this approach is to group cases together that show similar patterns of spikes and dips across variables (i.e., the same shape), regardless of the absolute level of the scores (see Figure 1). Under the correlational approach, Persons A and B would be classified as belonging to one group (or profile) and Persons C and D to another.

By contrast, a second approach to profiling participants is based on measures of distance, such as Euclidean distance or Mahalanobis's distance (see Figure 1). Here, the emphasis is on creating groups based on the extent to which case scores are close in absolute value (i.e., level), regardless of the similarity

Figure 1 Examples of Different Score Profiles

of pattern shape. Under the distance approach, Persons B and C would be classified as belonging to one group and Persons A and D another.

Key Assumptions

There are two key assumptions of any profile analysis:

1. The sample is representative of the population.
2. There is a minimum of multicollinearity in the data. The reason that this is problematic is that variables that are collinear receive more weight in the solution.

The Case Study and the Data

Consider a practical example in which students were administered an experimental Advanced Placement test in Psychology. The test consisted of items primarily tapping one of four cognitive processing skills: memory processing, analytical processing, creative processing, or practical processing. The researchers were interested in examining the extent to which students showed different profiles of strengths and weaknesses across these four processing skills. Consequently, a Q-factor analysis (a correlation-based profile analysis) was performed on the students who took the test to determine the extent to which different profiles of achievement were observed. Using a principal component analysis (of the cases, not the variables), the researchers arrived at a solution yielding

six general profiles in the data. Overall, the researchers were able to group each of the 1,262 cases in the data sets as belonging to one of the six empirically distinguishable profiles.

PROJECTIVE HAND TEST

The Hand Test is a projective test consisting of a set of 10 cards approximately 3 inches by 5 inches in size. The first nine cards portray a hand in an ambiguous position, and the tenth card is blank. The cards are presented one at a time with the question, “What might this hand be doing?” The tenth card is blank and is given to the subject with the instructions: “This card is blank. I would like you to imagine a hand, and tell me what it might be doing?” Subjects are not limited in the number of responses they give to any individual cards or the entire set; however, subjects are encouraged with the instruction “anything else?” if they give only one response to the first card. The Hand Test elicits responses that reflect behavioral tendencies. Specifically, the Hand Test measures reactions that are close to the surface of personality, and reactions that are likely to be expressed in overt behavior. The administration time is typically brief (approximately 10 minutes) and the Hand Test is meant to supplement other material in a test battery. The Hand Test can be used with anyone old enough to verbalize a response (age 5+ years).

To score the Hand Test, the clinician simply classifies the responses according to clear-cut quantitative

scores (such as Aggression, Exhibition, Communication, Dependence, Acquisition, Tension, and Withdrawal), which reflect the person’s behavioral action tendencies in terms of how they interact with others and the environment. The qualitative scores generally reflect feelings and motivations underlying the expressed action tendencies. The Hand Test also consists of six summary scales, such as an index of overall pathology and an acting-out ratio, which is used to predict aggressive behavior.

Since its development in 1962, the Hand Test has been administered to more than a million people. The Hand Test manual was revised in 1983 and provides means, cutoff scores, and typical score ranges for normal adults and a number of diagnostic/clinical groups such as schizophrenia, mental retardation, organic brain syndrome, anxiety disorders, affective disorders, somatoform disorders, older adults, and personality disorders. A manual supplement provides norms for 5- to 18-year-olds and offers guidelines for interpreting child and adolescent responses and for integrating the Hand Test into a standard psychoeducational evaluation. Extensive research (more than 40 years’ worth) and independent reviews comment favorably on the Hand Test’s reliability and validity.

PROJECTIVE TESTING

Testing is a form of precise measurement. Some tests are merely exact observations. Others involve

manipulation of the environment and a cataloging of results or reactions. Projective testing goes one step further: Stimuli are presented, reactions are monitored and recorded, and then aspects of personality are deduced from these responses. The projection involved here is actually two-fold: It is used to refer, by some, to the deductive process of the examiner, and it also is used to hypothesize the process by which the respondent is assumed to have arrived at the response by projecting material of which he or she is unaware.

There are areas of behavioral testing where self-report and observations are heavily relied upon by the diagnostician. However, the assessment of personality, psychopathology, and character disorder does not readily lend itself to observation at an evaluation. At the same time, reports of symptoms (by significant others, or even by trained professionals) are often too inexact and complicated to be reliable. Self-report by the client himself or herself is subject to distortion, defensiveness, and misinterpretation. This is the realm of projective testing.

The logic of projective testing has several foundations. Its logic is inferential, whereas its technique is psychodynamic. In practice, the process of assessment relies heavily on the unconscious and, to some extent, on defense mechanisms. Of the latter, the defense of projection is most crucial, as one might expect from the name of the testing approach. The elements of this defense mechanism entail the tendency for a person to find unacceptable aspects of his or her personality manifestations elsewhere. Dynamically, the person is consciously unaware of these aspects, but is unconsciously troubled by them. The ability to maintain consistent repression of these threatening aspects is enhanced by projecting them onto other persons or situations.

Reality and psychological functioning levels often dictate the possible breadth and parameters of projection. Although a nonpsychotic individual who is unconsciously tormented by repressed aggressive impulses is not likely to see the devil on the bus, he or she may interpret comments as more aggressive than they actually were. However, the more ambiguous or undefined a situation is, the greater the possibility for it to become the object of projection.

Projective tests differ in the degree of ambiguity versus definitiveness of their stimuli. These aspects circumscribe the realm of these tests respectively. Below is a presentation of the major contemporary projective tests, each representing different points on this continuum.

The Rorschach is perhaps the best known test in this realm. It consists of 10 (horizontally symmetrical) inkblots featuring variations in color, shading, and forms. It represents a fairly nondefined set of stimuli, where respondents can hardly be “defying reality” regardless of what they reportedly perceive. As such, it enhances and encourages projection to a significant degree.

Contrary to common assumptions, the content of Rorschach responses is barely relevant in interpretation. Instead, there exists a complex scoring system of many composites and ratios, featuring such elements as location choice, form accuracy, three-dimensionality, color categories, shading, texture, organization of disparate parts, symmetry, and others. The significance of these elements was originally spelled out by armchair analysis, essentially reflecting experts’ opinions of the assumed projective origin of the elements. This is no longer the case. Empirical correlational research has revolutionized Rorschach methodology, so that the interpretations of elements and ratios are based almost totally on meticulously collected data. Today, Rorschach enjoys high scoring reliability and strong interpretive validity. Indeed, it is reasonable to question whether the Rorschach should still be classified as a projective test, because most of its current interpretive base is clearly operationalized and does not require any projective theory to formulate findings. It is noteworthy that Rorschach interpretations have a wide scope: from cognitive processes, to reality testing, to emotional control, to psychiatric diagnoses, and beyond. Furthermore, face validity of the test is not high. This implies that typical respondents cannot easily intuit what the test elements are intended to measure. As such, it is less susceptible to deliberate distortion or “faking” by respondents.

The Thematic Apperception Test (TAT) is another classic projective test that has evolved well beyond its

original intent. It consists of a collection of cards and drawings, most of which contain people in various forms of interactions or emotional contexts. First designed to elicit a hierarchy of psychological needs, this test has been usurped by psychodynamic diagnosticians of all types, with the assumption that the attitudes, feelings, and behaviors that a respondent attributes to the people in the pictures represent projections of his or her own dynamics.

The TAT has more limited response options than the Rorschach. First, the forms of its stimuli are actual representations, not inkblots. Second, the administration asks respondents to tell a story about the card, again a more constricting task than the Rorschach direction, which merely asks, *What might this be?* As a result, there is more of an issue of “reality constraints” for this test, but, at the same time, there will be much richer direct emotionality expressed in relation to the figures as opposed to those expressed to inkblots. In addition, the scope of the TAT is more oriented to interpersonal relationships and self-reflection, and is hardly appropriate to elicit a clear picture of cognitive organization the way the Rorschach does.

The rather straightforward interpretation of projected attitudes or emotions as representing those of the respondents’ lends face validity to TAT test interpretation. Ironically, it is probably this face validity that has shielded the TAT from the kind of sophisticated psychometric development the Rorschach has witnessed. To date, there is no rigorous or reliable coding or interpretive method for the TAT. Instead, there are a host of interpretive schemes that are part of a larger, poorly operationalized methodology of fantasy interpretation. This renders the precision of the TAT interpretation not much more scientific than that of dream interpretation. This lack of a precise coding strategy for this test has also hampered empirical validity research for this test. However, some studies have been published using somewhat reliable methodologies, and these have made their way into the diagnostic literature. Nonetheless, it remains a popular diagnostic tool and is featured widely in interpretive reports because professionals of various disciplines who are not psychometrically trained can easily relate to its constructs.

Projective figure drawings come in a wide array of tests such as Draw a Person, the House-Tree-Person Test, the Family Kinetic Drawing Test, and others. The projective hypothesis here is that all of these drawings are self-representations. The literature here is not consistently systematized, but there are major authors whose work is authoritative across tests. Presently, there are hosts of systems and schemes that interpret various aspects of drawings. For example, small human drawings are often taken as evidence of projected low self-esteem, bare branches as signs of inefficacy, and the omission of a house entrance as evidence of defensiveness.

Two major limitations plague figure drawings. First, empirical data, other than compilations of anecdotal reports, are few. Validation studies that are well designed do not offer empirical support for the test. Another limitation is the confounding effects that poor eye-hand (especially graphomotor) coordination entails in drawings. Distortions that are interpreted projectively may, in fact, be due to intrinsic inability of examinees to draw properly regardless of what they are drawing.

Nonetheless, figure drawings are very popular as projective tests. It is noteworthy that they are progressively more popular in the literature of fields allied with psychology (e.g., art therapy) than they are in diagnostic psychology proper.

Incomplete sentence tests mark another point on the projective testing continuum. The best known exemplar of this test (by Julian Rotter, a social learning theorist) was, in fact, not designed as a projective. It features different 40-item sets of sentences that begin with several words (e.g., “Back home . . .” or “A mother . . .”), each followed by a blank that the respondent fills in. There are separate sets of items for different developmental/age ranges.

It should be noted that, other than the basic coding systems, which were originally designed by Rotter (and other technical variations), there is no standard projective scoring and interpretive system for this instrument. Clinicians who use it as a projective test often use similar (unstandardized) interpretive strategies here as they do for the TAT.

There are some psychometricians who question the propriety of classifying the Incomplete Sentences Blank as a test altogether. These critics see the instrument as a standard questionnaire that elicits information about one's attitudes and feelings, and assert that it might best be described as a typical intake tool one would use at a clinic instead of, or in conjunction with, a background interview. There is some evidence, nonetheless, that some respondents find the task of completing sentences distracting enough to lower their defenses. The result is that more information is revealed than one might expect to discover in a regular interview structured by a question-and-answer format.

Still, labeling the sentence completion task as a psychological test is equivocal, at best. Moreover, classifying the instrument as a projective test is seen by some as more incongruous yet. (It should be noted that some diagnosticians emphasize ancillary features, such as the significance of omitted responses, changed responses, or inordinate deliberations/hesitations for specific items, as the more projective anchors of this test.)

The critiques that challenge the status of this "test" are most salient, because the standard printed instructions for sentence completion tests (i.e., Rotter's) typically ask the respondent to answer truthfully in a manner that reflects his or her true feelings and opinions. Some clinicians sidestep this issue by deleting the instructions and then presenting alternate instructions. These alternate instructions present the sentence completion task as an academic exercise designed to test the respondent's approach to writing and sentence construction. The projective hypothesis is then appealed to, with the assumption that respondents will use the opportunity to project their inner conflicts and unacceptable emotions into this allegedly neutral task.

Although this alternative approach can be challenged as deceptive and as ethically questionable, many of the other projective tests cross that ethical line to some extent. Consider, for example, the standard instructions for the Rorschach, which state that "there are no right or wrong answers." In fact, there are precise statistical frequency tables that the examiner uses in interpreting the reality testing of the

respondent, belying the denial of right and wrong. Similarly, the TAT is often presented to respondents in a less-than-transparent approach, usually as a test of the creativity of the respondent in "making up a story." Some of the popular instructions include the examiner telling the respondent a script, which is approximately as follows: "You will be the author, and I will be the secretary. You can make up any story. There are no right or wrong answers here. All that matters is your imagination." Although it is true that there are no formal tables for the TAT, which resembles the Rorschach Form Quality tables, there are, in fact, accepted standards of what kinds of stories are appropriate or inappropriate for each card. Despite the fact that the appropriateness here is more on the emotional level and less related to reality testing, some deception seems to be present here. It is not surprising, however, that many diagnosticians are partial to projectives, and these specialists justify the misinformation as a necessary aspect of testing that puts respondents off guard to allow access to dynamics that are typically inaccessible and hidden—even from the respondent.

Projective testing—from the mystery-shrouded and infamous Rorschach, to the more intuitive TAT, to the somewhat obscure figure drawings, to straightforward sentence completion—was prominent in the beginning of the discipline of psychological testing, when psychometrics were neither systemized nor operationally defined. As more objective tests, systematized observations, and behavioral measures came to dominate diagnostics, projectives were marginalized in many professional circles and relegated, at best, to ancillary roles. (This pattern was least evident in specific urban centers in the United States, such as New York City, Boston, and San Francisco, where psychoanalysis still reigns. In addition, countries from the former Soviet Union, where Freudian thinking was banned for decades, have seen a keen interest in psychoanalysis as a theory and projectives as a methodology.) In response to the supremacy of objective diagnostics based on the *Diagnostic and Statistical Manual of Mental Disorders*, the past two decades have witnessed a resurgence of projective testing as a psychometrically

kosher approach, a move championed by operationally definitive Rorschach studies accompanied by impressive clinical validation research. Although stereotypical dismissive attitudes still prevail in many psychological circles (particularly in the Midwest bastions of behaviorism, where psychoanalysis, projective testing, and astrology are grouped together as “pseudo-sciences”), projective testing is now a common feature in clinical diagnostic, which is used in tandem with more objective psychological measures to yield a comprehensive picture of personality and pathology.

PROPENSITY SCORES

A propensity score is the conditional probability of a unit being assigned to a condition given a set of observed covariates. These scores can then be used to equate groups on those covariates using matching, blocking, or ANCOVA. In theory, propensity score adjustments should reduce the bias created by nonrandom assignment, and the adjusted treatment effects should be closer to those effects from a randomized experiment.

In a randomized experiment, a unit’s true propensity score is the known probability of being assigned to either the treatment or comparison condition. For instance, when using a coin toss, the true propensity score would be $P = .5$ for every unit. In nonrandomized studies, we do not know the true probability of

being in a condition; therefore, it must be estimated using observable variables.

Computing Propensity Scores

Propensity scores are probabilities that range from 0 to 1, where scores above .5 predict being in one condition (i.e., the treatment group) and those below .5 predict being in the other condition (i.e., the comparison group). Traditionally, propensity scores are computed using a logistic regression; however, more recently, other methods have been used, such as classification trees, bagging, and boosted modeling.

Logistic regression is the most common method for computing propensity scores. In this method, a set of known covariates is used in a logistic regression to predict the condition of assignment (treatment or control), and the propensity scores are the resulting predicted probabilities for each unit. The model for this regression equation is typically based on variables that affect selection into either the treatment or the outcome, including interactions among the predictors. It is not necessary that all predictors be statistically significant at $p < .05$ to be included in the model.

Classification and regression trees predict categorical outcomes (often dichotomous) from predictor variables through a sequence of hierarchical, binary splits. Each split is determined by the predicted probability that a unit will select into conditions based on a single predictor. With each dichotomous split, two branches result, and the splitting process continues for each new predictor until a certain number of nodes is obtained or all significant predictor variables are used. The result is a binary tree with terminal nodes (branches) representing groups of units that have the same predicted condition, although each node may have reached the same condition using different predictors. The predicted outcomes are propensity scores. A disadvantage of classification and regression trees is that their results are not very robust. The modeled trees are highly variable, and splits often change with minor variations in the data. One way to increase the stability of trees is to use bagging.

Bagging (bootstrap aggregation) averages results of many classification trees that are based on a series

of bootstrap samples. In this case, random samples (with replacement) are drawn from the observed data set and additional observations are simulated to mimic the observed distributions. A new classification tree is computed for each simulated data set. Bootstrapped trees are aggregated to form aggregated trees, resulting in a more stable prediction model.

Boosted modeling, like bagging, uses an algorithm to create multiple models using different predictors. Each model is weighted based on the strength of the model and aggregated to form a single, more stable model. It differs from bagging by (a) using the full, original sample for each model, whereas bagging uses bootstrap samples; and (b) weighting units based on how difficult they are to classify. Each iteration assesses how well each unit was correctly classified, and then assigns a greater weight to that unit for the next iteration. Boosted modeling is used with either logistic regression procedures or classification trees.

Regardless of the method used to create propensity scores, the primary goal is not to optimally predict assignment to conditions, but to balance the distributions of covariates over conditions. This is typically assessed by using a factorial ANOVA to test the interaction between the propensity score strata and conditions (as independent variables) on the covariates. A nonsignificant interaction indicates that the distributions are balanced.

Predicting Assignment for More Than Two Conditions

When propensity scores are to be estimated for units selecting into more than two conditions, devising these estimates is more complicated. Three methods for doing so are as follows:

1. *Paired comparisons*, in which a separate propensity score model is created for each possible pair of conditions (i.e., three conditions have three possible pairs and will have three different propensity score models)
2. *Ordinal predictions*, in which an ordinal logistic regression is used to predict ordered dose-like levels of conditions (i.e., no treatment, partial treatment, full treatment)

3. *Multivalued treatments using a generalized propensity score*, which computes the probability of receiving a certain dose or level of the treatment, but can be used for nominal or ordinal categories using multinomial or nested logit models.

Adjustments Using Propensity Scores

Once propensity scores are calculated, statistical adjustments can be made using those scores. Typically, this is done using matching, stratification, covariate adjustment, or weighting.

Matching identifies similar cases from experimental and control groups based on the proximity of their propensity scores. Methods for matching include exact matching (cases paired on exactly the same scores), and caliper, optimal, or greedy matching, in which scores are paired by proximity. The most preferred methods of matching are greedy matching, which selects the closest matches first and then progressively farther matches, and optimal matching, which finds the smallest cumulative distance from all possible pairs. To prevent dropping treated participants from the analyses, some researchers recommend using index matching, which matches treated participants with multiple control participants. Others recommend matching proportionately more participants in the control group to fewer participants in the treatment group.

Stratification divides the entire distribution into four to seven strata based on propensity scores, so observed variables are balanced for treated and control units within each stratum. To estimate the adjusted treatment effects, treatment and control group means are computed as the unweighted average of the cell means over strata for each group. Although stratification usually permits the inclusion of all cases, some cells may contain few or no units. Reducing the number of strata or changing the cut-points that define the blocks may reduce this problem, but determining ideal cut-points for strata can be difficult. Despite these concerns, stratification is often a favored method because it does not require modeling nonlinear trends, like covariate adjustments and weighting, and is less complicated than matching.

Covariate adjustment uses propensity scores as covariates in an analysis of covariance in order to

remove bias due to the covariates from the effect estimate. Although some studies have indicated that covariate adjustment can be an effective method for removing bias, Paul R. Rosenbaum and Donald B. Rubin do not recommend this method, particularly when variances among variables that created the propensity scores are heterogeneous.

Weighting attempts to balance treatment and control groups by multiplying (weighting) observations by the inverse of the propensity score. Weighting often uses propensity scores that are computed using nonparametric statistics, such as a series estimator, or semiparametric statistics, such as binary regression quantiles, as well as parametric statistics, such as logistic regression. The adjusted treatment effect, $\hat{\beta}$, is estimated using a formula, such as this one:

$$\hat{\beta} = \frac{1}{N} \sum_{i=1}^N \frac{Y_i(T_i)}{e(x_i)},$$

in which Y_i is the outcome variable, T_i is the treatment condition, and $e(x_i)$ is the propensity score for each unit.

Conclusions

Although the effectiveness of propensity scores is still under scrutiny, some work suggests that when propensity scores are used in accordance with the guidelines described by Rosenbaum and Rubin, they can reduce bias in quasi-experiments. However, even when used properly, propensity scores cannot adjust for hidden bias, which occurs when relevant covariates are not included in the propensity score model. Propensity scores can be only estimated from observed variables; however, many factors that are not measured may contribute to selection bias.

PSYCHOLOGICAL ABSTRACTS

Psychological Abstracts (PA, 1927–present) is a monthly publication produced by the American Psychological Association (APA). The publication provides bibliographic citations and abstracts of scholarly literature pertaining to the field of mental health and behavioral sciences. PA was preceded by the *Psychological Index* (1894–1935). The electronic version of the *Psychological Abstracts* is the PsycINFO database, first published in 1967. Literature coverage in PsycINFO spans from 1887 to present for more than 50 countries and more than 25 languages. It includes journal articles; book chapters and books; dissertations; technical reports; and other publications such as conference proceedings, program evaluations, or psychological assessment instruments. The database is updated weekly and contains more than 2 million publication records.

Each monthly issue of PA consists of the following parts: (a) an author index, (b) a brief subject index

based on controlled vocabulary, (c) a thesaurus of psychological terms used in the subject index, (d) a book title index, and (e) abstract volumes that present citations and nonevaluative summaries. An expanded and cumulative author and subject index is published annually and placed at the end of each volume. Searches on the PA can be conducted by author or subject by referring to the author and brief subject indexes in the back of each monthly issue. The main concepts of each cited document are summarized in up to five major terms or descriptors printed in the brief subject index. The subject terms used in this index are based on controlled vocabulary and scientific terminology provided in the *Thesaurus of Psychological Index Terms*.

Each PA record is divided into several fields. For instance, book entries contain the following elements in order: (a) record number, (b) author(s) or editor(s), (c) affiliation of first author, (d) book title, (e) publisher and bibliographic information, (f) table of contents listing PA record number for each chapter, and (g) quoted material indicative of the content. Abstracts are provided only for journal article entries. Because PA uses the same abstract numbers each year, abstract numbers should be looked up in the same year/volume as the index used.

PA is available through individual- or institution-based subscriptions obtained from the APA. Most academic institutions provide access to both PA and PsycINFO to their faculty, staff, and students. PA does not provide full text of the documented records. Full-text articles can be obtained through other APA services such as PsycARTICLES or directly from libraries or through interlibrary loan services.

PSYCHOMETRICS

Psychometrics is the systematic application of mathematical principles in order to measure (quantify) psychological constructs. Measurement consists of rules for assigning symbols to objects to (a) represent quantities of attributes numerically (scaling), or (b) define whether the objects fall in the same or different categories with respect to a given attribute (classification). The objects of study in psychometrics are usually people, but many studies involve other animals, or basic biological or psychological processes. Accurate measurement is essential for the development of any science because it permits objective quantification and communication of findings. Standardized measurement specifies the concept in which we are interested so that others can replicate or refute our work. Psychometric theory has been applied in a wide range of fields, including the measurement of intelligence, personality, attitudes and beliefs, and achievement, as well as in health-related disciplines.

Primary Approaches

Psychometric theory has evolved into several areas of study. Early psychometric work was in the area of intelligence testing. This work gave rise to classical test theory (CTT). More recently, item response theory has emerged to address some of the shortcomings of the CTT approaches.

Classical Test Theory

Core to the CTT approach are the concepts of reliability and validity. Reliability is the study of consistency in measurements. All measures contain some degree of error or imprecision, and CTT procedures are used to evaluate the amount of error present in a

measure and whether the observed error is systematic or random. Reliability is assessed statistically, often with correlational techniques. For example, test-retest reliability (stability) of a test or the reliability of alternate forms of a test is evaluated with the Pearson coefficient.

Validity, which is dependent on a measure first being reliable, refers to whether a measure is measuring what it is supposed to measure. Validity often is a multifaceted and ongoing research process that involves establishing various aspects of a measure's validity. For example, concurrent validity refers to a measure's correlation with a known criterion measure collected at the same time, whereas predictive validity is the ability of a measure to predict a criterion at some future point in time.

Item Response Theory

Item response theory (IRT) models the relationship between latent traits and responses to test items. In contrast to CTT approaches, IRT methods have the potential to produce measures that are (a) sample independent—item parameters can be created independent of the sample taking a test; (b) falsifiable models—direct tests are available to evaluate whether a specific IRT model is appropriate for a particular data set; and (c) directly addressing measurement bias at the individual item level before these items are combined to form a scale score.

Statistical Methods

The field of psychometrics uses a number of statistical procedures, particularly correlation and regression techniques. Multivariate descriptive methods frequently are used and include factor analysis to uncover underlying dimensions in a test data set, cluster analyses to find test items or test respondents similar to each other, and multidimensional scaling to find simple representations for complex test data. More complex nonlinear regression models are used to test IRT models.

PsycINFO

PsycINFO, produced and copyrighted by the American Psychological Association (APA), is an electronic database of bibliographic citations and abstracts of scholarly literature pertaining to the field of mental health and behavioral sciences, and psychology-related aspects of other disciplines. The literature coverage in PsycINFO, spanning from 1887 to present, covers more than 50 countries and more than 25 languages. It includes journal articles; book chapters and books; dissertations; technical reports; and other publications such as conference proceedings, program evaluations, and psychological assessment instruments. The database is updated weekly and contains more than 2 million publication records. Since its first publication in 1967, PsycINFO has become one of the most widely used resources for scholarly and professional research.

The PsycINFO database is an electronic version of the print publication *Psychological Abstracts*. As of August 2005, PsycINFO's journal coverage accounts for 78% of the database and includes 1,980 titles, 98% of which are peer reviewed. The journal coverage list changes monthly as journals are added or discontinued. Book chapters from edited books make up 7% of the database; authored and edited books make up 3%. The final 12% of the database is devoted to dissertations and other secondary publications. Nearly all publication records, from 1995 to present, provide abstracts and are provided in APA-style format.

Literature searches on PsycINFO records can be conducted in various ways. Records are divided into fields. The content of each field varies depending on

the type of literature documented within the database. For instance, one can complete a search by using one or more of the following fields: author, title, keywords, document type, language, population group, or publication year, or by choosing additional fields not mentioned here. Search results are listed by record date, beginning with the most recently published. Each record, at a minimum, generally contains the name and affiliation of the author, title, source, abstract, and publication year. To maximize the precision of research efforts, PsycINFO users can refer to the *Thesaurus of Psychological Index Terms*, which provides the most up-to-date controlled vocabulary terms and scientific terminology.

Access to PsycINFO is available through individual- or institution-based subscriptions obtained from the APA. Most academic institutions provide access to PsycINFO for their faculty, staff, and students. PsycINFO does not provide access to the full text of the documented records. Full-text articles can be obtained through other APA services such as PsycARTICLES or directly from libraries or through interlibrary loan services. Publishers and/or authors interested in submitting their publication for coverage in PsycINFO may do so by following the APA guidelines provided at <http://www.apa.org/psycinfo/about/covinfo.html>.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Lawrenz, F., Keiser, N., & Lavoie, B. (2003). Evaluative site visits: A methodological review. *American Journal of Evaluation*, 24(3), 341–352.

Site visits are a commonly employed, but little discussed, evaluation procedure. The purpose of this paper is to review the state of the art regarding site visits, as well as to catalyze a discussion of site visits centering on the question of whether or not existing practices constitute a set of methods or a methodology. The researchers define evaluative site visits and review the current state of practice (using **PsycINFO**) in site visits. They also outline the differences between methods and methodology and consider whether or not the current state of practice constitutes a methodology.

Q METHODOLOGY

Q methodology was invented by British psychologist and physicist William Stephenson (1902–1989) and provides both the tools and the philosophy for the systematic study of subjective behavior. Stephenson first introduced his innovation in 1935; however, it was publication of his *The Study of Behavior*, in 1953, that brought his ideas to a wider audience, and it is in this book that he fully explores the utility of Q methodology for researchers interested in studying subjectivity.

Elements of a Q Approach

Concourse and Q Samples

The concept of *concourse* refers to the stream of commentary revolving around any topic, be it the price of gasoline, the war in Iraq, the steroid scandal in baseball, or any other topic. These comments are matters of opinion and are shared with others in the culture. Researchers can gather concourses from a number of sources (e.g., interviews, texts,

etc.), with interview responses having the virtue of being in the natural language of participants. From this concourse, a selection of statements is drawn that constitutes the *Q sample*, which may be either structured or unstructured. Whereas an unstructured sample is composed unsystematically and is made up of statements relevant to the subject under consideration, a structured Q sample usually embodies a theoretical framework, with greater attention given to coverage of subissues in the statement selection process. Q samples are typically structured in terms of the principles of factorial experimental design, with statements provisionally placed into categories of the design. However, unlike the case in scale construction, there is no assumption that these categories will (or should) hold together once the participants begin to respond to these statements.

P Set

Individuals who serve as study participants are known as the *P set*, and their selection is a function of the research question. Participants may be chosen

because of theoretical concerns thought to be relevant. For example, a Q study concerning health care in the United States might predispose the researcher to try to get doctors, lawyers, patients, hospital administrators, politicians, insurance company representatives, and so on as participants. On the other hand, a Q study of understandings of the Judy Garland film *The Wizard of Oz* might lead the researcher to seek out participants who are readily available, assuming almost everyone has a level of familiarity with that classic film.

P sets in Q studies are typically small, most often 40 or fewer. The aim is to allow subjective viewpoints to be revealed, not to make the claim that all possible viewpoints are represented or that a certain percentage of the population holds a particular view.

Q Sorting

Participants are given the Q sample (each statement being printed on an individually numbered card) to rank order along an established continuum according to a “condition of instruction,” typically “most agree” to “most disagree.” However, the condition of instruction may be “most like me” to “most unlike me” or “most like my view in 20 years” to “most unlike my view in 20 years” and so on. Conditions of instructions can be used to create experimental conditions for testing theories. For example, conditions of instruction might be constructed to tap into interpersonal dynamics, for example, “most like the view my father would like me to have” to “most unlike the view that my father would like me to have.”

It is important for participants to have enough workspace so that all statements can be arrayed in front of them. Participants should first read through the cards in order to gain familiarity with them and then begin to make piles of statements that they agree or disagree with or feel neutral toward. The participant then begins to identify the most agreeable statements from the “agree” pile, placing them under the most positive end of the continuum, for example, +4. The

Table 1 Scoring Form

<i>Most Disagree</i>									<i>Most Agree</i>	
-4	-3	-2	-1	0	+1	+2	+3	+4		
(2)										(2)
	(3)									(3)
		(4)								(4)
			(5)							(5)
										(7)

sorter then singles out the next-most-agreeable statements and places them under +3. It is then advisable to turn to the “disagree” pile and identify those statements with which the person most disagrees (-4). This process is continued until each statement has found a place under the continuum. Sorters are then encouraged to examine the array and move statements from one column to another if they choose. Completed Q sorts are formal models of the sorter’s point of view with respect to the topic under study. Table 1 shows a possible scoring form, ranging from -4 to +4 for a Q sample of size $N = 35$ statements.

For theoretical purposes, Q sorters are encouraged to follow a quasi-normal distribution, requiring the person to think systematically about the statements and to make more distinctions. Some have criticized this “forced” distribution as creating an artificial constraint on the sorter, arguing for a “free” distribution in which the sorter can place any number of statements at any point along the continuum. The literature in Q methodology has consistently demonstrated the differences in forced-free distributions to be statistically insignificant; however, a forced distribution is preferred for the theoretical reasons stated above.

It is also advisable to conduct post-sort interviews with participants to gain deeper understandings of why they ordered the statements in the manner that they did. How did they construe the meanings of the statements that were of most salience (e.g., +4, -4),

and why were they determined to be of such importance? The statements placed in the more neutral columns (i.e., +1, 0, -1) may also be important for eliciting more information. Generally, these statements are placed in these middle positions because there is a feeling of neutrality (in a relative sense) toward these items. However, at times, statements are placed in these columns because sorters feel conflicted about them; that is, they may agree strongly with one part of the statement and disagree strongly with another part. Thus, a deeper understanding of why this statement was placed where it was will inform the researcher.

Statistical Procedures and Factor Interpretation

Once collected, the data are entered into dedicated statistical programs such as PQMETHOD or PCQ (both accessible at <http://www.qmethod.org>), and correlations are calculated between persons (not between items). The correlation matrix is then factor analyzed to reveal groups of individuals with shared viewpoints. In the more conventional R methodology, the correlating and factoring are performed on traits or scores on objective tests, whereas in Q, the correlating and factoring are done on the subjective assessments of persons. That is, contrary to widespread opinion, a Q analysis is not simply based on a transposed R data matrix; rather, R methodology focuses on matrices of objective scores (e.g., IQ scores, scores on authoritarianism scales), whereas Q focuses on entirely different matrices of subjective impressions.

By way of illustration, suppose that 10 individuals have sorted 35 statements concerning their views of the war in Iraq, resulting in the hypothetical factor structure in Table 2. Factor loadings in this case are statistical measures of the degree of correlation with that factor.

The data in Table 2 show that persons 1, 2, 4, 6, 7, 8, and 10 have statistically significant factor loadings on Factor A, while persons 3, 5, and 9 have statistically significant factor loadings on Factor B. The formula for determining the significance threshold for a factor loading at the .01 level is $2.58(1/\sqrt{35}) = .44$, where

Table 2 Factor Loadings in the Iraq War Study

	A	B
Person 1	.88	.21
Person 2	.76	.04
Person 3	.15	.81
Person 4	.59	.19
Person 5	.08	.89
Person 6	.71	-.19
Person 7	-.88	.15
Person 8	-.77	.20
Person 9	.12	.75
Person 10	-.70	.14

35 is the number of statements. Fundamentally, this means that persons with significant factor loadings on Factor A share a common viewpoint, while those with significant factor loadings on Factor B share a separate viewpoint. An array of factor scores (i.e., a composite Q sort) is estimated for each of the factors, and it is this array that provides the basis for interpretation.

Note that Factor A is bipolar; that is, that the significant loadings run in both positive and negative directions. This means that the statements judged “most agreeable” by persons at the positive end of the factor are the statements considered “most disagreeable” by those at the negative pole. In other words, Q sorters at both ends of the factor are responding to the same themes, but in reverse order. In the hypothetical study of the Iraq War, for instance, imagine that Factor A arises from partisanship, with those at the positive end of the factor (persons 1, 2, 4, and 6) being Republican supporters of President Bush’s war against terror and those at the negative end of the pole (persons 7, 8, and 10) being Democrats who just as avidly rejected the same statements that were so warmly embraced by the Republicans (and vice versa). The Q sorters who defined Factor A were thus seeing the statements through the prism of their own partisanship, and this would constitute the theme of Factor A.

Factor B is orthogonal to Factor A and thus represents a wholly different point of view. Once again, factor interpretations are reached through examining the array of statements as produced by Factor B. Assume hypothetically that the statements rank highest (+4, +3) had to do with concerns over preemptive war and the standing of the United States in the world community, and so on. Assume further that other statements receiving high positive scores did not hold President Bush responsible for the war and expressed the view that any U.S. president would have probably acted in the same manner. The theme of the factor would thus be concerned with larger, geopolitical issues that transcend partisan politics.

Q Methodology and the Single Case

Q methodology is also well suited for use in the study of single cases. What is of significance in Q methodology is the participant's point of view rendered manifest by the procedure of Q sorting; consequently, issues of reliability and validity (in an R-methodological sense) recede in importance. Single-case studies proceed in much the same manner as outlined above, the chief difference being that the individual performs a number of sorts under multiple conditions of instruction, with the factors pointing to different tendencies and response predispositions within the same individual.

Q-Q PLOT

The quantile-quantile, or Q-Q, plot is a graphical procedure used to visually assess goodness of fit to a particular distribution. While the Q-Q plot will not provide a numerical measure of the goodness of fit, unlike such common tests as the chi-square goodness-of-fit test, the Kolmogorov-Smirnov test, or the Cramer-von Mises test, the graph can provide insight into how a given data set deviates from the specified distribution.

There are two common situations in which a Q-Q plot is used. The first of these applications is in determining whether two data sets are from a common distribution. The following steps are used to construct the plot:

1. Order each of the two samples to obtain the n order statistics $x_{1:n}, x_{2:n}, \dots, x_{n:n}$ and $y_{1:n}, y_{2:n}, \dots, y_{n:n}$.
2. Plot the ordered pairs $(x_{i:n}, y_{i:n})$ and examine the plot for linearity. If the samples are identical, a line with slope 1 and intercept 0 is obtained. If the points come close to fitting such a line, it is concluded the two samples are drawn from a common distribution.

This use of the Q-Q plot is described in further detail online both at Eric Weisstein's MathWorld and in the National Institute of Standards and Technology *e-Handbook of Statistical Methods*.

The second common application of the Q-Q plot is in testing for univariate normality. This is often referred to as a *normal probability plot*. The following steps are used to construct a Q-Q plot when testing for normality:

1. Order the n original observations x_1, x_2, \dots, x_n to obtain the n order statistics $x_{1:n}, x_{2:n}, \dots, x_{n:n}$.
2. Find the n normal quantiles q_1, q_2, \dots, q_n , where q_i is the standard normal quantile associated with the i th

order statistic. The formula for q_i is given by

$$q_i = \Phi^{-1}\left(\frac{i - 3/8}{n + 1/4}\right), \text{ where } \frac{i - 3/8}{n + 1/4}$$

is a “continuity correction” or a “plotting position.”

Another common plotting position is $\frac{i - 1/2}{n}$.

3. When testing for fit to a distribution other than the normal distribution, the q_i 's are found by replacing the inverse normal function in Step 2 with the appropriate inverse function.
4. Plot the pairs $(q_i, x_{i:n})$ and examine the plot for linearity. If the data are univariate normal, the plot will be a straight line.

Example

Consider the data set of 15 numbers in Table 1. These numbers were generated from a normal distribution with mean 100 and standard deviation 15, so the Q-Q plot would be expected to have a linear pattern. The computations needed are shown in Table 1, using

Blom’s plotting position. In Figure 1, the observed values x_i are on the vertical axis, and the theoretical quantiles q_i are on the horizontal axis. The choice of axes is arbitrary since the main feature of interest is the linearity of the plotted points. The Q-Q plot was created with the free statistical package R. Similar plots can be made with any standard statistical software package such as SAS or SPSS. Some handheld graphing calculators can even make normal probability plots.

While the points do not fall perfectly on a straight line, particularly in the lower-left and upper-right portions of the Q-Q plot (see Figure 1), this plot does not indicate a serious deviation from normality that might prevent an analyst from using a standard statistical technique that requires the normality assumption. The Q-Q plot will also identify outliers; they will be seen as points in the lower-left or upper-right portions of the plot that deviate from the general linear pattern formed by the remaining observations. The analyst can then examine the outliers and decide how to proceed with the statistical analysis.

Figure 2 demonstrates what a Q-Q plot would look like when the data are drawn from a heavily right-skewed distribution. In this case, a random sample size of 15 was drawn from the exponential distribution, with the mean equal to 1, and the Q-Q or normal probability plot was again constructed using R. Notice how this scatterplot is much more curved in the middle portion of the graph than in the previous example.

Discussion

Unfortunately, assessing normality through examination of the Q-Q plot can be difficult. It is difficult to determine how much deviation from a straight line is acceptable. Also, small samples ($n < 20$) can have a good deal of variability from linearity, even when the data are known to be from a normal distribution. However, the Q-Q plot can indicate the presence of outliers and the possible reason for departure from univariate normality. When the points fall roughly on a straight line, with the exception of a few points at either edge of the plot, then these points are possible outliers. Rencher gave typical Q-Q plots that one would encounter if the data were heavy-tailed, light-tailed, or positively skewed. D'Agostino, Belanger, and D'Agostino also provided examples of Q-Q plots showing deviations from normality.

QUALITY OF WELL-BEING SCALE

The Quality of Well-Being Scale (QWB) is a generic measure of health-related quality of life (HRQOL) that combines preference-weighted values for symptoms and functioning. The QWB was developed in the early 1970s and is based on the general health policy model. In the general health policy model, a summary preference-based quality-of-life score is integrated with the number of people affected and the duration of time affected to produce the output measure of quality-adjusted life years (QALYs). QALYs combine morbidity and mortality outcomes into a single number.

In the original QWB, respondents report whether or not each of 27 symptoms were experienced on each of the 6 days prior to the assessment. Functioning is assessed by questions about the presence of functional limitations over the previous 6 days, within three separate domains (mobility, physical activity, and social activity). Unlike measures that ask about general time frames such as “the past 4 weeks” or “the previous month,” the QWB asks whether specific symptoms or functional limitations did or did not occur on a given day. Each symptom complex and functional limitation is weighted using preferences obtained from the ratings of 856 people randomly sampled from the general population. The four domain scores (three functioning, one symptom) are subtracted from 1.0 to create a total score that provides an expression of well-being that ranges from 0 for death to 1.0 for asymptomatic optimal functioning. References on the validation of the instrument are available from the University of California, San Diego, Health Outcomes Assessment Program (see Web site toward the end of

this entry). The questionnaire must be administered by a trained interviewer because it employs a somewhat complex system of questions, including branching and probing. The original questionnaire takes about 15 minutes to complete on average. The authors believe the length and complexity of the original measure has resulted in its underutilization.

In 1996, a self-administered version of the questionnaire was developed to address some of the limitations of the original version. The Quality of Well-Being Scale–Self-Administered (QWB–SA) improves upon the original version in a number of ways. First, the administration of the questionnaire no longer requires a trained interviewer and can be completed in less than 10 minutes. Second, the assessment of symptoms follows a clinically useful review of systems model, rather than clustering symptoms based on preference weights. Third, a wider variety of symptoms are included in the QWB–SA, making it more comprehensive and improving the assessment of mental health.

Both the QWB and QWB–SA are available free of charge to users from nonprofit organizations. A small fee is charged to for-profit users. Information on copyright agreements and user manuals are available at <http://www.medicine.ucsd.edu/fpm/hoap/>.

are sometimes referred to as *nonrandomized experiments* or *observational studies*). However, quasi-experiments differ from randomized experiments in that units are not randomly assigned to conditions. Quasi-experiments are often used when it is not possible to randomize ethically or feasibly. Therefore, units may be assigned to conditions using a variety of nonrandomized techniques, such as permitting units to self-select into conditions or assigning them based on need or some other criterion. Unfortunately, quasi-experiments may not yield unbiased estimates as randomized experiments do, because they cannot reliably rule out alternative explanations for the effects. To improve causal inferences in quasi-experiments, however, researchers can use a combination of design features, practical logic, and statistical analysis. Although researchers had been using quasi-experiments designs long before 1963, that was the year Donald T. Campbell and Julian C. Stanley coined the term *quasi-experiment*. The theories, practices, and assumptions about these designs were further developed over the next 40 years by Campbell and his colleagues.

Threats to Validity

In 1963, Campbell and Stanley created a validity typology, including *threats to validity*, to provide a logical and objective way to evaluate the quality of causal inferences made using quasi-experimental designs. The threats are common reasons that explain why researchers may be incorrect about the causal inferences they draw from both randomized and quasi-experiments. Originally, Campbell and Stanley described only two types of validity, internal validity and external validity. Thomas D. Cook and Campbell later added statistical conclusion validity and construct validity.

Of the four types of validity, threats to *internal validity* are the most crucial to the ability to make causal claims from quasi-experiments, since the act of randomization helps to reduce the plausibility of many internal validity threats. Internal validity addresses whether the observed covariation between two variables is a result of the presumed cause influencing the effect. These internal validity threats include the following:

QUASI-EXPERIMENTAL METHOD

Quasi-experiments, like all experiments, manipulate treatments to determine causal effects (quasi-experiments

- *Ambiguous temporal precedence*: the inability to determine which variable occurred first, thereby preventing the researcher to know which variable is the cause and which is the effect.
- *Selection*: systematic differences between unit characteristics in each condition that could affect the outcome.
- *History*: events that occur simultaneously with the treatment that could affect the outcome.
- *Maturation*: natural development over time that could affect the outcome.
- *Regression*: occurs when units selected from their extreme scores have less extreme scores on other measures, giving the impression that an effect had occurred.
- *Attrition*: occurs when those who drop out of the experiment are systematically different in their responses from those who remain.
- *Testing*: Repeatedly exposing units to a test may permit them to learn the test, giving the impression that a treatment effect had occurred.
- *Instrumentation*: Changes in the instrument used to measure responses over time or conditions may give the impression that an effect had occurred.
- *Additive and interactive threats to internal validity*: The impact of a threat can be compounded by, or may depend on the level of, another threat.

The other three types of validity also affect the ability to make causal conclusions between the treatment and outcome but do not necessarily affect quasi-experiments more than any other type of experiment. *Statistical conclusion validity* addresses inferences about the how well the presumed cause and effect covary. These threats, such as low statistical power and violation of statistical assumptions, are essentially concerned with the statistical relationship between the presumed cause and effect. *Construct validity* addresses inferences about higher-order constructs that research operations represent. These threats, such as reactivity to the experimental situation (units respond as they want to be perceived rather than to the intended treatment) and treatment diffusion (the control group learns about and uses the treatment), question whether the researchers are actually measuring or manipulating what they intended. *External validity* addresses inferences about whether the relationship holds over variation in persons, settings, treatment variables, and measurement variables. These threats, such as interactions of

the causal treatment with units or setting, determine how well the results of the study can be generalized from the sample to other samples or populations.

Basic Types of Quasi-Experiments

While there are many variations of quasi-experimental designs, basic designs include, but are not limited to, (a) *one-group posttest-only designs*, in which only one group is given a treatment and observed for effects using one posttest observation; (b) *nonequivalent control group designs*, in which the outcomes of two or more treatment or comparison conditions are studied, but the experimenter does not control assignment to conditions; (c) *regression discontinuity designs*, in which the experimenter uses a cutoff score from a continuous variable to determine assignment to treatment and comparison conditions, and an effect is observed if the regression line of the assignment variable on outcome for the treatment group is discontinuous from that of the comparison group at the point of the cutoff; and (d) *interrupted time series designs*, in which many (100 or more) consecutive observations on an outcome over time are available, and treatment is introduced in the midst of those observations to determine its impact on the outcome as evidenced by a disruption in the time series after treatment; and (e) *single-group or single-case designs*, in which one group or unit is repeatedly observed over time (more than twice, but fewer than in a time series), while the scheduling and dose of treatment are manipulated to demonstrate that treatment affects outcome.

The causal logic of threats to validity can also be applied to two other classes of designs that are not quasi-experiments because the cause is not manipulated, as it is in the previous five designs. These are *case-control designs*, in which a group with an outcome of interest is compared with a group without that outcome to see how they differ retrospectively in exposure to possible causes, and *correlational designs*, in which observations on possible treatments and outcomes are observed simultaneously to see if they are related. These designs often cannot ensure that the cause precedes the effect, making it more difficult to make causal inferences than in quasi-experiments.

Design Features

To prevent a threat from occurring or to diagnose its presence and impact on study results, researchers can manipulate certain features within a design, thereby improving the validity of casual inferences made using quasi-experiments. These design features include (a) adding observations over time before (pretests) or after (posttests) treatment to examine trends over time; (b) adding more than one treatment or comparison group to serve as a source of inference about the counterfactual (what would have occurred to the treatment group if they had not received the treatment); (c) varying the type of treatment, such as removing or varying a treatment; and (d) using nonrandomized assignment methods that the researcher can control or adjust, such as using a regression discontinuity design or matching. All quasi-experiments are combinations of these design features, chosen to diagnose or minimize the plausibility of threats to validity in a particular context.

New designs are added to the basic repertoire of designs using these elements. For example, by adding pretest observations to a posttest-only, nonequivalent control group design, existing pretest differences between the treatment and control groups can better be measured and accounted for, which helps reduce effects of selection. Likewise, adding a comparison group to a time series analysis can assess threats such as history. If the outcome for the comparison group varies over time in the same pattern as the treatment outcome, history is a likely threat.

Examples

In 1983 and 1984, the Arizona State Lottery implemented a campaign aimed at increasing the sale of state lottery tickets by offering free tickets to retail customers, who were not asked if they wanted to buy tickets by store clerks. While the researchers examined the effects of the campaign by using various designs, one of the methods used a nonequivalent control group design with pretests and posttests. The 44 retail stores that implemented the campaign were matched with 22 control stores on market shares (the proportion of total state ticket sales made by each retail store for a single game). All stores were measured on their market shares before the campaign

intervention (pretest) and after the program intervention (posttest). Results indicated that there were no differences between the treatment and control groups in market shares at pretest. However, stores that participated in the campaign profited significantly more in market shares than did the control group at posttest.

In 1974, Cincinnati Bell began charging 20¢ per call to local directory assistance and found an immediate and large drop in local directory-assisted calls once this charge was imposed. One hundred eighty monthly observations were collected from 1962 through 1976, which assessed the number of local and long-distance directory-assisted calls. Results of this study found that the number of local and long-distance directory-assisted local calls steadily increased from 1962 (approximately 35,000 calls per day for local calls and 10,000 calls per day for long-distance calls) until 1973 (approximately 80,000 calls per day for local calls and 40,000 calls per day for long-distance calls). However, once the charge for the local calls was imposed, the number of directory-assisted local calls decreased to approximately 20,000 calls per day in 1974. However, the directory-assisted long-distance calls, which did not have a fee imposed, continued to slowly increase over time. This study was an interrupted time series quasi-experiment using a nonequivalent control group (directory-assisted long-distance calls).

Statistical Adjustments

While Campbell emphasized the importance of good design in quasi-experiments, many other researchers sought to resolve problems in making causal inferences from quasi-experiments through statistical adjustments. One such method uses *propensity scores*, the conditional probability that a unit will be in a treatment condition given a set of observed covariates. These scores can then be used to balance treatment and control units on predictor variables through matching, stratifying, covariate adjustment, or weighting. Another method, *selection bias modeling*, attempts to remove hidden bias that occurs when unobserved covariates influence treatment effects by modeling the selection process. A third method uses *structural equation modeling* (SEM) to study causal relationships in quasi-experiments by

modeling latent variables to reduce bias caused by unreliable measures. While these statistical adjustments have been shown to reduce some of the bias present in quasi-experiments, each of these methods has limitations that prevent it from accounting for all of the sources of biased estimates. Therefore, it is often more effective to obtain less biased estimates through good designs than through elaborate statistics.

Conclusion

Quasi-experiments may never rule out threats to internal validity as well as randomized experiments; however, improving the designs can reduce or control for those threats, making causal conclusions more valid for quasi-experiments than they would otherwise be. This can most easily be done by using designs that are most appropriate for the research question and by adding design features to address particular plausible threats to validity that may exist. While certain conditions within field studies may hinder the feasibility of using more sophisticated quasi-experimental designs, it is important to recognize the limitations of designs that are used. In some cases, statistical adjustments can be used to improve treatment estimates; however, even then, causal inferences should be made with caution.

QUESTIONNAIRES

The term *questionnaire* denotes a collection of items designed to measure one or more underlying constructs. Given that questionnaires are one of the most widely used research tools in the social sciences, it is not surprising that a large body of literature has developed around various design features in their use.

Method of Administration

Researchers who use questionnaires must first decide what method of administration to employ. One approach is to use a self-administered questionnaire, such as the traditional paper-and-pencil-based booklet completed in a supervised setting or mailed to respondents and completed at their homes or workplaces. Recently, it has become popular to post self-administered questionnaires on Web sites that can be accessed via the Internet. Alternatively, questionnaires can be administered using interviewers to conduct telephone or face-to-face interviews. In choosing one of these methods, researchers should consider the attributes of the project, the possibility of social desirability effects, and the ease of administration.

Self-Administered Questionnaires

Due to their cost-effectiveness and ease of administration, self-administered questionnaires (in either

the traditional or Internet-based form) are popular among social scientists. Because of the sense of anonymity provided by self-administered measures, this method lessens the likelihood of social desirability effects. Thus, these types of questionnaires are especially useful when studying highly sensitive topics. Furthermore, self-administered measures are self-paced, which ensures that respondents have sufficient time to generate meaningful answers to the questions. Internet-based questionnaires tend to be especially cost-efficient, because expenses often associated with a research project (i.e., photocopying of materials and payment of research assistants) are minimized.

Despite such advantages, there are limitations associated with self-administered measures. If researchers mail their questionnaires, they may obtain very low response rates. Furthermore, individuals who take the time to complete the measure may not be representative of the intended sample. Self-administered questionnaires also may not be suitable for respondents with limited cognitive skills or topics that are complex and require extensive explanation.

Interviewer-Administered Questionnaires

One alternative to using self-administered questionnaires is to conduct telephone interviews. Telephone interviews are associated with substantially higher response rates than the use of self-administered questionnaires, which lessens the possibility that one's data will be compromised by nonresponse error. They also allow researchers to probe respondents' answers if they are initially unclear. Unfortunately, there are several drawbacks associated with this method of administration. These include substantially greater expense relative to self-administered questionnaires and increased vulnerability to social desirability effects.

Researchers may also administer their questionnaires via face-to-face interviews. Face-to-face interviews are ideal when one's sample consists of individuals with limited cognitive or verbal abilities, as this type of interview allows researchers to clarify

the meaning of more challenging items through the use of visual props (e.g., show cards). Like telephone interviews, face-to-face interviews also allow researchers to clarify the meaning of ambiguous questions and probe respondents for clarifications to their answers. However, face-to-face interviews are more costly and time-consuming than other methods of administration. Such interviews are also the most vulnerable to social desirability effects, potentially making them an inappropriate method of administration when highly sensitive topics are being studied.

Question Construction

Open- Versus Closed-Ended Questions

One decision that researchers must make in designing the actual questions that make up a survey is whether to use closed-ended questions (which include response alternatives) or open-ended questions (which allow respondents to generate their own answers). Measures containing closed-ended questions may be easier to interpret and complete. However, such questions may fail to provide response options that accurately reflect the full range of respondents' views. While open-ended questions eliminate this problem, they pose other difficulties. To interpret and analyze responses to open-ended questions, researchers must engage in the costly and time-consuming process of developing a coding scheme (i.e., a way to categorize the answers) and training research assistants to use it.

Question Wording

There are several guidelines with respect to question wording that should be followed in generating effective items. Questions should be short and unambiguous, and certain types of items should be avoided. These include "double-barreled questions," which constrain people to respond similarly to two separate issues. Consider the dilemma faced by the respondent who encounters the following question: "How positively do you feel about introducing new social programs, such as government-subsidized day care, to this state?" The respondent might generally harbor

negative feelings about social programs but might view subsidized day care programs quite positively. In light of such conflicting views, this question would be difficult to answer.

It is also worth noting that questions that are substantively identical may yield different answers from respondents, depending on the specific wording used. Consider the following two questions:

Is it appropriate for libraries to *not be allowed* to carry certain books?

Is it appropriate for libraries to be *forbidden* to carry certain books?

Technically, the meaning inherent in these two questions is the same. However, people might respond to them very differently, because “forbidden” has stronger negative connotations than “not allowed.” Thus, subtle variations in wording can have a dramatic effect on responses.

Rating Versus Rank Ordering Objects

If closed-ended questions are to be used, researchers must decide on an appropriate response format. When researchers wish respondents to indicate their relative preferences for a series of objects, they may choose to ask respondents to rank order them, instead of rating each one. The main advantage associated with this approach is that it eliminates the problem of nondifferentiation between objects. Specifically, when evaluating numerous objects using a rating scale, respondents will inevitably be forced to assign the same rating to several of them. If respondents rank order the objects, nondifferentiation ceases to be a problem.

However, there are difficulties associated with this approach. Rank ordering generally does not allow for the possibility that respondents may feel the same way toward multiple objects, and it may compel them to report distinctions that do not exist. Furthermore, respondents may find the process of ranking a large number of objects burdensome. Rank-ordered data can also be difficult to analyze, as it does not lend itself to many statistical techniques commonly used by social scientists.

Order Effects

When researchers employ questions that entail choosing between alternatives, the order of the response options may influence answers. The nature of such order effects depends on the method of administration. If self-administered measures are being used, *primacy effects* (i.e., biases toward selecting one of the first options presented) may pose a threat to the validity of the data. However, if the questionnaire is being orally administered by an interviewer, *recency effects* (biases toward selecting one of the latter options) may occur. Researchers can safeguard against these issues by counterbalancing response options across respondents and testing for order effects.

Number of Scale Points

If researchers employ scale-based measures, they must decide on the number of scale points to include. If an insufficient number of points are used, the measure may be insensitive to variability in respondents' answers. On the other hand, too many scale points may make the differences between points difficult for respondents to interpret, thereby increasing random error. Generally speaking, the optimal length for unipolar scales (measures used to assess the extremity or amount of a construct) is 5 points, while the optimal length for bipolar scales (measures in which the end points reflect opposing responses) ranges from 5 to 7 points.

Labeling Scale Points

Researchers must also decide whether to label the points on their scales. Labeling scale points generally helps respondents to interpret them as intended. However, if the questionnaire is to be administered via telephone, respondents may have difficulty remembering verbal labels. In such instances, numeric labels are preferable.

Including a Midpoint

Another decision is whether to include a midpoint in one's scale. Although midpoints are useful when

there is a meaningful neutral position associated with a question, there are potential disadvantages to including one. Because the midpoint of a scale is often interpreted as reflecting neutrality, people who are not motivated to consider the items carefully may automatically gravitate toward the middle of the scale. Furthermore, the meaning of the midpoint may be somewhat ambiguous. Unless a researcher stipulates what the midpoint signifies, respondents can interpret it in several ways. A midpoint response to an item could potentially indicate ambivalence, neutrality, or indifference on the part of the individual completing the questionnaire. As a result, researchers who fail to label their scales clearly may find it impossible to ascertain what midpoint responses signify.

Nonresponse Options

When people are queried about their attitudes, they may sometimes generate random, spur-of-the-moment responses. This is especially likely when respondents are asked about issues that they think about infrequently. One method of avoiding this problem is to incorporate nonresponse options into one's questions. This allows respondents to indicate that they are unsure of their opinions and alleviates the pressure to generate a substantive response instantaneously. The difficulty associated with this technique is that respondents who actually have opinions about an issue may simply select the nonresponse option if they are not motivated to consider the questions carefully. An alternative approach is to ask respondents to indicate how strongly they feel about their answers to each question (e.g., the certainty of their responses, how important they consider the issue to be). This method requires people to respond to each item, while allowing the researcher to gauge the strength of their answers.

Questionnaire Construction

Thematic Organization Versus Randomization

The way in which researchers structure their questionnaires can have a profound impact on the types of responses that people provide. Researchers can either

order questions by thematic content or randomize them. Often, social scientists have assumed that randomizing their items is more appropriate. However, studies have indicated that organizing items by thematic content makes it easier for respondents to process the content of the questions, thereby reducing random error.

Order Effects

Researchers should also minimize the potential for order effects in their questionnaires. When they complete questionnaire-based measures, people tend to adhere to conversational norms. More specifically, they adhere to the same set of implicit rules that keep regular social interactions running smoothly. For example, respondents avoid providing redundant information when they complete questionnaires. Thus, using questions that overlap in content (e.g., a question pertaining to how satisfied people are with their social lives, followed by a question pertaining to how satisfied people are with their lives in general) may prompt respondents to generate answers that are very different from the ones that they would have given if each question had been posed separately. On a related note, the initial questions in a measure may prime certain concepts or ideas, thereby influencing respondents' answers to subsequent items.

Several steps can be taken to circumvent the problems associated with question order effects. For instance, order effects can be minimized by counterbalancing items. Filler items (i.e., questions that do not pertain to the phenomena being studied) can also be used in order to "isolate" questions that could influence people's responses to subsequent items. Finally, sensitive, controversial questions should be situated at the end of a measure, so that they do not affect respondents' willingness to complete the other items.

In sum, if researchers exercise forethought in designing their questionnaires, the end product of their efforts will likely be a valid measure that is well suited to its purpose.

QUOTA SAMPLING

Quota sampling is a type of survey sampling in which interviewers are directed to gather information from a specified number of members of the population belonging to certain subgroups. The subgroups are sometimes called *strata* or *cells*. In contrast to stratified random sampling, in which interviewers are given specific instructions by the survey planners concerning which individuals to interview, interviewers in quota sampling are given some latitude in selecting the population members to interview. Quota sampling, therefore, is similar to convenience sampling in that the survey designers and planners do not strictly control the selection of the sample. Some control, however, is maintained in the distribution of some sample characteristics.

Suppose an insurance company wants to gather information on a sample of its policyholders. The company's database of clients contains records on the sex, age, and number of policies of all its policyholders. Interviews are to be conducted by telephone. The interviewers are directed to interview 75 individuals in each of 12 strata. The strata are defined by three factors: sex, age, and number of policies. Specifically, the strata are formed by grouping policyholders by sex (female or male), age group (18–35, 36–65, and over 65 years

old), and number of policies (one policy or more than one policy). These instructions will produce a quota sample because the interviewers may call as many customers as needed in order to quickly find people to complete the required interviews. In a stratified random sample, in contrast, the study planners would randomly select 75 individuals and instruct interviewers to gather data from the selected individuals.

Quota samples can be implemented in contexts other than telephone or in-person interviewing. Suppose a researcher wants to know the amount of herbicide per acre applied to agricultural land planted with corn and soybeans in the state of Iowa. The researcher picks 20 counties from around the state. He or she directs data gatherers to collect information on herbicide application for five farms growing corn and five others growing soybeans in the selected counties. If the data gatherers are allowed to choose the most convenient farms or the first farms that will participate, then it is a quota sample. The cells are defined by county and crop. If the researcher randomly selects the farms that the interviewers should visit, then it is not a quota sample.

Quota sampling is an example of *nonprobability sampling*. *Convenience sampling* is another nonprobability sampling scheme. The goal of a survey is to gather data in order to describe the characteristics of a population. A population consists of units, or elements, such as individuals, plots of land, hospitals, or invoices of purchases or sales for a company. A survey collects information on a sample, or subset, of the population. In nonprobability sampling designs, it is not possible to compute the probabilities of selection for the samples overall and, usually, for individuals. The probabilities are unknown, because typically data gatherers are allowed some freedom in selecting convenient units for data collection.

Estimates of population characteristics based on nonprobability samples can be affected by *selection bias*. Since the interviewers choose respondents that they want to interview, there is a potential for selection bias. If the respondents in the survey are systematically different on the variables being measured from the general population, then estimates of characteristics will be different on average from what they would have been with a controlled probability-sampling

scheme. In *probability sampling*, the survey planner or researcher controls which units are in the sample and selects the sample using known probabilities of selection. The probabilities of selection can be used to produce estimates of population characteristics without the problem of selection bias. Examples of probability sampling include simple random sampling, stratified random sampling, and cluster sampling.

Probability sampling is the standard methodology for large-scale surveys intended to support scientific studies and decision making for government policy. Theory supporting the use of probability sampling was developed beginning in the 1930s and has come to be appreciated widely. Quota sampling, on the other hand, is quite common in marketing surveys and less formal studies. Nonprobability sampling certainly can produce useful information for some purposes. One attempt to adjust for the fact that probabilities of selection are unknown is to use *weights*, usually called *survey weights*, in analysis. These weights are computed so that the sum of the weights for sampled individuals in a particular stratum sum to a number proportional to the actual number of people known to exist in the population in the stratum or cell. The cells for which quotas are set are often chosen due to the fact that the proportions of the population in the cells are known. Although this adjustment can help make the sample more representative of the population in analysis, it cannot overcome the fact that there could be a remaining bias due to noncontrolled random selection of the sample.

As an example of weighting or weight adjustment, suppose a bank conducts a quota sample of its account holders by selecting 100 individuals from each of four categories. The four categories are females holding single accounts, males holding single accounts, females holding multiple accounts, and males holding multiple accounts. If the hypothetical proportions of all account holders in these four categories are as given in Table 1, then the sample that contains 25% of

Table 1 Quota Sample of Account Holders

Percentage in the Population	Number of Accounts		
	One Account	More Than One	Total
Sex of Account Holder			
Female	21%	27%	48%
Male	24%	28%	52%
Total	45%	55%	100%

Table 2 Weights

Weights	Number of Accounts	
Sex of account holder	One account	More than one
Female	$25/21 = 1.19$	$25/27 = 0.93$
Male	$25/24 = 1.04$	$25/28 = 0.89$

the respondents in each category is slightly out of balance relative to the population counts.

Weights can be computed as the fraction of the sample in a category divided by the fraction of the population in the same category. The weights in this example are given in Table 2. The bank is interested in the amount of credit card debt held by its account holders. Since the credit cards might not be issued through the bank, the bank cannot simply compute the amount of debt; it must ask members of the sample for the information. A direct average of the amount of debt among the members of the sample might not represent the population very well, because the proportions by category are not exactly equal to those in the population. Instead, a weighted average using weights given in Table 2 might be better.

Of course, the selection bias produced by the quota sample might still lead to a systematic overestimate or underestimate of credit card debt.

The method of *focus groups* is another method of collecting information that can be seen as being similar in spirit to quota sampling. In focus groups, researchers meet with representatives of a population, ask questions, and hold discussions on topics of interest. Researchers conducting focus group studies and interviews with key informants about a population hope to gain insight into issues, concerns, and terminology relevant to the population's perception of an issue. Quota

sampling, instead of bringing a group together for an in-depth discussion, gathers data using a survey from a sample of individuals. A substantial research project might use several methods of gathering data, including focus groups, a pilot survey or a preliminary quota survey, and then a large-scale probability sample survey.

RANDOM NUMBERS

Random numbers are useful for a variety of purposes, such as generating data encryption keys, simulating and modeling complex phenomena, and selecting random samples from larger data sets. They have also been used aesthetically (e.g., in literature and music) and are, of course, ever popular for games and gambling. When discussing single numbers, a random number is one that is drawn from a set of possible values, each of which is equally probable (i.e., a uniform distribution). When discussing a sequence of random numbers, each number drawn must be statistically independent of the others.

There are two main approaches to generating random numbers using a computer. Pseudorandom number generators (PRNGs) are algorithmic approaches that use mathematical formulae (e.g., the linear congruential method) or simply precalculated tables to produce sequences of numbers that appear random. PRNGs are efficient and deterministic, meaning that they can produce many numbers in a short time and a given sequence of numbers can be reproduced at a later date if the starting point in the sequence is known. PRNGs are typically periodic, meaning that the sequence will eventually repeat itself. These

characteristics make PRNGs suitable for applications where many numbers are required and where it is useful that the same sequence can be replayed easily, such as in simulation and modeling applications. PRNGs are not suitable for applications where it is important that the numbers be really unpredictable, such as data encryption and gambling.

In comparison, true random number generators (TRNGs) extract randomness from physical phenomena, such as quantum events or chaotic systems. For example, random numbers can be generated by measuring the variations in the time between occurrences of radioactive decay (quantum events) or the variations in amplitude of atmospheric noise (caused by the planet's chaotic weather system). TRNGs are generally much less efficient than PRNGs, taking a considerably longer time to produce numbers. They are also nondeterministic, meaning that a given sequence of numbers cannot be reproduced, although the same sequence may, of course, occur several times by chance. TRNGs have no period. These characteristics make TRNGs suitable for roughly the set of applications for which PRNGs are unsuitable, such as data encryption, games, and gambling. Conversely, the poor efficiency and nondeterministic nature of TRNGs make them less suitable for simulation and modeling applications.

Many statistical tests exist that can be used to assess the randomness of numbers generated with either approach. Examples include the Chi-Square Test, the Run Test, the Collision Test, and the Serial Test. However, testing for randomness is not straightforward, because each possible sequence is equally likely to appear, and good random number generators therefore will also produce sequences that look non-random and fail the statistical tests. Consequently, it is impossible to prove definitively whether a given sequence of numbers (and the generator that produced it) is random. Rather, random numbers from a given generator are subjected to an increasing number of tests, and as the numbers pass more tests, the confidence in their randomness (and the generator that produced them) increases.

RANDOM SAMPLING

Three concepts that are relevant to understanding “random sampling” are population, sample, and sampling. A *population* is a set of elements (e.g., scores of a group of prisoners on a personality scale, weights of newborns of mothers younger than 18, longevity of smokers in New York City, and changes in the systolic blood pressure of hypertensive patients exposed to relaxation training) defined by the researcher's

interests. Populations can be defined narrowly or broadly and can consist of a few or many elements. For example, a researcher concerned with effects of relaxation training on systolic blood pressure might be interested only in pre- to posttreatment systolic blood pressure changes (i.e., pre–post) in the small group of patients included in her study, or she might be interested in the efficacy of relaxation training in the collection of all persons who could be classified as “elderly obese hypertensive patients” by some operational definitions of these terms.

A *sample* is a subset of a population, and *sampling* refers to the process of drawing samples from a population. Sampling is generally motivated by the unavailability of the entire population of elements (or “data”) to the researcher and by her interest in drawing inferences about one or more characteristics of this population (e.g., the mean, μ , or variance, σ^2 , of the population). Thus, in the hypertension example, the researcher might be interested in estimating from her sample data the mean (μ) or variance (σ^2) of pre- to posttreatment changes in systolic blood pressure of the population consisting of persons who fit the operational definition of “elderly obese hypertensive patients.” She might also be interested in using the sample data to test (the tenability of) some hypothesis about μ , such as the hypothesis that the average change in systolic blood pressure (μ) in the population of hypertensives exposed to relaxation training is zero. This hypothesis will be called the “null hypothesis” and will be abbreviated “ H_0 ” below. Because characteristics of a population, such as μ and σ^2 , are defined as “parameters” of the population, the principal objectives of random sampling can often be described in terms of (a) estimation of population parameters and (b) testing of hypotheses about population parameters. Parameters that are often of interest are means (μ s) and linear combinations of means that provide information about mean differences, trends, interaction effects, and so on.

Simple random sampling refers to a method of drawing a sample of some fixed size n from the population of interest, which ensures that all possible samples of this size (n) are equiprobable (i.e., equally likely to be drawn). Sampling can be carried out with

replacement or without replacement. Sampling is with replacement if, in the process of drawing the n elements of the sample consecutively from the population, each element is replaced in the population prior to drawing the next element. For example, if the population of interest consisted of Minnesota Multiphasic Personality Inventory Depression scores of 60, 65, and 70, drawing a sample of size $n = 2$ with replacement involves replacement of the first-drawn score prior to making the second draw. Sampling is without replacement in this example if the first-drawn score is not replaced prior to making the second draw. Therefore, there would be nine possible samples of size $n = 2$ (in this example) when sampling was with replacement, as shown below:

60,60	60,65	60,70
65,60	65,65	65,70
70,60	70,65	70,70

and six possible samples of size $n = 2$ if sampling is without replacement, as shown below:

	60,65	60,70
65,60		65,70
70,60	70,65	

If, in this example, the sampling is not only with replacement but also random, the probability or likelihood of drawing any one of the nine possible samples [e.g., (60,60), (60,65)] would be equal to that of drawing any of the other eight possible samples (i.e., $1/9 = .111$). However, if the sampling is random and without replacement, the probability of drawing any one of the six samples that are possible without replacement [e.g., (60,65), (60,70)] would be equal to that of drawing any of the other five possible samples (i.e., $1/6 = 0.167$).

Random Sampling and Representativeness

Authors sometime state or imply that random sampling generates samples that are representative of the populations from which they have been drawn. If this is true, then two random samples of size n drawn from the same population should be very similar. But

in fact, randomly drawn samples can have a non-negligible probability of being very unrepresentative of the population from which they were drawn, and two random samples drawn from the same population can be very dissimilar, especially when these samples are small. For example, suppose that relaxation training was ineffective in the sense that the average (pre-post) systolic blood pressure change was zero ($\mu = 0$) in the population of interest, and assume that the distribution of blood pressure changes of this population was actually bell-shaped (normal, Gaussian) with a standard deviation of $\sigma = 22$ mm Hg. Then it can be shown (using the central limit theorem) that (a) the mean (M) of a *random sample* of $n = 4$ drawn from this population would have the nonnegligible probability of .36 of under- or overestimating the population mean (i.e., $\mu = 0$) by more than 10 mm, and (b) a *random sample* of that size would have a probability of 0.18 of having a mean $M > 10$ mm. Furthermore, two independently drawn random samples of this size could, with nonnegligible probability, yield very different sample means.

Suppose that the probability that the two sample means differ by more than 10 mm Hg is 0.52. Because systolic blood pressure changes of 10 or more mm are associated with important health benefits or risks (for example, it has been estimated that every 10 mm Hg increase in systolic blood pressure is associated with a 30% increase in the risk of heart attack), nonnegligible overestimation or underestimation of effects of relaxation training on systolic blood pressure, as well as important nonequivalence of samples with respect to average blood pressure changes, could occur quite frequently with random samples of that size. Clearly, random sampling need not ensure representativeness or equivalence of samples. However, random sampling generally permits drawing useful inferences about population characteristics from sample data, regardless of the sizes of the samples (as illustrated below).

Random Sampling and the Estimation of Parameters

When a sample of size n is drawn at random from a population with mean μ , the mean of that sample (M)

will be an unbiased estimator of μ . This means that if this sampling “experiment” (the drawing of the random sample) was repeated an infinitely large number of times, the mean (also called the “expected value”) of the M s would be equal to μ . Thus, if the mean of change scores in a population of hypertensive patients who were exposed to relaxation training was in fact $\mu = 5$ mm, and if independent random samples of size 4 were to be drawn an infinitely large number of times from this population, the mean or expected value of the sample means would be 5 mm; in this situation, random sampling would result in “absence of bias” of the statistic M in the sense that the average M would be equal to 5. The sample mean M would be described as a “point estimate” of the parameter μ . [The expression “point estimate” refers to the fact that the M of a sample is a single value or point, as opposed to a range of values or intervals (see below).]

Given that the distribution from which the sample of size n has been randomly selected is normal and that its mean is μ and its standard deviation is σ , it can be shown that an interval that is defined as extending from $[M - z_{.025} \sigma/n^{.5}]$ to $[M + z_{.025} \sigma/n^{.5}]$ has a probability of 0.95 of including μ (where $z_{.025}$ is 1.96, the 97.5th centile of the standard normal distribution). This interval estimate of μ is called a two-sided 95% confidence interval. The probability that a 95% confidence interval constructed in this way includes the parameter that it is used to estimate is 0.95. For example, given that $n = 49$, $\sigma = 22$, and $M = 10$, the 95% confidence interval would extend from $[10 - 1.96(22/7)]$ to $[10 + 1.96(22/7)]$, that is, from 3.84 to 16.16. The researcher could be quite sure or confident that the average drop in systolic blood pressure in the population of hypertensives would be somewhere between 3.84 and 16.16. However, if the sample size had been $n = 4$, the same sample mean of $M = 10$ would yield a much larger 95% confidence interval. With $n = 4$, $\sigma = 22$, and $M = 10$, the 95% confidence interval would extend from $[10 - 1.96(22/2)]$ to $[10 + 1.96(22/2)]$, that is, from -11.56 to 31.56 . A much wider range of values of μ would be consistent with the sample data. It should be noted that in these examples, the

construction of the confidence intervals required knowledge not only of sample data but also of σ , a parameter that is often unavailable to the researcher. However, given random sampling, confidence intervals for μ s can also be constructed (using methods discussed in most statistic textbooks) without knowledge of σ . These examples illustrate the fact that, irrespective of the representativeness of random samples, random sampling generally permits interpretable inferences about parameters of interest to the researcher.

Random Sampling and Parametric Hypothesis Testing

Testing a hypothesis about the value of a parameter (e.g., $H_0: \mu = 0$) can be viewed as determining whether this value is or is not consistent with the sample data. Thus, a researcher who tests $H_0: \mu = 0$ in the above example in effect determines whether $\mu = 0$ is or is not plausible given the observed sample data. What is apparent from this perspective on hypothesis testing is that confidence intervals, whose construction assumes random sampling, can provide the information needed for hypothesis testing by explicitly specifying a range of values of the parameter that would be plausible given the sample data. Thus, the fact that the 95% confidence interval for the sample of $n = 49$ excluded zero would usually lead to a decision to reject the null hypothesis that $\mu = 0$ because this interval did not include zero. On the other hand, the fact that the 95% confidence interval for the sample of $n = 4$ included zero would generally lead to the conclusion that $\mu = 0$ was consistent with the sample data—that is, consistent with the possibility that the average change in systolic blood pressure of patients in the population could be zero. Clearly, because the methods used to construct the confidence intervals assume random sampling, the hypothesis tests based on information yielded by the confidence intervals also require tenability of the random sampling assumption. Random sampling implies models that make possible both estimation (point and interval estimation) and hypothesis testing about parameters of interest to researchers.

Random Sampling Versus Randomization

Random sampling, as noted above, refers to a method of drawing a sample of size n from a population, which ensures that all possible samples of that size are equiprobable. Randomization, on the other hand, refers to a method of assigning or allocating $n = n_1 + n_2 + \dots + n_k$ participants in a study to k groups where n_1 subjects are assigned to Group 1, n_2 subjects to Group 2, . . . , and n_k subjects to Group k , which ensures that all of the possible ways of making the assignments are equiprobable. For example, with $n = 5$ participants (ABCDE) and two groups, there would be 10 ways of making the assignments so that $n_1 = 2$ and $n_2 = 3$: (AB,CDE), (AC,BDE), (AD,BCE), (AE,BCD), (BC,ADE), (BD,ACE), (BE,ACD), (CD,ABE), (CE,ABD), (DE,ABC); random assignment or randomization would refer, in this example, to a method that would ensure equiprobability ($1/10 = 0.10$) of the 10 possible allocations. Randomization is feasible with a “sample of convenience,” that is, a sample of n available subjects all of whom will be used in a study, and inferential statistical methods (e.g., hypothesis testing) can be used both with random sampling (from populations whose characteristics are of interest to researchers) and with random assignment of subjects from a sample of convenience (i.e., randomization). However, although random sampling allows statistical inferences to be drawn (from a study’s sample data) about characteristics of populations from which random samples have been drawn, randomization (without random sampling) allows statistical inferences only about the participants of the study. Nevertheless, nonstatistical inferences about individuals not included in the study are often possible with randomization.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Gershater-Molko, R. M., Lutzker, J. R., & Wesch, D. (2002). Using recidivism to evaluate Project SafeCare: Teaching bonding, safety, and health care skills to parents. *Child Maltreatment*, *7*(3), 277–285.

Project SafeCare was an in-home research and intervention, grant-funded program designed to teach parents who were reported for child abuse and neglect. Parents who participated in Project SafeCare received training in three aspects of child care: treating illnesses and maximizing their health care skills (health), positive and effective parent-child interaction skills (bonding), and maintaining hazard-free homes (safety) for their children. True **random sampling** was used to select families for participation. Postcontact (after initial intake was made and the program began) incidents of child abuse and neglect for maltreating parents who participated in and completed Project SafeCare were compared to a comparison group of maltreating families from the point of initial intake through a 24-month follow-up period. The comparison group (the Family Preservation group) received intervention from Family Preservation programs. Families who participated in Project SafeCare had significantly lower reports of child abuse and neglect than did families in the comparison group.

RANGE

Among all the measures of variability, the range is the most general and is an overall picture of how much variability there is in a group of scores. It provides an impression of how far apart scores are from one another and is computed by simply subtracting the lowest score in a distribution from the highest score in the distribution.

In general, the formula for the range is

$$R = H - L,$$

where

R is the range,

H is the highest score in the data set,

L is the lowest score in the data set.

Take the following set of scores, for example (shown here in descending order):

98, 86, 77, 56, 48

In this example, $98 - 48 = 50$. The range is 50.

Although the formula you see above is the most common one for computing the range, there is another definition and formula as well. The first is the exclusive range (as shown above), which is the highest score minus the lowest score (or $h - l$) and the one that was just defined. The second kind of range is the inclusive range, which is the highest score minus the lowest score plus 1 (or $h - l + 1$). The exclusive range is the most common, but the inclusive range is also used on occasion. There are other types of ranges as well, such as the semi-interquartile range.

The range is used almost exclusively to get a very general estimate of how wide or different scores are from one another—that is, the range shows how much spread there is from the lowest to the highest point in a distribution. So, although the range is fine as a general indicator of variability, it should not be used to reach any conclusions regarding how individual scores differ from one another.

Shortcomings of the range as a measure of variability are two. First, because the range reflects the difference between only two numbers (and not any others), the only thing we know about the set of scores is these two numbers and nothing about potential outliers or scores that are far beyond the general characteristics of the distribution. For example, a range of 60 (100–40) may very well include only one number above 80 (which is 100), while the same range might reflect a distribution of scores with 20 data points above 80 (83, 92, and 97, for example). Second, because only two numbers are used, there is no discerning the shape or meaning or patterns of a set of data. Knowing the range tells us nothing about the shape of a distribution.

RASCH MEASUREMENT MODEL

A Rasch measurement model is an example of additive, conjoint, fundamental measurement by which one can create linear, objective measures applicable to the human sciences (such as in, but not limited to, education, psychology, medicine and health, marketing and business, and judging in sports). Rasch measurement models show how to determine what is measurable on a linear scale, how to determine what data can be used reliably to create a linear scale, and what data cannot be used in the creation of a linear scale. In a linear scale, equal differences between the numbers on the scale represent equal amounts of the measure.

Raw Scores to Linear Measures

Rasch measurement models can be used to convert many different types of raw score data to a linear

scale, such as dichotomous data; rating response scores; partial credit scores; skills or achievement judging scores (from, say, 1 to 10); essay marks; partial skills development; quality levels or levels of success; and so on. They can be applied to achievement data (as in subjects at schools and universities); attitude data; personality data; quality of life data; levels of health data; behavioral data; data given by groups of judges on tasks or skills (such as in diving, dancing, and ice skating); and so on.

“Scale-Free” Measures and “Sample-Free” Item Difficulties

An important point to understand is that when the data fit a Rasch measurement model, the differences between the person measures and the item difficulties can be calibrated together in such a way that they are freed from the distributional properties of the incidental parameter, because of the mathematics involved in the measurement model. This means that “scale-free” measures and “sample-free” item difficulties can be estimated with the creation of a mathematically objective linear scale with standard units. The standard units are called logits (the log odds of successfully answering the items).

A requirement for measurement is that the units should be the same size across the range of the variable measures, and this is not true with percentage scores, or summed scores from a set of achievement or attitude items, where small changes in the probability of success are related to large changes in person abilities at the bottom and top of percentage scales, all of which are nonlinear. By converting the probability of success to log odds and logits as the unit in Rasch measurement, the nonlinear problem is greatly reduced, particularly at the top of the scale.

The Simple Logistic Model of Rasch

The simplest Rasch measurement model for creating a linear scale was developed by Georg Rasch (1901–1980) and published in 1960. The simple logistic model (SLM) of Rasch has two parameters: one representing a measure for each person on a variable

and the other representing the difficulty for each item (it is sometimes called the *one-parameter model* in the literature).

Requirements of the SLM of Rasch

1. Items are designed to be conceptually ordered by difficulty along an increasing continuum from easy to harder for the variable being measured.

2. In designing the items (using three as an example), one keeps in mind that person measures of the variable are conceptualized as being ordered along the continuum from low to high according to certain conditions. The conditions in this example are that persons with low measures will have a high probability of answering the easy items positively, and a low probability of answering the medium and hard items positively. Persons with medium measures will have a high probability of answering the easy and medium items positively, and a low probability of answering the hard items positively. Persons with high measures will have a high probability of answering the easy, medium, and hard items positively. These conditions are tested through a Rasch analysis.

3. Data are collected from persons on the items and scored dichotomously (0/1 or 1/2), as in, for example, wrong/right, no/yes, none/a lot, or disagree/agree.

4. Each item is represented by a number, estimated from the data that represent its difficulty (called an item parameter in the mathematical representation of the Rasch model) that does not vary for persons with different measures of the variable. Persons with different measures responding to the items have to agree on the difficulty of the items (such as easy, medium, and hard, as used in this example). If the persons do not agree on an item’s difficulty, then this will be indicated by a poor fit to the measurement model, and then the item may be discarded as not belonging to a measure on this continuum.

5. Each person is represented by a number, estimated from the data that represent his or her measure of the variable (called a person parameter in the mathematical representation of the Rasch model) that does

not vary for items of different difficulty along the continuum. If different items do not produce agreement on a person measure, then this will be indicated by a poor fit to the measurement model, and then one examines the person response pattern (and the items).

6. Rasch measurement models use a probability function that allows for some variation in answering items such that, for example, a person with a high attitude measure sometimes might give a low response to an easy item, or a person with a medium achievement measure sometimes might answer a hard item correctly. If the person response pattern shows too much disagreement with what is expected, then it may be that the person has not answered the items properly or consistently, and that person's results may be discarded, or the item may be too hard or too easy.

Equations for the Simple Logistic Model of Rasch

$$\begin{array}{l} \text{Probability of answering} \\ \text{positively (score 1)} \\ \text{for person } n \end{array} = \frac{e^{(B_n - D_i)}}{1 + e^{(B_n - D_i)}}$$

$$\begin{array}{l} \text{Probability of answering} \\ \text{negatively (score 0)} \\ \text{for person } n \end{array} = \frac{1}{1 + e^{(B_n - D_i)}}$$

where

e is the natural logarithm base ($e = 2.718$),

B_n is the parameter representing the measure (ability, attitude, performance) for person n ,

D_i is the parameter representing the difficulty for item i .

These equations are solved from the data by taking logarithms and applying a conditional probability routine with a computer program such as the Rasch Unidimensional Measurement Models (RUMM), Winsteps, or ConQuest. The RUMM program is currently the best of the main computer programs for Rasch measures for two reasons. One is that the RUMM program provides a comprehensive set of

output data to test many aspects of the conceptual model of the variable, the answering consistency of the response categories, both item and person fit to the measurement model, and targeting. And second, the RUMM program produces a wonderful set of colored, graphical maps for many aspects of the measurement.

The Partial Credit Model of Rasch

The partial credit model (PCM) of Rasch can be thought of as an extension of the SLM from two response categories to three or more response categories or outcomes. The conditions, requirements, and output of the PCM are similar to the SLM, except that there are now more item parameters and more item output, and the equations are more complicated. The PCM can be applied to any set of data scored, judged, or answered in three or more ordered outcome categories where the level of outcome is conceptualized on a continuum from low to high. Seven examples of data that can be analyzed with the PCM are listed.

1. Ordered levels of knowledge, understanding, or skills, such as school tests in which questions (items) are marked in a set of categories, such as 0, 1, 2, 3, 4, 5, depending on the level of understanding displayed. One might have a standard for each of the six levels to help with consistency of scoring.
2. Ordered levels of tasks in problem solving where, for example, completion of a complex problem requires three intermediate ordered tasks to be completed, so the problem is scored 0,1, 2, 3, 4, depending on the level completed.
3. Ordered levels of health after an operation where, for example, patients describe their level of well-being on a scale from 1 (*unable to eat and move without pain*) to 10 (*able to eat and walk around without discomfort*)
4. Rated level of marks, for example, by one teacher assigning scores of 0 to 10 on a task such as writing an essay or completing an assignment
5. Respondents' self-ratings on attitude, personality, or behavior items using, for example, a unipolar set of responses such as *no agreement* (0), *weak agreement* (1), *strong agreement* (2), and *very strong agreement* (3), or using a bipolar set of responses such as *strongly disagree* (0), *disagree* (1), *agree* (2), *strongly agree* (3)

6. A single judge, teacher, or coach providing a judgment on the level of skill achieved in a sport or activity
7. A computerized test item that is programmed to provide a series of ordered feedback hints to allow further chances to answer correctly and ordered scores given accordingly

Equations for the Partial Credit Model of Rasch

Probability of person n scoring in outcome category x of item $i =$
 (for $x = 1, 2, 3, 4, \dots, Mi$)

$$\frac{e^{\sum_{j=1}^x (Bn - \delta_{ij})}}{1 + \sum_{k=1}^{Mi} e^{\sum_{j=1}^k (Bn - \delta_{ij})}}$$

Probability of person n scoring in outcome category x of item $i =$
 (for $x = 0$)

$$\frac{1}{1 + \sum_{k=1}^{Mi} e^{\sum_{j=1}^k (Bn - \delta_{ij})}}$$

where

e is the natural logarithm base ($e = 2.7318$),

$\sum (Bn - \delta_{ij})$ is the sum of $Bn - \delta_{ij}$,

Bn is a parameter representing the measure (ability, attitude, skill or performance) for person n ,

$\delta_{i1}, \delta_{i2}, \delta_{i3}, \dots, \delta_{iMi}$ are a set of parameters for item i that jointly locate the model probability curves for item i . There are Mi item parameters for an item with $Mi + 1$ outcome categories.

Rasch Data Analysis With the RUMM Computer Program

Using the PCM of Rasch with the RUMM computer program, there are eight data analysis tests (output) provided in the creation of a linear, unidimensional scale. This output is similar for the PCM, the ELM, the RRM, and the SLM (except that for the SLM, there are no ordered thresholds, just one threshold).

1. *Testing that the response categories are answered consistently and logically.* The RUMM program does this with two outputs: (a) It calculates

threshold values between the response categories for each item (where there are odds of 1:1 of answering in adjacent categories), and (b) it provides response category curves showing the graphical relationship between the linear measure and the probability of answering each response category.

2. *Testing for dimensionality.* An item-trait test of fit is calculated as a chi-square with a corresponding probability of fit. It tests the interaction between the responses to the items and the person measures along the variable and shows the collective agreement for all items across persons of different measures along the scale. If there is no significant interaction, one can infer that a single parameter can be used to describe each person's response to the different item difficulties, and thus we have a unidimensional measure.

3. *Testing for good global item-person fit statistics.* The item-person test of fit examines the response patterns for items across persons, and the person-item test of fit examines the response patterns for persons across items using residuals. Residuals are the differences between the actual responses and the expected responses as estimated from the parameters of the measurement model. When these residuals are summed and standardized, they will approximate a distribution with a mean near zero and standard deviation near one, when the data fit a Rasch measurement model.

4. *Person Separation Index.* Using the estimates of the person measures and their standard errors, the RUMM program calculates a Person Separation Index that is constructed from a ratio of the estimated true variance among person measures and the estimated observed variance among person measures. This tests whether the standard errors are much smaller than the differences between the person measures.

5. *Testing for good individual item and person residuals.* Residuals are the differences between the observed values and the expected values estimated from the parameters of the Rasch measurement model. It is instructive to examine these outputs because they give an indication of whether persons are answering items in a consistent way, and they also give an indication of individual person and individual item fit to the measurement model.

6. *Item characteristic curves.* Item characteristic curves examine how well the items differentiate between persons with measures above and below the item location. It also shows a comparison between the observed and expected proportions correct for a number of class intervals of persons.

7. *Person measure/item difficulty map.* The RUMM program produces two types of person measure/item difficulty maps. These maps show how the person measures are distributed along the variable and how the item difficulties are distributed along the same variable (measured in logits). They show which items are easy, which ones are of medium difficulty, and which ones are hard. They show how well the item difficulties are targeted at the person measures. That is, they show whether the items are too easy or too hard for the persons being measured and whether new items need to be added, or whether there are too many items of similar difficulty (some of which are thus not needed).

8. *Testing for construct validity.* Suppose that your items are conceptually ordered by increasing difficulty (downward) and the perspectives are ordered by increasing difficulty (to the right), and this represents the structure behind your variable. In Rasch measurement, all the item difficulties are calculated on the same linear scale, and so the item difficulties can be compared with their conceptualized order. In this case, the item difficulties increase vertically downward for each perspective by item and they increase horizontally to the right for each item by perspective. This provides strong support for the structure of the variable because it was postulated before the data were collected and analyzed.

The Many-Facets Model of Rasch

The Many-Facets Model of Rasch (MFMR) applies to situations where judges rate persons on, for example, skills, items, essays, or behaviors. The model states that persons have an estimated probability of being given any rating on an ordinal scale (e.g., 1–10, as given by judges of diving) on any item by any judge. Each observation is modeled by an ordinal rating from a loglinear combination of the measures of one element from the appropriate facets, for example, a person performance

from the person ability facet, a judge severity from the judge facet, and an item difficulty from the item facet. True to Rasch measurement, the measures are estimated from the data but are statistically independent of observations comprising the data. These measures form a linear scale on which the elements of all the facets are located. Estimates of fit to the measurement model can be made by examining the differences between the actual observations and the predicted observations estimated from the parameters of the measurement model, as is done in the other Rasch models.

An Equation for a Many-Facets Model of Rasch

The following equation applies to an example where persons are rated by judges on three or more items, each of which has its own ordinal rating scale:

$$\text{Ln} (P_{nij} / P_{nij} - 1) = B_n - D_i - C_j - F_{ik},$$

where

Ln is the natural logarithm (to the base e),

P_{nij} is the probability that person n will gain a rating of category k from judge j on item i ,

B_n is a parameter representing the ability, skill, or performance of person n ,

D_i is a parameter representing the difficulty of item i ,

C_j is a parameter representing the severity of judge j ,

F_{ik} is a parameter representing the additional difficulty of being rated in category k beyond that of being rated in category $k - 1$ for item i ,

K_i is the highest rating scale category. Zero is the lowest.

Some Special Applications of Rasch Measurement

The creation of linear measures in the human sciences through Rasch measurement and the development of personal computers has allowed for the use of two special applications: item banks and computerized adaptive testing. Item banks involve the collection of thousands of school achievement items relating to a topic, such as algebra, that have been calibrated on a linear scale. Teachers can choose a set of items on the

topic, calibrated from easy to hard, and use the items to test their students. If an appropriate computer program has been created, students can use a computer to select items appropriate to their level of understanding and attempt only those. Because all the items have been calibrated on the same linear scale, students (and their teachers) can obtain a measure of their level of understanding.

RATIO LEVEL OF MEASUREMENT

The most precise of the four levels of measurement is called the ratio level. The ratio scale is unique because, unlike the interval scale, it contains an absolute rather than arbitrary zero. In other words, a score of 0 on a ratio-level measure indicates a complete absence of the trait or construct being measured. Whereas at a temperature of 0° on a Fahrenheit scale, some molecules are still moving (because the zero of the scale is arbitrary), a reading of 0° on a Kelvin temperature scale signifies a total lack of molecular movement. Therefore, the Fahrenheit scale is an example of interval measurement, whereas the Kelvin scale is considered ratio-level measurement.

The reason the absolute zero makes the ratio scale unique is that it allows us to make meaningful fractions. On the Kelvin scale, 20° is twice as “hot” (has twice the amount of moving molecules) as 10°, and 150° is three times as “hot” as 50°. Using the Fahrenheit scale, we cannot make such a comparison; 20° is not twice as hot as 10° because the zero point on the scale does not indicate a complete absence of molecular movement and because temperatures below 0° are possible.

Whereas ratio-level data are fairly common in physical sciences (zero molecular movement, zero light, zero gravity), they are rarer in behavioral and social science fields. Even if someone scores a zero for whatever reason on an IQ test, the tester would not declare that the test taker has no intelligence. If a student receives 0 points on a vocabulary quiz, the teacher still cannot claim the student has no vocabulary.

An example of a case in which ratio data could be used in the behavioral sciences is if a researcher is using as a variable the amount of practicum hours students have logged during a semester. The researcher would give a score of 0 to any student who has seen no clients and logged no hours. Likewise, the researcher could accurately say that a student who has logged 50 hours of client contact during practicum has had twice the amount of client contact as a student who has logged 25 hours.

Although ratio-level measurement is not common in the behavioral and social sciences, its advantages

Figure 1 Progressing Levels of Measurement

make it a desirable scale to use. Because it is the most precise level of measurement, and because it contains all of the qualities of the three “lower” levels of measurement, it provides the richest information about the traits it measures.

Ratio data let us know that Person A, who earns an annual income of \$1 million, makes 100 times the amount of money as Person B, who earns an annual income of \$10,000. We can tell more from this comparison than we could if we knew only that Person B makes \$990,000 less per year than Person A (interval-level measurement), that Person A has a larger income than Person B (ordinal-level measurement), or that the incomes of Person A and Person B fall under different socioeconomic categories (nominal-level measurement). This information would give us a more accurate conception of the construct being measured.

RAVEN'S PROGRESSIVE MATRICES

Raven's Progressive Matrices, published by Lewis, is a test that was originally introduced in 1938. Its purpose is to measure Spearman's *g* factor or general intelligence. For this reason, Raven chose a spatial format for the test, which required the education of relations among abstract items, that is, the visualizing of relationships that are based on perceptual similarities between stimuli.

It is a nonverbal test of reasoning ability that comes in three forms; Coloured Progressive Matrices, Standard Progressive Matrices, and Advanced Progressive Matrices (Sets I and II). The test can be administered in groups or individually, and each form takes from 15 to 30 minutes to complete.

The Coloured Progressive Matrices is a 36-item test that can be used mainly with children from 5 to 11 years of age. In this form, the figures are in color in order to appeal to the children and sustain their attention. The Standard Progressive Matrices consists of 60 items that are presented in five sets, with 12 items per set. The test is employed mostly with persons from 6 to 14 years of age. The Advanced Progressive Matrices is appropriate for older adolescents and adults, primarily for individuals with higher than average intellectual ability. It contains 12 items in Set I and 36 in Set II.

In each form of the test, the examinee is presented with a design or matrix from which a part has been removed. The testee has to look through the matrix and decide which of six or eight pieces given below the matrix is the right one to complete the matrix. The first item in a set is intended to be self-evident, and it is followed by another 11 items of increasing difficulty.

The items referred to are (a) consecutive patterns, (b) analogies between pairs of figures, (c) progressive modifications of patterns, (d) transformations of figures, and (e) disentangling of figures into component parts. Thus, the test estimates the ability to make comparisons, to

deduce by analogy, and to organize spatial patterns into wholes.

The test items can be solved by employing problem-solving strategies. The principle that has to be used to solve each item is either to put forward orally or to draw information from visual perceptual recognition of the stimulus. In the first occasion, an analytical method is used, whereas in the second, a Gestalt procedure involving visual perception is used to solve the items.

The reliability and validity of the test is excellent, but the construct validity of the test is not supported by research because the very easy and very difficult items of the test measure different operations.

Although the test does not respond to the initial Raven's intentions of measuring Spearman's *g* factor, it is a useful indicator of nonverbal reasoning ability. More specifically, it is easy to administer and useful for screening the intelligence of children and adults with language difficulties and auditory or physical disabilities. Furthermore, it is useful for testees who do not speak English or have a restricted command of English.

RECORD LINKAGE

Record linkage, or exact matching, refers to the activity of linking together two or more databases on a single population. The U.S. Bureau of the Census uses record linkage in its efforts to estimate the population undercount of the decennial census. The two files that Census links together are a sample of the decennial census and a second, independent enumeration of the population areas covered by the sample. Some individuals are counted in both the census and the second enumeration, whereas others are absent from one or both of the

Table 1 Counts From Two Enumerations Based on Record Linkage

		Second Enumeration		
		Yes	No	Total
Census Enumeration	Yes	n_{yy}	n_{yn}	n_{census}
	No	n_{ny}	?	?
	Total	n_{second}	?	?

canvasses. Suppose that the numbers of individuals who are enumerated are given in Table 1. The question marks indicate counts of individuals that are not known.

The total size of the population can be estimated if assumptions about the two enumeration efforts and the population are made. Under standard assumptions of capture-recapture models, the total size of the population can be estimated as $n_{\text{census}}n_{\text{second}}/n_{yy}$. If 250 people were counted in the census sample, 200 were counted in the second enumeration, and 125 were common to both lists, then the population size would be estimated as $250(200)/125 = 400$. However, if only 100 people were common to both lists, then one would estimate the population size to be $250(200)/100 = 500$.

Record linkage is challenging when the sizes of the files being linked are very large and unique identifying information on every individual is not available. Examples of unique identifiers (IDs) include Social Security numbers (SSNs); U.S. passport numbers; state driver's license numbers; and, except for identical twins, a person's genetic code. The decennial census does not collect SSNs or any other unique ID number. The number of people in the census undercount sample is a few hundred thousand. Thus, record linkage in this context needs to be computerized and automated.

Entries in the two databases are compared on the fields of information common to two files. Consider the following hypothetical records in the two files called File A and File B:

File A Record	File B Record
Wayne Feller	W. A. Fuller
Male, Married, Age 70	Male, Married, Age 71
202 Snedecor Rd.	202 Snedecor, Apt. 3
Ames, Iowa	Aimes, IA

These records, although containing clear differences, could correspond to the same person. Alternate versions of names and addresses, nicknames and abbreviations, and misspellings and typographical errors are frequently encountered in large, population databases. The U.S. Bureau of the Census and other U.S. and foreign statistical agencies use sophisticated methods to address these and other challenges.

Large-scale record linkage operations typically standardize information such as names and addresses, create groups or blocks of records by geography and other factors, and score the degree of agreement between pairs of potential matches. Scores can be based on rules for adding points, also called weights, for agreements and subtracting points for disagreements. A pair of records with a high score is likely to correspond to a single person, whereas a pair with a low score is likely to represent two different people. The weights can be based on characteristics of records in the two files or estimated using statistical models, such as latent class models. The accumulation of similarities and dissimilarities, such as those found when comparing the two hypothetical records above, lead one to believe that a pair of records represents either one person or two different people.

Record linkage, or exact matching, is different from statistical matching. A use of statistical matching is to create matched pairs of people who are similar to one another on key variables, such as age, sex, race, and health status. Matched pairs can be used, for example, in experiments and observational studies to compare medical treatments.

Record linkage (RL) is used in many applications. Besides population undercount estimation, Census and major survey organizations use RL in the creation of sample frames of addresses, businesses, and establishments. The National Center for Health Statistics uses RL for comparing employment records and historical survey records to the National Death Index, a compilation of state death certificate records. Health insurance and medical organizations can use record linkage to link patient records over time in order to form cumulative health histories. Record linkage in these and other applications enable

statistical analyses and studies that otherwise would not be possible. Of course, there is a great concern for the confidentiality of respondent information and the privacy of individuals that must be protected when RL is used.

REGRESSION ANALYSIS

Regression analysis is the name for a family of techniques that attempts to predict one variable (an outcome or dependent variable) from another variable, or set of variables (the predictor or independent variables).

We will illustrate this first with an example of linear regression, also called (ordinary) least squares (OLS) regression. When people say “regression” without any further description, they are almost always talking about OLS regression. Figure 1 shows a scatterplot of data from a group of British ex-miners, who were claiming compensation for industrial injury. The *x*-axis shows the age of the claimant, and the *y*-axis shows the grip strength, as measured by a dynamometer (this measures how hard the person can squeeze two bars together).

Running through the points is the *line of best fit*, or *regression line*. This line allows us to predict the conditional mean of the grip strength—that is, the mean value that would be expected for a person of any age.

The line of best fit, or regression line, is calculated using the least squares method. To illustrate the least squares method, consider Figure 2, which is simplified, in that it has only four points on the scatterplot. For each point, we calculate (or measure) the vertical distance between the point and the regression

line—this is the residual, or error, for that point. Each of these errors is squared and these values are summed. The line of best fit is placed where it minimizes this sum of squared errors (or residuals)—hence, it is the least squares line of best fit, which is sometimes known as the ordinary least squares line of best fit (because there are other kinds of least squares lines, such as generalized least squares and weighted least squares). Thus, we can think of the regression line as minimizing the error (note that in statistics, the term *error* is used to mean deviation or wandering, not mistake).

The position of a line on a graph is given by two values—the height of the line and the gradient of the line. In regression analysis, the gradient may be referred to as b_1 or β_1 (β is the Greek letter beta). Of course, because the line slopes, the height varies along its length. The height of the line is given at the point where the value of the *x*-axis (that is, the predictor variable) is equal to zero. The height of the line is called the intercept, or *y*-intercept, the constant, b_0 (or β_0), or sometimes α (the Greek letter alpha).

Calculation of the regression line is straightforward, given the correlation between the measures. The slope of the line (b_1) is given by

$$b_1 = \frac{r \times s_y}{s_x},$$

Figure 1 Scatterplot Showing Age Against Grip Strength With Line of Best Fit

Figure 2 Example of Calculation of Residuals

where

r is the correlation between the two measures,
 s_y is the standard deviation of the outcome variable, and
 s_x is the standard deviation of the predictor variable.

The intercept is given by

$$b_0 = \bar{y} - b_1 \bar{x},$$

where

i is the intercept,
 \bar{y} is the mean of the outcome variable, and
 \bar{x} is the mean of the predictor variable.

In the case of the data shown in Figure 1, the intercept is equal to 50.9, and the slope is -0.41 . We can calculate the predicted (conditional mean) grip strength of a person at any age, using the equation

$$\hat{s} = 50.9 + a \times -0.41,$$

where \hat{s} is the predicted strength and a is the age of the individual. Notice the hat on top of the s , which means that it is *predicted*, not actual. A very similar way to write the equation would be

$$\begin{aligned}\hat{s} &= 50.9 + a \times -0.41 + e \\ s &= \hat{s} + e.\end{aligned}$$

In this equation, we are saying that s is the person's actual strength, which is equal to the expected value plus a deviation for that individual. Now we no longer have the hat on the s , because the equation is stating that the person's *actual* score is equal to that calculated, plus e , that is, error.

Each of the parameters in the regression analysis can have a standard error associated with it, and hence a confidence interval and p value can be calculated for each parameter.

Regression generalizes to a case with multiple predictor variables, referred to as multiple regression. In this case, the calculations are more complex, but the principle is the same—we try to find values for the

parameters for the intercept and slope(s) such that the amount of error is minimized. The great advantage and power of multiple regression is that it enables us to estimate the effect of each variable, controlling for the other variables. That is, it estimates what the slope would be if all other variables were controlled.

We can think of regression in a more general sense as being an attempt to develop a *model* that best represents our data. This means that regression can generalize in a number of different ways.

Types of Regression

For linear regression as we have described it to be appropriate, it is necessary for the outcome (dependent) variable to be continuous and the predictor (independent) variable to be continuous or binary. It is frequently the case that the outcome variable, in particular, does not match this assumption, in which case a different type of regression is used.

Categorical Outcomes

Where the outcome is binary—that is, yes or no—logistic or probit regression is used. We cannot estimate the conditional mean of a yes/no response, because the answer must be either yes or no—if the predicted outcome score is 0.34, this does not make sense; instead, we say that the probability of the individual saying yes is 0.46 (or whatever it is). Logistic or probit regression can be extended in two different ways: For categorical outcomes, where the outcome has more than two categories, multinomial logistic regression is used. Where the outcome is ordinal, ordinal logistic regression is used (SPSS refers to this as PLUM – PoLytomous Universal Models) and models the conditional likelihood of a range of events occurring.

Count Outcomes

Where data are counts of the number of times an event occurred (for example, number of cigarettes smoked, number of times arrested), the data tend to be positively skewed, and additionally, it is only sensible to predict an integer outcome—it is not possible to be arrested 0.3 times, for example. For count outcomes

of this type, Poisson regression is used. This is similar to the approaches for categorical data, in that the probability of each potential value is modeled—for example, the probability of having been arrested 0 times is 0.70, one time is 0.20, three times 0.08, and four times 0.02.

Censored Outcomes

Some variables are, in effect, a mixture of a categorical and a continuous variable, and these are called censored variables. Frequently, they are cut off at zero. For example, the income an individual receives from criminal activities is likely to be zero, hence it might be considered binary—it is either zero or not. However, if it is not zero, we would like to model how high it is. In this situation, we use Tobit regression—named for its developer, James Tobin, because it is Tobin’s Probit regression (Tobin himself did not call it this, but it worked so well that it stuck). Another type of censoring is common where the outcome is time to an event, for example, how long did the participant take to solve the problem, how long did the patient survive, or how long did the piece of equipment last. Censoring occurs in this case because, for some reason, we didn’t observe the event in which we were interested—the participant may have given up on the problem before he or she solved it, the patient may have outlived the investigator, or the piece of equipment may have been destroyed in a fire. In these cases, we use a technique called Cox proportional hazards regression (or often simply Cox regression).

Uses of Regression

Regression analysis has three main purposes: prediction, explanation, and control.

Prediction

A great deal of controversy arises when people confuse the relationship between prediction in regression and explanation. A regression equation can be used to predict an individual’s score on the outcome variable of interest. For example, it may be the case that students who spend more time drinking in bars perform less well in their exams. If we meet a student

and find out that he or she never set foot inside a bar, we might predict that he or she will be likely do better than average in his or her assessment. This would be an appropriate conclusion to draw.

Explanation

The second use of regression is to *explain* why certain events occurred, based on their relationship. Prediction requires going beyond the data—we can say that students who spend more time in bars achieve lower grades, but we cannot say that this is *because* they spend more time in bars. It may be that those students do not like to work, and if they didn’t spend time in bars, they would not spend it working—they would spend it doing something else unproductive. Richard Berk has suggested that we give regression analysis three cheers when we want to use it for description, but only one cheer for causal inference.

Control

The final use of regression is as a control for other variables. In this case, we are particularly interested in the residuals from the regression analysis. When we place the regression line on a graph, everyone above the line is doing better than we would have expected, given his or her levels of predictor variables. Everyone below the line is doing worse than we would have expected, given his or her levels of predictor variables. By comparing people’s residuals, we are making a fairer comparison. Figure 2 reproduces Figure 1, but two cases are highlighted. The case on the left is approximately 40 years old, the case on the right approximately 70 years old. The 40-year-old has a higher grip strength than the 70-year-old (approximately 31 vs. approximately 28 kg). However, if we take age into account, we might say that the 40-year-old has a lower grip strength than we would expect for someone of that age, and the 70-year-old has a higher grip strength. Controlling for age, therefore, the 70-year-old has a higher grip strength.

We will give a concrete example of the way that this is used. The first example is in hospitals in the United Kingdom. Dr Foster (an organization, rather than an individual) collates data on the quality of care in different hospitals—one of the most important

variables that it uses is the standardized mortality ratio (SMR). The SMR models an individual's chance of dying in each hospital. Of course, it would be unfair to simply look at the proportion of people treated in each hospital who died, because hospitals differ. They specialize in different things, so a hospital that specializes in heart surgery would have more patients die than a hospital that specialized in leg surgery. Second, hospitals have different people living near them. A town that is popular with retirees will probably have higher mortality than a hospital in a town that is popular with younger working people. Dr Foster attempts to control for each of the factors that is important in predicting hospital mortality, and then calculates the standardized mortality ratio, adjusting for the other factors. It does this by carrying out regression, and examining the residuals.

RELATIVE RISK

The relative risk (RR) is the most common measure epidemiologists use to quantify the association between a disease and a risk factor. It may be most easily explained in the case where both the disease and the risk factor may be viewed as binary variables. Let p_1 and p_0 denote the probabilities that a person with the risk factor develops the disease and that an unexposed person develops the disease, respectively. Then the relative risk is given by $RR = p_1/p_0$. In the

following discussion, we will take risk factors to be exposures. These could be toxic substances to which a subject is exposed, such as cigarette smoke or asbestos, or potentially beneficial foods, such as cruciferous vegetables. But risk factors can also refer to the expression of the disease in relatives or to genetic polymorphisms, to name a few examples. Regardless of the disease or risk factor, an RR greater than one indicates an association between the risk factor and development of the disease, whereas an RR less than one indicates that the risk factor has a protective effect. An important feature of the RR is its multiplicative interpretation—if the RR for a particular exposure is 5, then an individual with that exposure is five times more likely to develop the disease than an unexposed individual.

The most direct way to estimate the relative risk is through a prospective study. In such a study, exposed and unexposed individuals who are free of the disease are recruited into the study and then followed for disease information. After a period of time long enough for sufficient numbers of the patients to develop the disease, the relative risk may be calculated as the ratio of the proportion of exposed subjects who develop the disease to the proportion of unexposed subjects who develop it. A well-known example is a study of lung cancer and smoking among British doctors. The study, reported in the *British Medical Journal* by Doll and Peto in 1976, with a follow-up in 1994, involved recruiting 34,440 British doctors in 1951. The subjects filled out questionnaires on smoking habits and were followed for 40 years. The risks of death from lung cancer among smokers and lifelong nonsmokers were, respectively, 209 and 14 per 100,000. The relative risk is thus 14.9. As this example illustrates, prospective studies require large numbers of subjects who are followed for long periods of time, often decades. Such studies are often the most definitive in establishing a causal relationship, and they allow one to study the effects of the exposure on a variety of diseases. But the time and expense of conducting them can be prohibitive. Furthermore, for very rare diseases, it may not be possible to recruit enough healthy subjects to produce

enough disease cases to calculate a reliable estimate of the RR.

Case control (or retrospective) studies are an alternative form of study that can be used to estimate the RR for an exposure and a rare disease. In a case control study, the sampling is the reverse of that in a prospective study. One starts by sampling a set of individuals who have already developed the disease and a set of control patients who have similar characteristics to the cases, but who haven't developed the disease. One then compares the proportion of cases exposed to the risk factor to the proportion of controls who were exposed.

To understand how a case control study can estimate the RR requires an understanding of two key concepts. The first is the odds ratio (OR), which we will explain in terms of a prospective study. The odds of developing the disease among exposed individuals are $p_1/(1 - p_1)$, and the odds among unexposed individuals are $p_0/(1 - p_0)$. Then the odds ratio is given by the ratio of these two quantities, which may be expressed as $OR = p_1(1 - p_0)/p_0(1 - p_1)$. If the disease is rare, so that both p_1 and p_0 are small, then the OR is a good approximation of the RR.

The second key concept underlying case control studies is that the odds ratio of *exposures* estimated for cases and controls from a case control study equals the odds ratio of *disease* for exposed and unexposed individuals that would be estimated from a prospective study. To see this, let P_1 denote the probability of exposure to the risk factor among the cases and P_0 the probability of exposure among the controls. Then it may be shown that

$$OR = \frac{p_1(1 - q_0)}{p_1(1 - p_0)} = \frac{P_1(1 - Q_0)}{Q_1(1 - P_0)}.$$

That is, the odds ratio for exposure for cases versus controls, computed from a case control study, is equal to the odds ratio for disease for exposed versus nonexposed individuals from a prospective study. Thus, for a rare disease, the odds ratio computed from a case control study is a good approximation to the relative risk.

Case control studies require far fewer individuals than do prospective studies, and they can be carried out in a much shorter period of time. For these reasons, case control studies are the most common observational tool epidemiologists use for measuring relative risks. Bear in mind that the validity of case control studies depends on the assumption that the sampling of cases and controls are random samples from the population of interest. Thus, identifying and adjusting for potential confounding factors is essential to a successful case control study.

Logistic regression is the main statistical tool for estimating odds ratios that adjust for risk factors. The binary outcome is disease status, and the primary predictor is exposure. The exposure variable may be binary, as discussed above, or it could be a quantitative measure of the level of exposure. Other covariates may be included in the model to adjust for other factors. The parameter estimate associated with exposure is the log-odds ratio, which may be interpreted as the log relative risk for rare diseases. A related form of epidemiological study that one may use to estimate the RR is the *matched* case control study. A simple version of this uses multiple sets of one case and one control each, matched for potential confounding factors. A common variation is to create sets with one case and two to five controls each. With matched designs, a modified form of logistic regression known as *conditional* logistic regression is necessary to obtain unbiased estimates of the RR. The suggested readings contain more details about these methodologies.

RELIABILITY THEORY

Reliability and validity are two major requirements for any measurement. Validity pertains to the correctness of the measure; a valid tool measures what it is supposed to measure. Reliability pertains to the consistency of the tool across different contexts. As a rule, an instrument's validity cannot exceed its reliability, although it is common to find reliable tools that have little validity.

There are three primary aspects to reliability: (a) A reliable tool will give similar results when applied by different users (such as technicians or psychologists). (b) It will also yield similar results when measuring the same object (or person) at different times. In psychometrics, reliability also implies a third feature, which is relevant to scales (measures that include various submeasures or items). Specifically it entails the requirement that (c) all parts of the instrument be interrelated.

1. *Interrater Reliability*: Some measurements require expertise and professional judgments in their use. The reliability of such a tool is contingent on the degree to which measurements of the same phenomenon by different professionals will yield identical results. What we want to avoid is a test that essentially relies on undefined judgments of the examiner, without concrete criteria that are clearly spelled out.

Statistically, this aspect of reliability is usually determined by having several raters measure the same phenomena, and then computing the correlations between the different raters. For typical measures that yield numerical data, a correlation index needs to be high (e.g., in the .90s) to demonstrate good interrater reliability.

2. *Test-Retest Reliability*: This feature, often referred to as *temporal stability*, reflects the expectancy that the measurement of a specific object will yield similar results when it is measured at different times. Clearly, this is based on an assumption that one does not expect the object to be changing between the

two measurements. In fact, this may not be the case for many constructs. (Consider, for example, blood pressure or stress, both of which would be expected to vary from one time to another—even for the same person.) Specifically within psychology, it is important to understand that this aspect of reliability pertains only to measures that refer to traits (aspects of personality that are constant regardless of environmental events or context); it does not pertain to states (specific aspects of behavior or attitudes that vary based on situations and interactions at the moment).

Statistically, this aspect of reliability is usually determined by having a group of people measured twice with the instrument. The time interval can vary, based on specific studies, from several weeks to a year or two. Unfortunately, testing experts often choose a short duration between tests (there are published test-retest time periods of only 6 hours!), which make their claim of testing an actual trait equivocal. Correlations are computed between the two trials. For typical measures that yield numerical data, a correlation index needs to be high to demonstrate good interrater reliability (although .70 would be sufficient).

3. *Internal Consistency*: This usually entails the reliability of measures that have multiple items; such measures are known as scales.

Consider, for example, a scale of irritability. Such a scale might include 20 items that focus on different aspects of this construct. One might ask how often the person gets into arguments, another might look into how often the person changes doctors, whereas a third could ask about the person's rejection patterns of potential dates. Obviously, the experts who constructed this scale believed that all of these items are indicative of irritability. Indeed, it may well be true that irritable people would show high scores on all of these items. However, it is feasible that the major reason most people reject dates differs significantly from the reason people change doctors.

Another aspect of the problem of internal consistency might be understood from the perspective of the meaning of the score on a scale. Take, for example, the case of a firm that is interested in hiring interviewers

who will be pleasant to potential customers. Such a firm might decide to use a 100-item scale of pleasantness, which contains imagined scenarios that are presented to respondents, each having a specific response that is considered “pleasant.” In the real world, the firm cannot expect to find sufficient interviews that will score 100, so the firm decides to hire those candidates who score highest. Say that two candidates scored 98; one of the respondents “failed” two items indicating that she would ask loud people to keep it down in a theater and that she would not allow someone to cut in line in front of her at a bank. The other respondent “failed” two items indicating that she has been a party to a lawsuit and that she would hang up on a telemarketer. By assigning these respondents equal scores, the instrument implies that they are at an equivalent level of pleasantness. But what evidence is there that the items they failed are just as meaningful in terms of the overall scale? Furthermore, is it possible that there are different factors in unpleasantness, and that these items don’t really speak to the same construct?

There are several methods of establishing internal consistency, all of which are based on intercorrelations between items. One method is called split half, where the scale is divided into different sets, each containing half the items, and the halves are then tested for an acceptable relationship using the correlation statistic. Often, item-total correlations are used to establish internal consistency (that is, correlations between each of the items and the total scale score). Typically, an item must correlate .3 or higher with the total score in order to remain part of the scale. A popular overall statistic that takes into account all of the possible item intercorrelations is Cronbach’s alpha (alternatively, the Kuder Richardson-20 formula for dichotomous items), where an alpha of .70 or higher is considered acceptable to establish this form of reliability.

Scaling issues that are related to internal consistency often are found in weighting procedures. Some tests contain items that are given more weight in the total score than others. These features introduce statistical complications in the process of establishing consistency, which are often solved through multiple regression methods.

All in all, reliability is a major part of the preparatory work that goes into scale construction, often in conjunction with factor analysis. It is not featured emphatically in test descriptions, but poor reliability will doom a test’s validity and its usefulness to measure anything meaningful.

REPEATED MEASURES ANALYSIS OF VARIANCE

In a repeated measures analysis of variance, we are faced with the task of comparing means of groups that are dependent. Unlike the usual analysis of variance (ANOVA), where the groups are independent, in repeated measures ANOVA, the groups and the group means are dependent. Because the group means are dependent, we must adjust the usual statistical and inferential processes to take the dependencies into account. Before going on with our discussion of repeated measures ANOVAs, let’s consider two situations that are likely to yield correlated means.

To begin with, consider a situation in which we have 10 raters (judges) and five job applicants. In this situation, each rater would rate each candidate, but the five ratings generated by a rater are very likely to be dependent. If we were to create a table with candidates making the columns and raters making the rows, then the observations in each column would be independent, but not so across each row. The mean ratings for the candidates would then be dependent; comparing the means requires a procedure that takes into consideration the dependencies.

Consider another example where individuals are observed over time. In this type of experimental design, one or more groups of individuals are observed before and after a treatment. This design is traditionally called a pre-post design, and the number of posttreatment observations is usually greater than one. For instance, the individuals can be observed at 3-month intervals for a period of a year, yielding four posttreatment observations and one pretreatment observation. Just as in the previous example, these five means are likely to be correlated, and comparing them necessitates a procedure that takes the correlation into account.

We have seen two examples in which the means are probably dependent. However, there are many additional situations that can generate dependent means. For instance, using groups that have been matched along specific criteria to make them equivalent can also undermine the assumption of independence. Researchers must be vigilant and always look for design characteristics or constraints that may render the means dependent.

When repeated measures designs are compared to other designs, we see a number of advantages and disadvantages. Some of the advantages are that (a) they use fewer subjects; (b) they tend to be more efficient (subject variability is controlled better, which often increases power); and (c) they cost less to implement. Of course, not all studies can use repeated measures. There are many situations that preclude the use of repeated measures. For instance, if a prior treatment affects performance on a subsequent treatment—due to contrast effects, fatigue, emotional reaction, and so on—and one can't control for this nuisance effect, a

repeated measures design would not be appropriate. (Keppel and Wickens have provided more information on nonstatistical problems that may affect the interpretation and execution of repeated measures studies.)

These advantages do not come without disadvantages. The major disadvantages of repeated measures designs are that they are harder to analyze and interpret. They are harder to analyze because the groups are not independent, and they are harder to interpret and design because of the possibility of carryover or similar effects.

Traditionally, the data in most analyses of variance (ANOVAs) have been analyzed with the F test. The assumptions for the F test are normality, homogeneity of variances, and independence. As it works out, however, the F test is capable of handling certain dependencies between groups. These dependencies are subsumed under what is called the circularity or sphericity assumption. The repeated factors and the interactions involving repeated factors require the circularity assumption for the validity of the F ratios. (The assumption in essence transfers the independence requirement to the contrasts implicitly tested by the F test.) Thus, the assumptions for the repeated factors are normality and circularity.

The most restrictive form of the circularity assumption demands that the observations between any two levels of the repeated factor be equally correlated. In a simple repeated measures design with three levels in the repeated factor T , this restrictive form of the assumption requires that the three correlations between the levels of the repeated factor be equal:

$$r(T_1, T_2) = r(T_1, T_3) = r(T_2, T_3).$$

This extreme form of the circularity assumption is known as the compound symmetry assumption. If the circularity assumption is met, the usual F tests are valid and the repeated measures analysis resembles the usual ANOVA procedure.

It is not unusual, however, for the circularity assumption to fail. In these situations, we must reduce the degrees of freedom (df) of the F test before looking up the critical value in the F table. Alternatively,

we could have our computer package find the p value for the F ratio with the reduced degrees of freedom. The degrees of freedom are reduced to the degree that we violate the circularity assumption. More severe violations reduce the df more than less severe violations. The F tests based on reduced df are approximate in that they depend on the unknown population variances and covariances between the levels of the repeated factors, which are never known in practice. However, it has been found that procedures are very accurate when they are based on sample estimates of these parameters.

Many computer packages, in addition to providing tests that reduce the df , provide multivariate tests of the univariate repeated measures hypotheses. If one conceptualizes a repeated measures design as a multivariate analysis of variance (MANOVA), we can test the univariate hypotheses by creating a set of dependent variables that represents the differences between the levels of the repeated factor. By conceptualizing a repeated measures design as a multivariate analysis of variance, we get around the circularity assumption. The MANOVA makes no structural assumption about the variance-covariance matrix.

With the new advances in the analysis of mixed model designs, we can yet provide another approach to the analysis of repeated measures data. We can estimate the structure of the variance-covariance matrix underlying the repeated measures and carry out a large-sample maximum likelihood analysis of the repeated factor; such approach can be found in SAS's Proc Mixed and in other computer packages. The maximum likelihood approach is generally more efficient than the multivariate approach when we have missing data.

All of these approaches to the analysis of repeated measures have different strengths and weaknesses. The choice of what technique to use depends on the assumptions that one can make, the availability and familiarity with computer packages, and the researcher's preference. To this date, no clear winner has been identified. However, it is clear that routinely we should carry out more than one procedure and never assume that we have met the circularity assumption. Next, we provide an example in which the circularity assumption is met, because there are

only two levels of the repeated factor. Although the example is computationally simple in that we do not need to be concerned with circularity, it illustrates the fundamental ideas behind the analysis of a repeated measures design.

Example

Does flexibility training help improve spinal extension (bending backward) in elderly women? Based loosely on research by Rider and Daly, this research had 20 female volunteers with an average age of 71.8, who were in moderately good health including no orthopedic problems. Ten women were randomly assigned to the experimental condition, a 10-week program with 3 days per week of spinal mobility and flexibility exercises. The other 10 women were randomly assigned to a control condition, which was a regular exercise program without flexibility training. All women were measured before and after the 10-week program. Table 1 shows the scores on a spinal extension measure (higher scores mean better extension).

Table 2 shows the F tests from an SAS ANOVA on these data, with F ratios for g (experimental vs. control), t (pretest vs. posttest), and the $g \times t$ interaction.

The results show that trial effect and the group-by-trial interaction are significant. There was no group effect. The significant F ratio for the group-by-trial interaction shows that spinal extension flexibility differences between the pretest and posttest depend upon whether the women were in the experimental group or control group. Using multiple comparison procedures, we can explain this interaction by showing a significant gain in flexibility from pretest to posttest for the experimental group but not for the control group.

This example illustrates that in pre–posttest designs, the hypothesis of interest is often the interaction hypothesis and not the main effects. In this example, we met the circularity assumption. Had we presented an example in which the circularity assumption had not been met, we would have proceeded in the same manner except that we would have evaluated the interaction and trials effects with corrected F ratios (or multivariate tests).

RESIDUALS

Residuals play an important role in statistical modeling. The most common definition of residual is the difference between the observed and expected response based on the estimated model so that each observation has a corresponding residual. This definition of residual is frequently encountered in most regression models and analysis of variance models. Loosely speaking, residual is interpreted as the portion of the observed response not explained by the model with the set of predictor variables.

Use of Residuals

A key step in modeling is the examination of the residuals for the purpose of checking if the model is a good fit in light of the data. In particular, residuals are used to check the validity of the assumptions of the model and to identify observations that are considered outliers (unusually large or small observations) and influential in estimating the model. These may be achieved through graphical techniques or performing formal statistical tests applied to residuals. One may work with raw residuals or standardized residuals. Standardized residuals are obtained

by dividing the raw residuals by their estimated standard error.

An Illustration

In ordinary regression modeling, a response variable (denoted by Y) is modeled using a linear relationship with a single variable, known as the predictor variable (denoted by X). Mathematically, this model is represented by the following equation:

$$Y = \beta_0 + \beta_1 X + \varepsilon,$$

where β_0 and β_1 are the intercept and slope of the line, respectively, and ε is the random error term. As an example, suppose it is of interest to model job satisfaction (Y) based on the number of years on the job (X). The data are given in Table 1. A scatterplot of the data is displayed in Figure 1, represented by dots. The estimated model is given by

$$\hat{Y} = 4.83 + 0.17 X,$$

which is represented by the solid line in Figure 1. Residual is graphically represented as the difference between a given observation and the fitted line, as illustrated by the vertical line in Figure 1. For this particular observation, $Y = 5.2$ and $X = 7$, so that the estimated response is given by

$$\hat{Y} = 4.83 + (0.17) \cdot (7) = 6.02.$$

Table 2 Data on Job Satisfaction and Number of Years on the Job

<i>Number of Years</i>	<i>Job Satisfaction</i>
7	5.2

10	5.9
15	7
12	7.3
9	6.5
14	8.1
20	8

Figure 1 Scatterplot of Job Satisfaction Data With Best Fit Line

Consequently, the residual for this observation is

$$e = Y - \hat{Y} = 5.2 - 6.01 = -0.82.$$

A plot of the residuals versus the predictor variable checks the assumption that the relationship between X and Y is linear. This residual plot applied to the current example is displayed in Figure 2. If the assumption of linearity is appropriate, there should not be any obvious systematic pattern in this residual plot, which is true in this case. Hence, there is no evidence to reject the linearity assumption of the model.

Other Types of Residuals

In more complex statistical models, residuals are defined differently, and, in some cases, there may be

Figure 2 Residuals Versus Number of Years on the Job

more than one type of residual. For instance, in logistic models, there are deviance residuals in addition to the commonly defined residuals. In survival models, where the response variable of interest is time until an event occurs, there are also deviance, Cox-Snell, martingale, and score residuals, to name a few. The definitions of these residuals are no longer as simple as observed minus expected. However, no matter how these residuals are defined, their main purpose is still the same, that is, checking the appropriateness of the model.

RESPONSE TO INTERVENTION

Response to Intervention (RTI) refers to a student-centered assessment and intervention model that has been proposed recently as an alternative approach to the identification of specific learning disabilities (SLDs) under the 2004 reauthorization of Individuals with Disabilities in Education Improvement Act (IDEIA). The IDEIA eliminates the longstanding requirement (i.e., since 1977) that a significant discrepancy between IQ and achievement must be demonstrated to classify a child as a child with an SLD. Although states may still use the IQ-achievement discrepancy model, the U.S. Department of Education, in its proposed IDEIA regulations, is encouraging adoption of the RTI model instead. RTI reflects a reconceptualization of how learning disabilities are assessed and identified by determining whether a child responds to

scientific, research-based interventions as part of the evaluation criteria used to determine if the child has a learning disability, regardless of the existence of an IQ-achievement discrepancy.

Background

The term RTI was first conceptualized in 1982 by leaders in the field of education, who proposed that the validity of a special education classification be judged according to three criteria. The first criterion was whether the quality of the general education program was such that adequate learning might be expected. The second criterion was whether the special education program would lead to academic improvements justifying the classification. The third criterion was whether the assessment process was accurate and meaningful. Under this model, all three criteria must be met for the classification to be considered valid. This new framework required judgments about the quality of instruction in both the general education and special education settings as well as judgments about the way students responded to these learning environments, all based on accurate and meaningful assessments.

The main premise of RTI is that students are identified as having an SLD when their response to effective academic interventions is significantly lower than that of peers. The inference is that students who fail to make adequate progress in response to scientific interventions that are proven successful for most students must have a deficit that requires specialized treatment beyond what general education programs can offer. RTI is sometimes referred to as the problem-solving method because it focuses on applying a problem-solving framework to identify and address student difficulties.

Prior to the RTI conceptualization, SLD was viewed exclusively as a within-child deficit, despite awareness that learning is influenced by the context in which instruction takes place. Instead of making the assumption that the underlying cause of the learning difficulty lies within the child, RTI models recognize that the difficulty may also lie within instruction, within the child, or a combination of the two. Thus,

the new approach focuses on early identification/prevention of learning problems and the contribution of the instructional environment to the child's academic growth. Instead of measuring a student's skills at a single point in time and identifying the student as SLD, assessment and intervention occur on an ongoing basis.

RTI Models

Currently, there are many ways to implement RTI; however, there are some common elements that distinguish a RTI model from other approaches to SLD identification. The core characteristics of RTI include the following:

- Students receive high-quality instruction by their classroom teacher in their general education classrooms while their progress is monitored.
- Those who do not respond receive additional or alternative instruction while their progress continues to be monitored.
- Students who still do not respond may qualify for comprehensive special education evaluation or special education services.

This multiple-step process may vary in terms of the number of levels or tiers in the process; the person(s) responsible for the assessments and interventions; and whether the process is a forerunner to a formal comprehensive evaluation for special education eligibility, or if RTI is itself considered the eligibility evaluation. Several components are necessary to enhance the effectiveness of RTI approaches: (a) ongoing, frequent assessment of student progress, (b) knowledge and skill in implementing evidence-based instruction, (c) a system to screen and track the progress of a large number of students, and (d) systematic assessment of the fidelity or integrity with which the assessments and interventions are implemented.

The Three-Tier RTI Model

Among the most well-conceptualized RTI models is the three-tier model proposed by L. S. Fuchs from Vanderbilt University, also known as “treatment

validity.” Tier I uses classwide assessment to determine whether the overall rate of responsiveness to instruction for the general education environment is generally effective so that adequate student progress is expected. Tier II assessment consists of identifying those students whose *level* of performance and *rate* of improvement are significantly below those of classroom peers. These children are identified as *dually discrepant* because their level of performance and their rate of performance (i.e., slope) fall below the level and rate of classmates. In Tier III, alternative or additional evidence-based interventions are implemented in the general education setting to enhance the quality of education. If intervention fails to promote student growth, comprehensive special education evaluation is considered.

Curriculum-Based Measurement in RTI

Curriculum-based measurement (CBM) is a multiple-probe, brief-duration (e.g., 1 minute) assessment method designed to measure student performance over time to identify students whose level and rate of performance are below those of the reference group. Equal importance is given to skill level (low achievement) and progress (slope). A student who is achieving significantly below level and whose rate of progress is similarly deficient is considered to be at risk. This dual discrepancy of low achievement and low rate of progress becomes the index by which responsiveness to instruction is judged. Students who are dually discrepant undergo additional interventions in the general education classroom while being monitored with CBM “probes” (i.e., student brief, timed samples) to determine if they will respond to the additional instruction. Special education evaluation or placement is considered only if they continue to demonstrate a dual discrepancy after an evidence-based intervention has been tried for some time (e.g., 8 weeks).

RTI Models Address Poor Instruction

RTI models address an often overlooked criterion in the IDEIA regulations—whether the student has

received adequate instruction in general education but failed to benefit from it. Under RTI, students cannot be identified as dually discrepant unless there is indication that most students in the classroom are responding to the curriculum. If the classroom as a whole is not performing at the same level and rate as other classrooms, then a classroom-level intervention geared to improving the academic performance of all students occurs before individual deficits are considered. In this way, RTI proponents maintain that they can rule out poor-quality instruction as a cause of a child's learning difficulty.

On the other hand, if a student responds inadequately to instruction that benefits the majority of students, poor-quality instruction can be ruled out as a feasible explanation for poor academic progress, suggesting instead that a disability is responsible for a child's lack of progress. In other words, the possibility of a neurological deficit (a within-the-child deficit) is not ruled out until the child is unresponsive to quality instruction.

Advantages of RTI Models

RTI models can provide assistance more quickly to a greater number of low-performing students than is possible with IQ-achievement discrepancy models. RTI models emphasize classwide assessment, enabling early identification of struggling students. Because RTI focuses on effective instruction and early intervention, it may benefit all children, including those who enter school with limited literacy and language proficiency who may be at risk for failure, as well as children with disabilities. RTI proponents argue that RTI represents a switch from assessment for eligibility purposes to assessment for instructional purposes, and that RTI ensures that student progress is monitored and instructional interventions are tested. Using an RTI model as part of an overall universal screening may also reduce the reliance on teacher referral, thereby decreasing possible referral bias. Finally, because RTI relies on ongoing data collection, this approach can reduce the influence of measurement error that characterizes assessments administered at a single point in time. A more accurate picture of the student may be

possible because the focus is not only on level of performance but also on growth over time.

Controversial Aspects of RTI

In spite of the increasing popularity and acceptance of RTI, there are many controversial issues that require resolution. Critics assert that children who are identified with an SLD under the RTI-only model may not have a true disability, particularly because no description of cognitive deficits can be identified within the RTI framework, although the IDEA definition of SLD specifically requires cognitive processing deficits. Opponents of RTI argue that if dual discrepancy is a valid SLD marker, then children identified as SLD should be distinguishable from other groups (e.g., low-achievement children). Yet when RTI has been studied, the distributions of children defined as learning disabled and low achievers overlap substantially, and reading improvement is basically the same for both groups.

Another controversial issue is whether failure to RTI may be attributable to other causes (e.g., mental retardation, emotional disturbance) rather than SLD. Critics also point out that RTI requires arbitrary cut-off points to identify those who fail to RTI. However, the arbitrary cut-off point is a limitation for other approaches for SLD identification as well.

Durability of response to instruction is another controversial area. If a student responds to relatively intensive but short-term instruction treatment, the assumption under RTI is that a disability has been ruled out. Although this may be true for many students, research evidence suggests that the difficulty will reemerge for others when the intensive instruction ceases. Feasibility of evidence-based instruction for the general education classroom is another issue. Interventions that are research-based but not feasible are not likely to be implemented with fidelity, which would undercut the validity of RTI decision making.

Implementing RTI in a way that enables procedural standardization across classrooms, schools, districts, and states is also a challenge for RTI. In addition, research support for RTI is uneven. Adequate research support exists for RTI with reading fluency, particularly

in the early elementary grades. CBM probes for assessing growth have been established in mathematics, spelling, and written expression, but research-based intervention methods for these areas await development. Finally, adequately trained personnel are not yet available on a nationwide basis. A growing number of school districts in Florida, Iowa, Kansas, Minnesota, Ohio, Pennsylvania, South Carolina, and Wisconsin already use RTI to identify students for special education services. Yet most efforts have been implemented on a small scale, and most states lacked personnel trained and skilled in RTI when the IDEIA took effect on July 1, 2005. Perhaps more importantly, RTI implementation requires a paradigm shift for many professionals in conceptualizing assessment and intervention, and resistance to change is to be expected.

In spite of the enormity of the task, and the many accompanying challenges, RTI is at the forefront of a nationwide change in the SLD identification process.

REVERSE SCALING

Scales are sets of items measuring similar constructs on questionnaires. For example, a questionnaire

designed to measure students' satisfaction with a course might contain scales on the instructor, content, course workload, and so on. Generally, scale items are constructed so that participants who have a favorable disposition toward the construct being measured would agree, or strongly agree, with the statements. Examples of such items include the following:

- The instructor's explanation of concepts was clear.
- The instructor responded well to student questions.
- The instructor is competent in his/her area.

Reverse coded items are items phrased in the semantically opposite direction. Examples of reverse coded items are as follows:

- The instructor is impatient with students.
- The instructor did not present concepts clearly.

Reverse scaling is the use of reverse coded items on scales.

Purpose of Reverse Scaling

In his presentation of scaling, Likert recommended constructing scales to balance the item wording and phrase approximately half the items in the reverse. The recommendation to use reverse scaling continues because many psychometricians believe that the inclusion of reverse coded items motivates participants to process items more carefully and prevents negative respondent behaviors such as response set, satisficing, and acquiescence. Response set is the tendency of participants to respond to the set of scale items rather than individual items. For example, a respondent may have a positive impression of an instructor being evaluated and simply respond to the entire set of items positively rather than processing the nuances of each item individually. The inclusion of an item worded in the opposite direction could encourage participants to read and process each item more carefully. Psychologists contend that people prefer to answer in agreement rather than disagreement; therefore, participants may acquiesce or simply agree with an item out of some form of social desirability. Furthermore, participants may also satisfice or agree

with an item because doing so requires minimal cognitive effort. Therefore, reverse coded items are prescribed to force participants to process individual items more carefully and accommodate participants who wish to vary their responses and not always provide the same answer.

Coding and Scoring of Reverse Coded Items

For initial coding purposes, it is best to code reverse coded items in the same way that the traditional items are coded (i.e., *strongly agree* = 5, *agree* = 4, *neutral* = 3, *disagree* = 2, and *strongly disagree* = 1). However, once the data have been entered, the scores for all reverse coded items should be recoded to facilitate consistent interpretation of the data and must be recoded if items are to be combined to form scales. Suppose a scale contained four traditionally worded items and one reverse coded item. If a respondent strongly agreed with the construct measured by the scale, they should respond *strongly agree* to the four traditionally worded items and *strongly disagree* to the reverse coded item. Thus, the raw scale score for the respondent would be 21 (i.e., 5 + 5 + 5 + 5 + 1 = 21). This score of 21 is misleading because of the score of 1 for the reverse coded item. The score of 21, rather than 25, indicates less than strong agreement with the scale items. Therefore, the scores for all reverse coded items must be recoded. Researchers using any instrument must always search for reverse coded items that might be included in the instrument.

To recode reverse coded items, the numerical values assigned to each category must be reversed (i.e., *strongly agree* = 1, *agree* = 2, *neutral* = 3, *disagree* = 4, and *strongly disagree* = 5). If the data are analyzed with Statistical Package for the Social Sciences (SPSS), then you can either *recode into the same variable* or *recode into a different variable*. If you choose to recode into the same variable, then your original data will be overwritten. Therefore, a safer practice is to recode into a different variable. To begin the recoding process,

- On the top tool bar, click *Transform*.
- From the drop-down menu, click *Recode*.
- From the next drop-down menu, click *Into Different Variable*.

Now, a dialog box should appear to *Recode into Different Variables*. The first steps are to select and rename any variables that need recoding. To do this,

- Select the first variable to be recoded from the variable list on the far right column, and then click the arrow to send the variable into the *Numeric Variable* → *Output Variable* box.
- Enter the information for the new variable in the *Output Variable* area on the far left of the dialog box.
 - Enter the name for the new variable in the *Name* box (e.g., the original variable name with the letter *r* added to the end to indicate that it has been reverse coded).
 - If you choose, enter the label for the new variable in the *Label* box.
 - Click *Change*.
- Repeat this process for all variables to be recoded with the same codes.
- To enter the new codes, click the button *Old and New Values . . .*

Now, a dialog box should appear to *Recode into Different Variables: Old and New Values*. To recode the values,

- On the left side of the box, in the area marked *Old Value*, enter the initial value in the box labeled *Value*.
- On the right side of the box, in the area marked *New Value*, enter the new value in the box labeled *Value*.

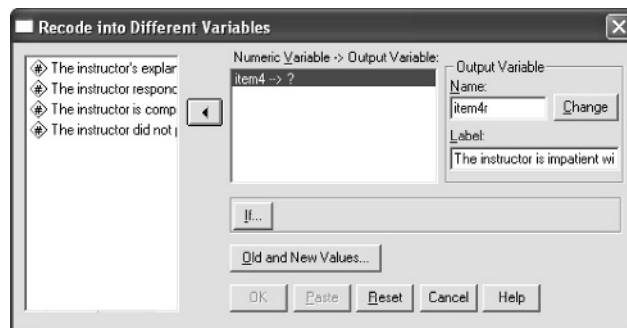

Figure 1 SPSS Recoding Dialog Box

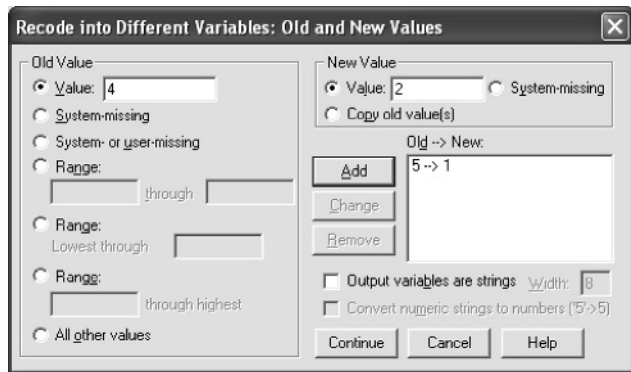

Figure 2 SPSS Old and New Values Dialog Box

- Click *Add*.
- Repeat this process for all values (i.e., $5 = 1$, $4 = 2$, $3 = 3$, $2 = 4$, and $1 = 5$). Check the list that appears in the *Old*→*New* box. This is the only time to view the changes that will be made to the variables.
- Click *Continue*.

The *Recode into Different Variables* should reappear. To complete the recoding, click *OK*.

Finally, you may verify that the recoding was done correctly by computing a correlation coefficient between the initial variable and the new, recoded variable. If the recoding was conducted properly, there should be a perfect negative correlation of -1 between the variables.

Cautions

Recent evidence suggests that the use of scales with a mixed format, traditionally and reverse coded items on the same scale, can adversely affect the psychometric properties of scales. If participants misinterpret a reverse coded item, then the score used in the analysis is not a true measure; in fact, the score is in error by the maximum amount detected on the scale (i.e., a score of 1 instead of a score of 5). The inclusion of reverse coded items on an instrument necessitates the assumption that participants both interpret and respond to the items in the same manner, irrespective of item wording. However, researchers have found that mixed format scales may potentially confound factor structure; result in a separate factor for the

reverse coded items; result in significant differences from responses to traditionally worded items; reduce scale reliability; and result in less accurate responses, therefore hindering the validity of the results.

If participants do interpret and/or react differently to negatively worded items, then what contributes to this difference? Participants may overlook the word or phrase that reversed the meaning of the item (e.g., The instructor did *not* present concepts clearly) or may have difficulty with the mental processing required to strongly disagree to a reverse coded item in an effort to give a positive rating to the construct under measurement (e.g., The instructor is impatient with students). To date, researchers have attributed differential response patterns to mixed item wordings to age, careless responses, culture, educational level, insufficient cognitive ability, instrument wording, interest in topic, personality traits, reading ability, and the actual measurement of a different construct.

Therefore, when using reverse coded items, researchers must determine if the potential benefits outweigh potential costs. Recommendations made from research in the area of scales with a mixed format include using only positively stated items, avoiding the comparison of scores from scales with different numbers of reverse coded items, and conducting separate analyses for the reverse coded items.

ROBERTS APPERCEPTION TEST FOR CHILDREN

The Roberts Apperception Test for Children (RATC), published by Western Psychological Services, is a projective test used to assess children's psychological development. Its primary purpose is to assess children's perceptions of common interpersonal situations as an aid to general personality description and clinical decision making. Interpretation of the RATC is based on the "projective hypothesis," an assumption that children, when presented with ambiguous drawings of children and adults in everyday interaction, will project their characteristic thoughts, concerns, conflicts, and coping styles into the stories they create. During the test, the individual is presented with a series of drawings and is asked to create stories describing what is happening in each situation, what led up to it, and how it will end. Usually, the child is asked to explain what the main characters are thinking and feeling. For example, a child is pictured sitting at a desk, surrounded by books and papers, apparently engaged in homework. In another picture, a child is pictured kneeling in front of, and clasping, a female figure who has her arms around the child in an apparently comforting posture.

The test's standardized and formally coded content scales indicate where the child is on a continuum of social understanding. Typically, as children become more socially experienced, their stories reflect greater awareness of social convention, more differentiated themes, and clearer resolution of themes and conflicts. Moreover, the inclusion of clinical scales calls attention to the likely presence of social and emotional problems that are outside the norm. Thus, the RATC assesses two independent dimensions: adaptive social perception and the presence of maladaptive or atypical social perception. The RATC takes approximately 20–30 minutes to administer when all stimulus cards are presented. After recording the stories, the clinician scores the responses for the presence or absence of specific characteristics. Stories are rated on seven scales: Theme Overview, Problem Identification, Emotion, Available Resources, Resolution, Outcome, and Unusual or Atypical Responses. Scores are

plotted onto a profile sheet that shows *T*-score equivalents of raw scores and a shaded area between $40T$ and $60T$ denoting the "normal range."

The RATC was standardized on a sample of 200 children who had been described as "generally well adjusted" by their teachers. This standardization sample has been criticized by a number of researchers who have shown that the RATC is of questionable value for distinguishing between clinical and nonclinical populations, and they have suggested that the norms not be used for clinical diagnosis. There have also been debates about the reliability and validity research on the RATC, despite it being the second most popular projective test used with children in the USA. However, in the Roberts-2 (the second edition of the RATC, which was published in late 2005), new norms, grouped by age and sex, are based on a sample of 1,000 children and adolescents (age extended to 18 years), and this test is better representative in terms of gender, ethnicity, and parental education than the original sample. The Roberts-2 also includes data on a clinically referred sample of more than 500 children and adolescents. The authors suggest that this new evidence supports the use of the Roberts-2 in both research on the development of social understanding in normal children, and the clinical assessment of children experiencing adjustment problems. The Roberts-2 also includes new test pictures that feature current hair and clothing styles but retain the thematic content of the original pictures, as well as three parallel versions of the test pictures—one showing White children, one featuring Black children, and a third depicting Hispanic children.

RORSCHACH INKBLOT TEST

The Rorschach is the well-known inkblot technique, named for its inventor, a Swiss psychiatrist who noticed that mental patients responded to inkblots differently from normal people. Published by Hans Huber of Bern, the 10 inkblots are among the most widely used and most roundly criticized assessment techniques in psychology. Subjects are asked to find images in the ink, and their response tendencies are inferred from what they saw and from how they used the ink.

The Rorschach has three basic uses. One, the inkblots are standardized stimuli that invite a wide variety of responses. Complete and leisurely inspection of the stimulus that occasions a response is a rarity for psychologists and allows for careful consideration of the functional relationship between the two. The psychologist infers what kinds of variables were operating on the subject to produce this particular response to this particular stimulus. Research has shown that managing the gradient from abstraction (they do represent some things) to concreteness (they are only inkblots) may be particularly difficult for seriously disturbed people. Detractors note that research has also shown that interpretations sometimes say more about the psychologist than the subject.

Two, comparison of a subject's responses with what the inkblots actually look like provides a test of the subject's ability to perceive reality accurately. Detractors note that it is hard to say what something actually looks like. Any test of perceptual accuracy, however, will either produce little variation among subjects or raise questions about the psychologist's subjective evaluation. Clinicians frequently make

judgments about people based on subjective evaluations; the standardized stimuli of the Rorschach at least allow for a second opinion.

Three, the Rorschach is widely used as a nomothetic device, meaning that responses are coded for how the ink was used, the content that was seen, and numerous other variables. An individual's codes are then compared with population averages, and inferences are drawn about subjects by comparing their performance with most people's. Nomothetic use has proliferated since John E. Exner published the Comprehensive System (CS) in 1974, with its extensive research base. Critics have attacked the CS as not meeting nomothetic standards with respect to reliability, norming, and validity.

Few critics take issue with the utility of examining a subject's responses to ambiguous stimuli under controlled conditions. Many Rorschach interpretations, however, go far beyond this. The CS, for example, derives 113 codes and 32 indexes, ratios, and percentages from as few as 14 answers. The Rorschach takes a relatively long time to learn, and critics are also concerned that this investment makes practitioner constraint more difficult.

Many of the studies purportedly demonstrating validity are flawed, and none of the projective test scores have been well replicated.

R_V AND CONGRUENCE COEFFICIENTS

The congruence coefficient was first introduced by Burt under the name of *unadjusted correlation* as a measure of the similarity of two factorial configurations. The name *congruence* coefficient was later tailored by Tucker. The congruence coefficient is also sometimes called a *monotonicity* coefficient. The congruence coefficient takes values between -1 and $+1$.

The R_V coefficient was introduced by Escoufier as a measure of similarity between squared symmetric matrices (specifically, positive semi-definite matrices; see the Appendix section at the end of this entry for a proof) and as a theoretical tool to analyze multivariate techniques. The R_V coefficient is used in several statistical techniques such as STATIS and DISTATIS. In order to compare rectangular matrices using the R_V coefficient, the first step is to transform them into square matrices. The R_V coefficient takes values between 0 and $+1$ (because it is used with positive semi-definite matrices).

These coefficients are similar to the correlation coefficient and are sometimes called *vector* or *matrix* correlation coefficients. This is a potentially misleading appellation because these coefficients are *not* correlation coefficients because contrary to the correlation coefficient, the mean of the observations is not subtracted prior to the computation.

The computational formulas of these coefficients are identical, but their usage and theoretical foundations differ. Also, their sampling distributions differ because of the types of matrices with which they are used.

Notations and Computational Formulas

Let \mathbf{X} be an $I \times J$ matrix and \mathbf{Y} be an $I \times K$ matrix. The *vec* operation transforms a matrix into a vector whose

entries are the elements of the matrix. The *trace* operation applies to square matrices and gives the sum of the diagonal elements.

The congruence coefficient is defined when both matrices have the same number of rows and columns (i.e., $J = K$). These matrices can represent factor loadings (i.e., factors by items) or factor projections (i.e., observations by factors). The congruence coefficient is denoted φ or sometimes r_c , and it can be computed with three different equivalent formulas:

$$\varphi = r_c = \frac{\sum_{i,j} x_{i,j} y_{i,j}}{\sqrt{\left(\sum_{i,j} x_{i,j}^2\right)\left(\sum_{i,j} y_{i,j}^2\right)}} \tag{1}$$

$$= \frac{\text{vec}\{\mathbf{X}\}^T \text{vec}\{\mathbf{Y}\}}{\sqrt{(\text{vec}\{\mathbf{X}\}^T \text{vec}\{\mathbf{X}\})(\text{vec}\{\mathbf{Y}\}^T \text{vec}\{\mathbf{Y}\})}} \tag{2}$$

$$= \frac{\text{trace}\{\mathbf{XY}^T\}}{\sqrt{(\text{trace}\{\mathbf{XX}^T\})(\text{trace}\{\mathbf{YY}^T\})}} \tag{3}$$

The R_V coefficient was defined by Escoufier as a similarity coefficient between positive semi-definite matrices. Escoufier and Robert and Escoufier pointed out that the R_V coefficient had important mathematical properties because it can be shown that most multivariate analysis techniques amount to maximizing this coefficient with suitable constraints. Recall, at this point, that a matrix \mathbf{S} is called *positive semi-definite* when it can be obtained as the product of a matrix by its transpose. Formally, we say that \mathbf{S} is positive semi-definite when there exists a matrix \mathbf{X} such that

$$\mathbf{S} = \mathbf{XX}^T. \tag{4}$$

Note that as a consequence of the definition, positive semi-definite matrices are square and symmetric, and their diagonal elements are always larger or equal to zero.

If we denote by \mathbf{S} and \mathbf{T} two positive semi-definite matrices of same dimensions, the R_V coefficient between them is defined as

$$R_V = \frac{\text{trace}\{\mathbf{S}^T\mathbf{T}\}}{\sqrt{(\text{trace}\{\mathbf{S}^T\mathbf{S}\}) \times (\text{trace}\{\mathbf{T}^T\mathbf{T}\})}}. \quad (5)$$

This formula is computationally equivalent to

$$R_V = \frac{\text{vec}\{\mathbf{S}\}^T \text{vec}\{\mathbf{T}\}}{\sqrt{(\text{vec}\{\mathbf{S}\}^T \text{vec}\{\mathbf{S}\})(\text{vec}\{\mathbf{T}\}^T \text{vec}\{\mathbf{T}\})}}. \quad (6)$$

$$= \frac{\sum_i^I \sum_j^I s_{i,j} t_{i,j}}{\sqrt{\left(\sum_i^I \sum_j^I s_{i,j}^2\right) \left(\sum_i^I \sum_j^I t_{i,j}^2\right)}}. \quad (7)$$

For rectangular matrices, the first step is to transform the matrices into positive semi-definite matrices by multiplying each matrix by its transpose. So, in order to compute the value of the R_V coefficient between the $I \times J$ matrix \mathbf{X} and the $I \times K$ matrix \mathbf{Y} , the first step is to compute

$$\mathbf{S} = \mathbf{X}\mathbf{X}^T \text{ and } \mathbf{T} = \mathbf{Y}\mathbf{Y}^T. \quad (8)$$

If we combine Equations 5 and 8, we find that the R_V coefficient between these two rectangular matrices is equal to

$$R_V = \frac{\text{trace}\{\mathbf{X}\mathbf{X}^T\mathbf{Y}\mathbf{Y}^T\}}{\sqrt{(\text{trace}\{\mathbf{X}\mathbf{X}^T\mathbf{X}\mathbf{X}^T\}) \times (\text{trace}\{\mathbf{Y}\mathbf{Y}^T\mathbf{Y}\mathbf{Y}^T\})}}. \quad (9)$$

The comparison of Equations 3 and 9 shows that the congruence and the R_V coefficients are equivalent only in the case of positive semi-definite matrices.

From a linear algebra point of view, the numerator of the R_V coefficient corresponds to a scalar product

between positive semi-definite matrices, and therefore gives to this set of matrices the structure of a vector space. Within this framework, the denominator of the R_V coefficient is called the Frobenius, or Schur, or Hilbert-Schmidt matrix scalar product, and the R_V coefficient is a *cosine* between matrices. This vector space structure is responsible for the mathematical properties of the R_V coefficient.

Sampling Distributions

The congruence and the R_V coefficients quantify the similarity between two matrices. An obvious practical problem is to be able to perform statistical testing on the value of a given coefficient. In particular, it is often important to be able to decide if a value of a coefficient could have been obtained by chance alone. To perform such statistical tests, we need to derive the sampling distribution of the coefficient under the null hypothesis (i.e., in order to test if the population coefficient is null). More sophisticated testing requires deriving the sampling distribution for different values of the population parameters. So far, analytical methods have failed to characterize such distributions, but computational approaches have been used with some success. Because the congruence and the R_V coefficients are used with different types of matrices, their sampling distributions are likely to differ, and so, work done with each type of coefficient has been carried independently of the other.

Congruence Coefficient

Recognizing that analytical methods were unsuccessful, Korth and Tucker decided to use Monte Carlo simulations to gain some insights into the sampling distribution of the congruence coefficient. Their work was completed by Broadbooks and Elmore. From this work, it seems that the sampling distribution of the congruence coefficient depends upon several parameters, including the original factorial structure and the intensity of the population coefficient, and therefore, no simple picture emerges, but some approximations can be used. In particular, for testing that a congruence coefficient is null in the

population, an approximate conservative test is to use Fisher Z transform and to treat the congruence coefficient like a coefficient of correlation. Broadbooks and Elmore provide tables for population values different from zero. With the availability of fast computers, these tables easily can be extended to accommodate specific cases.

R_V Coefficient

Statistical approaches for the R_V coefficient have focused on permutation tests. In this framework, the permutations are performed on the entries of each column of the rectangular matrices \mathbf{X} and \mathbf{Y} used to create the matrices \mathbf{S} and \mathbf{T} . Interestingly, work by Kazi-Aoual, Hitier, Sabatier and Lebreton has shown that the mean and the variance of the permutation test distribution can be computed directly from \mathbf{S} and \mathbf{T} .

The first step is to derive an index of the dimensionality or rank of the matrices. This index, denoted β_S (for matrix $\mathbf{S} = \mathbf{X}\mathbf{X}^T$), is also known as ν in the brain imaging literature, where it is called a *sphericity* index and is used as an estimation of the number of degrees of freedom for multivariate tests of the general linear model. This index depends upon the eigenvalues of the \mathbf{S} matrix, denoted $s\lambda_\ell$, and it is defined as

$$\beta_S = \frac{\left(\sum_{\ell}^L s\lambda_{\ell}\right)^2}{\sum_{\ell}^L s\lambda_{\ell}^2} = \frac{\text{trace}\{\mathbf{S}\}^2}{\text{trace}\{\mathbf{S}\mathbf{S}\}}. \tag{10}$$

The mean of the set of permuted coefficients between matrices \mathbf{S} and \mathbf{T} is then equal to

$$E(R_V) = \frac{\sqrt{\beta_S\beta_T}}{I - 1}. \tag{11}$$

The case of the variance is more complex and involves computing three preliminary quantities for each matrix. The first quantity is denoted δ_S (for matrix \mathbf{S}), and it is equal to

$$\delta_S = \frac{\sum_i^I s_{i,i}^2}{\sum_{\ell}^L s\lambda_{\ell}^2}. \tag{12}$$

The second one is denoted α_S , for matrix \mathbf{S} , and is defined as

$$\alpha_S = I - 1 - \beta_S. \tag{13}$$

The third one is denoted C_S (for matrix \mathbf{S}) and is defined as

$$C_S = \frac{(I - 1)[I(I + 1)\delta_S - (I - 1)(\beta_S + 2)]}{\alpha_S(I - 3)}. \tag{14}$$

With these notations, the variance of the permuted coefficients is obtained as

$$V(R_V) = \alpha_S\alpha_T \times \frac{2I(I - 1) + (I - 3)C_S C_T}{I(I + 1)(I - 2)(I - 1)^3}. \tag{15}$$

The sampling distribution of the permuted coefficients is relatively similar to a normal distribution (even though it is, in general, *not* normal), and therefore, we can use a Z criterion to perform null hypothesis testing or to compute confidence intervals. For example, the criterion

$$Z_{R_V} = \frac{R_V - E(R_V)}{\sqrt{V(R_V)}} \tag{16}$$

can be used to test the null hypothesis that the observed value of R_V was due to chance.

An Example

As an example, we will use two scalar product matrices from the STATIS example entry (Experts 1 and 3). These matrices are listed as follows:

$$\mathbf{S} = \begin{bmatrix} 29.56 & -8.78 & -20.78 & -20.11 & 12.89 & 7.22 \\ -8.78 & 2.89 & 5.89 & 5.56 & -3.44 & -2.11 \\ -20.78 & 5.89 & 14.89 & 14.56 & -9.44 & -5.11 \\ -20.11 & 5.56 & 14.56 & 16.22 & -10.78 & -5.44 \\ 12.89 & -3.44 & -9.44 & -10.78 & 7.22 & 3.56 \\ 7.22 & -2.11 & -5.11 & -5.44 & 3.56 & 1.89 \end{bmatrix} \tag{17}$$

and

$$\mathbf{T} = \begin{bmatrix} 11.81 & -3.69 & -15.19 & -9.69 & 8.97 & 7.81 \\ -3.69 & 1.81 & 7.31 & 1.81 & -3.53 & -3.69 \\ -15.19 & 7.31 & 34.81 & 9.31 & -16.03 & -20.19 \\ -9.69 & 1.81 & 9.31 & 10.81 & -6.53 & -5.69 \\ 8.97 & -3.53 & -16.03 & -6.53 & 8.14 & 8.97 \\ 7.81 & -3.69 & -20.19 & -5.69 & 8.97 & 12.81 \end{bmatrix} \tag{18}$$

We find the following value for the R_V coefficient:

$$\begin{aligned} R_V &= \frac{\sum_i \sum_j s_{i,j} t_{i,j}}{\sqrt{\left(\sum_i \sum_j s_{i,j}^2\right) \left(\sum_i \sum_j t_{i,j}^2\right)}} \\ &= \frac{(29.56 \times 11.81) + (-8.78 \times -3.69) + \dots + (1.89 \times 12.81)}{\sqrt{[(29.56)^2 + (-8.78)^2 + \dots + (1.89)^2] [(11.81)^2 + (-3.69)^2 + \dots + (12.81)^2]}} = .79. \end{aligned} \tag{19}$$

To test the significance of a value of $R_V = .79$, we first compute the following quantities:

$$\begin{aligned} \beta_S &= 1.0954 & \alpha_S &= 3.9046 & \delta_S &= 0.2951 & C_S &= 1.3162 \\ \beta_T &= 1.3851 & \alpha_T &= 3.6149 & \delta_T &= 0.3666 & C_T &= 0.7045 \end{aligned} \tag{20}$$

Plugging these values into Equations 11, 15, and 16, we find

$$E(R_V) = 0.2464, V(R_V) = 0.0422, \text{ and } Z_{R_V} = 2.66. \tag{21}$$

Assuming a normal distribution for the Z_{R_V} gives a p value of .0077, which would allow for the rejection

of the null hypothesis for the observed value of the R_V coefficient.

Appendix

The R_V coefficient takes values between 0 and 1 for positive semi-definite matrices.

Let \mathbf{S} and \mathbf{T} be two positive semi-definite matrices. From the Cauchy-Schwartz inequality, we know that the absolute value of the numerator is always smaller or equal to the denominator (and so R_V is smaller than 1); therefore we only need to prove that the numerator of the R_V coefficient is positive or null. This amounts to showing that

$$\text{trace}\{\mathbf{ST}\} \geq 0. \quad (22)$$

Because \mathbf{T} is positive semi-definite, the left part of Equation 22 can be rewritten as

$$\text{trace}\{\mathbf{T}^{\frac{1}{2}}\mathbf{S}\mathbf{T}^{\frac{1}{2}}\}. \quad (23)$$

Because \mathbf{S} is positive semi-definite, the matrix $(\mathbf{T}^{\frac{1}{2}}\mathbf{S}\mathbf{T}^{\frac{1}{2}})$ is also positive semi-definite, and therefore all its eigenvalues are positive or null. Thus, its trace being equal to the sum of its eigenvalues is also positive or null, and this completes the proof.

SAMPLE

It is very rare that all units in a population can be measured. More commonly, a selection of units from a population is chosen, and only these selected units are measured. A population may be all the people who live in a city, all the children currently enrolled in a school, all the trees of a particular species in a forest, or all the sales transactions of a shop this month. The selection of elements from a population is called a *sample*. In these examples, the samples would be samples of people, of children, of trees, or of transactions.

Samples are selected according to a *sampling scheme*. The size of the sample to be selected should be defined in the scheme. Summary statistics are calculated from the sample and are used to estimate population parameters. Choosing the best sample scheme and selecting the most appropriate method to estimate population parameters are the main interests in research in sample surveys.

The most elementary sample scheme is simple random sampling. With a finite population of N units, the number of ways the population can be arranged into subsets of n distinct units can be calculated as follows:

$$\binom{N}{n} = \frac{N!}{n!(N-n)!}$$

The subsets represent all the possible samples of size n distinct units that could be taken from a finite population of size N . In simple random sampling, all these possible samples have an equal chance of being selected. For example, consider a population in which $N = 5$. For convenience, the units are labeled A, B, C, D, and E. Ten possible samples of size 3 could be taken:

A	B	C
A	B	D
A	B	E
B	C	D
B	C	E
C	D	E
A	C	D
A	C	E
A	D	E
B	D	E

Samples can be chosen so that each unit appears in the sample only once, or they can be chosen so that each unit can in the sample more than once. When units can appear only once in the sample (as in the example above), the process is called *sampling without replacement*, and when units can appear more than once, the process is *sampling with replacement*. Drawing names or numbers out of a hat is an example

of sampling without replacement, provided none of the names or numbers is returned to the hat. Selecting units from the population by means of a random table of numbers that correspond to the unit labels is an example of sampling with replacement because the same random number can appear more than once, and hence the same population unit can be selected more than once. Sampling without replacement may be more informative than sampling with replacement because every unit in the sample appears only once and brings new information. If the same unit appeared twice, the second occurrence of the unit would not bring new information.

SAMPLE SIZE

Determination of sample size involves methods for deciding how much data should be collected in a statistical study. The sample size is chosen to meet one or more goals, which could relate to precision of estimation, power, cost, or some other criterion. Sample size is not equally important in all studies. It is relatively unimportant in planning a pilot study or in cases in which additional data, if needed, can be collected quickly with minimal planning. However, when one is planning a definitive study, sample size determination can be critical, especially when the process of acquiring subjects or participants, materials, measurements, budgetary support, or grant funding is lengthy.

It is important to know that in sample-size planning, science must come before statistics. That is, we first must establish the scientific goals of the study and then address the statistical issues in meeting those goals. There are often a number of intermediate steps—for example, deciding the target population, the way measurements are to be made, and so

forth. Typically, the scientific goals are stated in terms of a difference (or other measure of effect size) expressed in the same units as the planned measurements; we choose an effect that would be deemed important based on substantive considerations. Once the scientific goals are established, we can address the statistical design to be used and, finally, the sample size.

It is seldom possible to do a definitive statistical study in one step. Unless there is substantial past experience with the measurements to be used and the participant populations to be studied, a pilot study is necessary. The results of the pilot study provide estimates of variances and other quantities needed as inputs to the calculations to determine sample size. A pilot study also helps ensure that the planned scheduling and procedures will actually work and that the training program is adequate for those conducting interviews and collecting data.

Sample Size for Specified Confidence Interval Width

Perhaps the simplest approach to sample-size estimation is to specify the desired width of the confidence interval for some parameter of interest. For example, suppose that an achievement test is to be administered to selected ninth graders in an alternative instructional program, and we want to estimate the mean achievement, μ , to within a margin of error of ± 5 points (with 95% confidence); past experience with this achievement test, when administered to other populations, suggests that the standard deviation (SD) of the scores is about 15. We plan to use the usual confidence interval based on the t distribution. For a confidence coefficient of $1 - \alpha$, the sample-size formula is

$$n = \left(\frac{t_{\alpha/2, n-1} \sigma}{\delta} \right)^2,$$

where

$t_{\alpha/2, n-1}$ is the critical value for an upper tail area of $\alpha/2$ on the t distribution with $n - 1$ degrees of freedom (df),

σ is the population *SD*, and
 δ is the desired margin of error.

The *t* critical value depends on *n*, but not strongly; we can start with, say, 30 *df*, and iterate once or twice until it stabilizes. In the example, we use $\alpha = .05$, start with $t_{\alpha/2, n-1} = t_{.025, 30} = 2.042$ (from standard *t* tables), $\sigma = 15$, and $\delta = 5$, to obtain a starting value of

$$n = \left(\frac{2.042 \times 15}{5} \right)^2 = 37.53,$$

which would round to $n = 38$. For this *n*, we should use 37 *df* or $t_{.025, 37} = 2.026$, so in a new iteration, we get $n = (2.026 \times 15/5)^2 = 36.94$, rounded to $n = 37$. Correcting to 36 *df* will not change the result enough to matter, and our conclusion is that 37 participants are enough to estimate the mean to within 5 points. Strictly speaking, fractional results for *n* should always be taken to the next higher whole number; but in practice, it makes little difference except when *n* is very small.

Sample Size to Meet Power Requirements

In many studies, the primary statistical inferences will be the results of one or more significance tests. In those cases, it is common practice to choose sample size so that the power of the test has at least a specified value, given a specified significance level and effect size of scientific or clinical interest. Typically, for significance level $\alpha = .05$, one chooses a target power of $\pi = .8$ or $\pi = .9$. One rationale for such a choice is to weigh the severity of a Type I error (rejecting the null hypothesis when it is true) and a Type II error (failing to detect an effect of the specified size). For example, if one chooses $\alpha = .05$, and $\pi = .8$, the latter is equivalent to a Type II error probability of $\beta = 1 - \pi = .20$, so there is an implicit statement that a Type I error is 4 times worse than a Type II error. Another way to look at the same situation would be to specify $\alpha = .05$ and $\pi = .8$, then specify the effect size for which a Type II error is one fourth

as bad as a Type I error; or to choose $\pi = .95$ and choose a (larger) effect size such that failing to detect it would be equally bad as a Type I error.

First, consider a two-sided hypothesis test of the form

$$H_0: \theta = \theta_0 \text{ versus } H_1: \theta \neq \theta_0,$$

where θ is a parameter of interest and θ_0 is a null value, and a test statistic of the form

$$z = \frac{\hat{\theta} - \theta_0}{c\sigma/\sqrt{n}} \text{ or } t = \frac{\hat{\theta} - \theta_0}{cs/\sqrt{n}},$$

where

$\hat{\theta}$ is an estimate of θ ,

$\sigma(c/\sqrt{n})$ is the standard error of $\hat{\theta}$ (here, *c* is some known value), and

s is an estimate of σ .

Then an approximate sample-size formula for achieving power π when $\theta = \theta_1$ at significance level α is

$$n = c^2 \left(\frac{(z_{\alpha/2} + z_{1-\pi})\sigma}{\theta_1 - \theta_0} \right)^2.$$

This formula is exact for the *z* test, but it underestimates sample size somewhat for the *t* test. In the latter case, a better approximation is obtained using *t* critical values in place of the *z* critical values, but the method is still only approximate.

For illustration, suppose that we plan to do a *t* test of independent samples to compare the mean reaction times of laboratory rats under two types of conditioning. Based on pilot data collected using the same instrumentation, we estimate that the *SD* of reaction times is 320 msec. It is decided that a difference of means of 250 msec or more would be regarded as clinically important, and we want to be able to detect such a difference with a power of .90 based on a test with significance level .02. The corresponding hypotheses are

$$H_0: \mu_1 = \mu_2 \text{ versus } H_1: \mu_1 \neq \mu_2,$$

and the t statistic, based on independent samples of equal size n and sample means \bar{y}_1 and \bar{y}_2 and SDs s_1 and s_2 , is

$$t = \frac{\bar{y}_1 - \bar{y}_2}{s\sqrt{2/n}},$$

where $s = \sqrt{(s_1^2 + s_2^2)/2}$ is the pooled SD. By examining the t statistic, we see that $c = \sqrt{2}$, and hence the required sample size is

$$\begin{aligned} n &= \left(\sqrt{2}\right)^2 \left(\frac{(z_{.01} + z_{.10})\sigma}{\mu_1 - \mu_2}\right)^2 \\ &= 2 \left(\frac{(2.326 + 1.282) \times 320}{250}\right)^2 \\ &= 42.65; \end{aligned}$$

that is, we need 43 rats in each group to meet the stated goals. Moreover, since we know that the formula underestimates sample size, it makes sense to adjust it upward slightly, say to 44 or 45.

Use of Software

Most statistical packages provide some capabilities for sample-size calculations, and some stand-alone sample-size programs are available commercially or for free over the Internet. Some of this software uses approximations such as the formulas above for t tests, others use exact calculations, and some use simulation methods, especially in especially complex situations. Figure 1 shows how the previous example can be done using Piface software, available online. Piface does exact calculations, and it is found that with $n = 44$, a power of nearly .9 is achieved.

Besides saving labor and producing more-reliable results for more situations, sample-size software often affords some flexibility in the way a problem is defined. For example, suppose that in the previous example, the sample size of 44 per treatment is not tractable in terms of available time and resources but that $n = 30$ is considered reasonable. By manipulating the options in the Piface dialog, we can easily find what power is achieved for the same effect size (the

Figure 1 Piface Dialog for a Two-Sample t Test (Reaction-Time Example)

answer is about .735, which is still reasonable). Or we could ask the software to solve for effect size instead of sample size, as shown in Figure 2; it turns out that we would be able to detect a difference of means of about 305 msec with a power of .9.

Analysis of Variance

In the analysis of variance (ANOVA), an F test is constructed for a null hypothesis that k means are equal:

$$H_0: \mu_1 = \mu_2 = \dots = \mu_k.$$

Figure 2 Using the Piface Dialog to Solve for Effect Size

For studying the power of the F test, we must specify an alternative hypothesis H_1 of substantive interest, that is, a set of values of μ_j . The power of the test depends on the SD of these μ_j . For example, when $k = 8$, consider the following two sets of μ_j : $\{5, 25, 25, 25, 25, 25, 25, 45\}$ and $\{15, 15, 15, 15, 35, 35, 35, 35\}$. Since these have the same SD , the power of the ANOVA F test is the same when either of these sets is specified as the alternative hypothesis of interest, even though the smallest and largest means differ by 40 in the first set and only 20 in the second. Unless a particular relationship among the means is contemplated in advance as a likely outcome, it can be quite difficult to discuss a relevant effect size for the F test at any kind of practical level. The best strategy is probably to construct examples of patterns of means that would be detectable.

An alternative approach, which may be more accessible for discussion purposes, would be to work in terms of effect sizes for pairwise comparisons or contrasts of means. We would then arrive at a suitable sample size for achieving a specified power for a particular comparison of two means. Typically, some type of correction is made for multiple testing, such as a Bonferroni correction or Tukey's honestly significant difference. A similar approach extends to multi-factor ANOVA. For illustration, Figure 3 shows the Piface dialog for a two-factor experiment with factors "treatment" and "dose," where it is desired to be able to detect a difference of 6.0 or more between two cell means. Tukey's honestly significant difference is used to compare the five treatment means at the same dose, and we find that when the error SD is $\sigma = 3.89$, a sample size of 11 observations per cell is adequate to exceed a power of .80.

Sample-Size Allocation

Another aspect of sample size is that of allocation; that is, when there are several groups and we wish to collect N observations total, how should these N

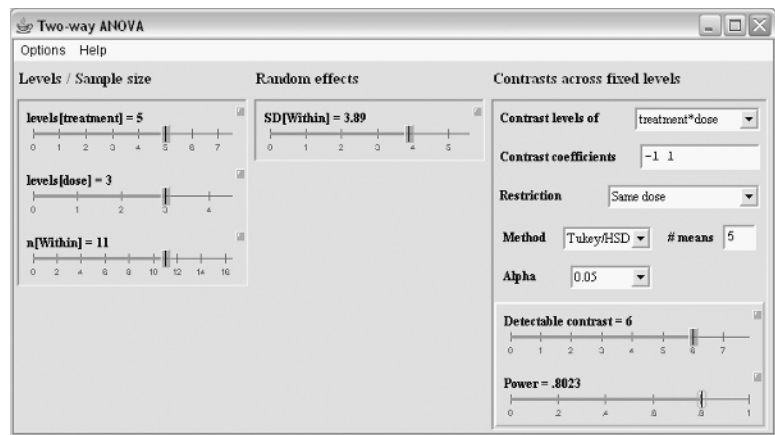

Figure 3 Piface Dialog for Comparing Cell Means in a Two-Factor ANOVA

observations be distributed among the groups? In a comparison of two independent sample means, each group should be allocated $N/2$ observations if an ordinary pooled t test is used; however, if we cannot assume that the SD s are equal, the test should be done using the Satterthwaite approximation, and the sample sizes should be allocated in proportion to the SD s; for example, if one SD is twice as large as the other, the group with the larger SD should get twice as many observations.

Effect-Size Conventions

The approach emphasized here requires one to specify an effect size in terms of the actual units of measurement; accordingly, one also needs an idea of the error SD , perhaps based on pilot data. Another popular approach is to specify effect size in SD units. For example, in a two-sample t test, a difference of half an SD is regarded as a "medium" effect size. This convention is based on a survey of the social science literature conducted by Cohen. The advantage of this approach is that it is easy, requires less thinking, and does not require pilot data. The disadvantage is that it is an elaborate way to choose a predetermined sample size. For example, the sample size for a medium effect is 64 per treatment, regardless of the importance of the research, the reliability of the instrumentation, or the breadth of the population under study. By choosing a medium effect size, we are simply choosing to do a

medium-size study relative to those published in the social science literature. A definitive study requires more stringent scientific standards than that.

SAMPLING DISTRIBUTION OF A STATISTIC

The term *sampling distribution of a statistic* refers to the theoretical, expected distribution for a statistic that would result from taking an infinite number of repeated random samples of size N from some population of interest and calculating the statistic of interest for each sample. The resulting distribution of values is called the sampling distribution of that statistic. For example, the sampling distribution for a sample mean could be constructed by obtaining a random

sample of individuals from a population of interest, computing the mean of observed values, and then repeating this process. That is, one could theoretically obtain repeated random samples of individuals from the population and for each random sample compute the sample mean of values. If this process were repeated indefinitely, the resulting distribution of sample means would be the sampling distribution of the sample mean. This process could be conducted for any given statistic (e.g., sample mean, variance, or correlation).

In practice, a researcher cannot actually create the sampling distribution of a statistic, because it is a theoretical process that requires the creation of an infinitely large number of random samples from some population of interest. However, the concept of the sampling distribution of a statistic is important because it creates the cornerstone for all of inferential statistics. All inferential statistics have in common the process of hypothesis testing. Generally, the process of hypothesis testing entails the assumption that some null hypothesis is true, and then a determination about the likelihood of observing a sample statistic given the null hypothesis. If the observed sample statistic appears very unlikely given the null hypothesis, the analysis results in a p value less than a predetermined critical value, or “alpha level.” In this situation, the null hypothesis is rejected in favor of the alternative hypothesis. For example, a null hypothesis may state that the treatment and control groups from a study have equal means in the population, which would indicate that the treatment has no effect on the outcome of interest. To determine if an observed mean difference is statistically significant, a standardized mean difference is computed between the treatment and control groups. Under the assumption that the treatment has no effect, a large difference between the two groups would be relatively improbable. The p value from this analysis indicates the probability that the null hypothesis is true, given the observed difference. If that p value is small, it indicates that the null hypothesis is probably not true, and the null hypothesis is therefore rejected by the researcher.

This process is familiar enough to most researchers, but it depends entirely on knowing the sampling distribution for the statistic of interest. Without knowing how sample mean differences were distributed in the population, it would be impossible to determine the likelihood of a given mean difference's occurring under the assumption of the null hypothesis. Knowing how a statistic is distributed in the population allows the statistician to make an inference about how likely or unlikely it is that any given sample statistic would have come from some population of interest. This is possible because when a researcher obtains a sample of data and computes some statistic of interest, this value can be treated as one of the possible infinite number of random values that could have been drawn from the population. Then, if the sampling distribution of the statistic is known, the observed sample statistic can be compared to this distribution to determine the probability of its occurring. The sampling distribution of a statistic can be properly thought of as the probability density function for the statistic.

Any inferential statistical analysis requires knowledge of the sampling distribution for that statistic. Different sample statistics, such as sample means, sample mean differences, sample variances, and sample correlations, all follow different sampling distributions, and those sampling distributions may fluctuate depending on the details of a particular analysis, such as sample size, population variability, and population effect sizes. When the parameters that govern the shape of the sampling distribution for a statistic are known, inferences can then be made on the basis of the observed sample statistics.

SAMPLING ERROR

The process of sampling, while essential to the theory and use of inferential statistics, is not perfect, and there is almost always a difference between the sample statistics and the population parameters that are collected. For example, if a population of 1,000 data points has a mean of 14.5, and a sample consisting of 50 data points from that population has an average of 14.1 on the same measure, then the difference is .4. That difference is the error in sampling. The population value is often seen as the true value, and any deviation from that value is seen as an error.

Sampling errors are better understood when they are considered as standard errors, which are simply a standard deviation of the sampling distribution of the statistic under consideration.

For example, the standard error of the mean (*SEM*) is the standard deviation of the sample mean for n observations reflecting the variability in sampling error and is computed as follows:

$$SEM = \frac{\sigma}{\sqrt{n}},$$

where

σ is the standard deviation of the original set of scores, and

n is number of sample observations.

For a sample of 9 scores with a standard deviation estimate of 2, the *SEM* is

$$SEM = \frac{\sigma}{\sqrt{n}} = \frac{2}{\sqrt{9}} = \frac{2}{3} = .67.$$

Given what we know about any normal distribution, one would expect that 68% of simple means would fall within ± 1 *SEM* or $\pm .67$ units from the grand, or overall, mean.

As one would expect, sampling error decreases as the sample gets larger and the sample more closely approximates the characteristics of the population.

For an infinitely large sample, there would be no sampling error (indeed, σ would equal 0 because the sample and the population values would be identical).

SCALING

Scaling is the activity of attempting to measure or quantify psychological attitudes or attributes. The term can also refer to attempts to measure people on some dimension, but here we are concerned with the first-mentioned meaning. The roots of the scaling enterprise go back notably to the German scientist and mystic Gustav Theodor Fechner, who on October 22, 1850 (so he recounted), had an idea that he thought could connect the psychological and the physical realms. Simply phrased, his idea was this: We all know that physical sensory stimuli give rise to perceptions that seem to be quantitative. For example, if two rocks differ in weight by a sufficient amount, one will feel heavier than the other when they are lifted. There were good physical methods for measuring weight. Was there a way to measure the rocks' felt "heavinesses," and could we connect by some mathematical formula the felt heavinesses of the rocks to their weights? Fechner thought he saw a theoretical argument that would connect the physical and psychological magnitudes and concluded that psychological magnitudes were related to the logarithms of their inducing physical intensities. His theoretical argument hinged on some observations of the "just noticeable difference," roughly the minimum difference in stimuli that could be reliably detected. This just noticeable difference appeared in some settings to be a constant proportion of the stimuli's values. So, for example, two rocks could reliably be distinguished in weight if their weights differed by approximately 3%. Combining this observation with the theoretical notion that all just noticeable differences between stimulus weights gave rise to the same constant heaviness difference, Fechner adduced his logarithmic formula connecting physical to psychological magnitudes. The *dol* scale for pain is an application of this approach.

All the schemes for scaling discussed here provide values that are relative. That is, they permit assessment of how different two rated objects are without providing an absolute location on the scale for any single object.

Discriminability Scaling

One early schematic approach to scaling, following on Fechner's interest in discriminability, stems largely from the work of Louis Leon Thurstone and explicitly utilizes some statistical ideas. It relies on the fact that there are comparisons that people make with less than perfect reliability. For example, when repeatedly presented with two objects that differ only a little in physical weight and asked which of the two is the heavier, a person will not always make the same selection. Thus we can theorize that although each object's physical weight is constant, its psychological heaviness undergoes some variation from encounter to encounter. That variation in heaviness is presumed to be the source of the unreliability in a person's selections. The variation takes place in the psychological dimension of heaviness, and it can be presumed to follow a normal distribution. In the simplest version of his work (Case V of the Law of Comparative Judgment), Thurstone added some assumptions that entailed the plausible idea that if stimulus A is judged heavier than stimulus B 80% of the time and stimulus X is judged heavier than stimulus Y 67% of the time, then the heavinesses of A and B differ by more than do the heavinesses of X and Y. A final assumption was that the variation in heaviness had as its form the normal distribution, allowing the translation of the probability with which one stimulus was judged heavier than another into the difference between their heavinesses measured as z scores in a normal distribution. Thus a person's performance in an elaborate experiment involving the comparative judgments of many weights can give rise to a scale of heavinesses in which the difference between two weights' scale values accurately predicts the likelihood that one will be judged heavier than the other. Applications of this approach might include having students who had experience with a group of teachers indicate their

favorite in every possible pair of teachers; this could produce scale values for the teachers' "goodnesses." Notice that these scales say nothing about the "absolute" heaviness or goodness of any particular things; they inform us only about the separations among the things being judged.

Magnitude Scaling

Another approach to scaling involves the procedure called *magnitude estimation*, in which people give numerical ratings to stimuli based on some attribute. For example, people might be asked to heft objects of different weights and to assign numbers to the objects so that the numbers are "proportional" to the perceptual experiences of heaviness. This approach presumes that people can make ratio-like comparisons among their sensations in a consistent and unbiased way. (Often, but not necessarily, this is carried out with some particular weight [the *standard*] being assigned a particular numerical value [the *modulus*] and more recently, verbal labels such as "very strong" being attached to some numbers.) The extensive tradition of work in this vein stems largely from the work of Stanley Smith Stevens (who also created the typology of measurement scales—nominal, ordinal, ratio, and interval; he championed the use of magnitude estimation though he did not introduce it). The average (usually the geometric mean) of the numbers assigned to an object is taken to be a measure of its perceived heaviness. In a wide variety of situations involving stimuli that vary in "intensity" (such as lights, sounds, smells, etc.), a simple form of algebraic equation characterizes the relation between the physical intensities of the stimuli and the numbers people assign to them. The numbers people assign vary as some power of the physical intensities of the stimuli, or equivalently, the numbers are a power function of the physical intensities. So, for example, the loudness ratings of 1,000 Hertz tones are linearly related to approximately the cube roots of the sounds' physical intensities (i.e., to the intensities raised to the $1/3$ power, or to intensities with an exponent of $1/3$). Such relations, called power functions, are found in many studies of this sort (e.g., the brightness of lights,

the saltiness of salt solutions, the painfulness of electric shocks). Power function relationships are linear when graphed in double-logarithmic coordinates (i.e., when both axes of the graph [the stimulus intensities and the numbers people say] are logarithmic; this arrangement makes it easy to determine whether a given set of data is consistent with that algebraic form). The power to which the intensities are raised is equal to the slope of the line that connects the data in double-logarithmic coordinates and is usually the main result of interest (although its value may vary with, among other things, the range of stimulus intensities employed in any particular investigation). The same scale of loudness, adopted by the International Organization for Standardization, is based on this approach. Magnitude estimation has been profitably applied in the assessment of how one's degree of stage fright is related to the size of a prospective audience and of the analgesic value of hypnosis. It has also been used to evaluate the diminution of fear experienced by phobic persons over the course of therapy for their condition.

A procedure that should be equivalent to magnitude estimation is magnitude production, in which people are given a number and told to adjust a stimulus so that its attribute level is equal to that number. For example, a person might be told to adjust the intensity of a sound so that its loudness was 60. Results of this procedure also exhibit power function relations between numbers and stimulus intensities. However, the exponent relating numbers to stimulus intensities is rarely the same as that found with magnitude estimation and is usually larger. Where sufficient data are available, averaging the results of the two methods is often recommended for deriving a more accurate function relating stimulus intensities and sensation magnitudes.

The coherence of magnitude scaling approaches is seen in the procedure of cross-modality matching, in which, for example, people hear a sound and are asked to adjust a light's intensity so that its brightness is equivalent to the loudness of the sound. If one knows the two power functions relating loudness to sound intensity and brightness to light intensity, then one can predict the power function that will relate

sound intensity to light intensity at perceptual equivalence. Agreement of experimental data with these predictions is very good.

Although doubts remain as to the ultimate validity of these approaches, magnitude scaling methods have a central place in the scaling of perceptual magnitudes.

Category Scaling

More familiar are category scaling procedures, in which people are asked to rate things using a scale that ranges from 1 to 10 or from -5 to $+5$ or over some other range of numbers. Here again, the average ratings constitute the psychological scale values for the things being rated. Scale values for the same set of objects may vary in complicated ways depending not only on the range of stimuli employed but also on the particular rating scale used by the observers—both its range and its location. For example, when people were asked to rate how successful they had been in their lives, 34% of them chose a rating in the lower half of a -5 to $+5$ scale, but only 13% did so with a 1 to 11 scale, highlighting the fact that these scales do not provide information on the absolute levels of people's perceptions. In addition, people exhibit a tendency to try to use all available ratings roughly equally often on category scales; this can give distorted results if the things being rated have a skewed distribution on the attribute being rated.

Category-based scales and magnitude-based scales on the same stimuli are often found to be nonlinearly related, a problem that has not been satisfactorily resolved in general.

Difference-Based Scaling

Based on work of Roger Shepard and J. B. Kruskal, nonmetric scaling permits the construction of an interval scale using people's assessments of differences between objects. An exhaustive ranking of the sizes of the pairwise differences among objects can give rise to an interval scale for the values of the objects on the dimensions along which they vary (and to the number of dimensions, or attributes, being measured);

multidimensional differences can be handled with this approach. If there are n objects, then there are $n(n - 1)/2$ pairwise differences between them. Having 10 objects that vary in one dimension provides sufficient constraint to adduce interval-scale values for the 10 objects. This approach has been used successfully in, for example, the measurement of occupational prestige.

Item Response Theory

Georg Rasch, building on the work of Thurstone, developed item response theory (IRT), a scheme for measuring attributes such as knowledge of some domain in a way that can give rise to interval scales. IRT, unlike many other schemes, does not treat all items on a test as equivalent (and hence does not simply rely on a total score for its measure) but recognizes that the questions vary in difficulty so that there are some questions that only the most knowledgeable test taker will answer correctly and others that most people will answer correctly. Easy questions allow us to distinguish among the knowledge levels of people who know little because some such people will get more easy questions right than others will; easy questions cannot help us distinguish among the very knowledgeable, who will get all of them right. Similarly, hard questions will be gotten wrong by all those who know little but can help us distinguish among those who know a lot. The probability that someone will get a question right grows with that person's knowledge level. We can imagine, then, for any question, a graph relating the probability of a correct answer on the ordinate to the test taker's knowledge level on the abscissa. For easy questions, the probability of a correct answer rises to near 1.0 "early" in the graph, that is, at low knowledge levels. For a hard question, the probability will remain at zero until knowledge level is fairly high, at which point the probability will start to rise toward 1.0. Wherever along the abscissa the curve rises steeply defines a range of knowledge levels that the question helps us distinguish among; where the curve is flat or shallow, the question provides little discrimination among knowledge levels. IRT uses these ideas to produce simultaneous measurement of (a) question difficulty

and (b) knowledge levels, utilizing as input the question-by-question performance of a large number of testees. A person's pattern of correct and incorrect answers permits measurement of the person's knowledge level. In many cases, these are interval-scale measures.

SCAN STATISTIC

Scan statistics are used for detecting unusual clusters of points scattered randomly on a line or events occurring randomly over time. Traditionally, the scan statistic is defined as the maximum number of points contained in a window of fixed length w sliding along a continuous interval of real numbers, say, from 0 to 1. The points on the interval may represent events over

time. An exceptionally large value for the scan statistic will indicate the presence of a cluster.

In 1965, Joseph Naus showed that the scan statistic is the test statistic in a generalized likelihood ratio test for the null hypothesis of n points independently sampled from a uniform distribution on $[0,1]$ versus an alternative of the existence of a cluster. Naus proved that among a class of tests for the presence of clusters among uniformly distributed points, N_w is the most powerful test statistic. Since then, there have been numerous applications of scan statistics in mathematics, science, and industry, such as the generalized birthday problems, clustering of diseases in time, clustering of defective items in manufacturing processes, and many more.

How large a value must the scan statistic of a cluster have before it can be declared unlikely to occur by chance? To answer this question, one needs a mathematical formula for the probability distribution of the scan statistic. Finding the distribution function of the scan statistic has become an object of intense interest. In 1977, F. K. Hwang derived the general formula for the distribution of the scan statistic. However, the practical use of this elegant formula is severely restricted because of the formidable computations involved in the complicated sum of matrix determinants. Considerable efforts, therefore, have been channeled to finding accurate approximate distributions that are computationally more tractable. A number of these approximations are presented in the book *Scan Statistics and Applications* by J. Glaz and Balakrishnan, published in 1999.

In applying the scan statistics, choosing an appropriate value of the window size w is usually not a straightforward matter. In many cases, significant clusters may not be detected because the window size is either too small or too big. It is generally advisable to perform the analysis using a variety of window sizes in any application of scan statistics to detect clusters. It has been noticed that the repetitive applications of scan statistics on the computer can be carried out more conveniently if we use an equivalent form of scan statistics known as r -scan, put forth by Amir Dembo and Samuel Karlin at Stanford University in 1992, while the original form of scan

statistics is called w -scan. We present the definitions of both the w -scan and the r -scan below with an explanation of their duality relationship.

Let X_1, X_2, \dots, X_n be n points independently sampled from the unit interval of real numbers between 0 and 1, and let $X_{(1)}, X_{(2)}, \dots, X_{(n)}$ be their order statistics from the smallest to the largest. That is, $X_{(1)}$ is the smallest one among X_1, X_2, \dots, X_n , $X_{(2)}$ the second smallest, and so on. Let

$$S_i = X_{(i+1)} - X_{(i)}, \quad i = 1, \dots, n-1$$

denote the spacing between adjacent points, and let

$$A_r(i) = S_i + \dots + S_{i+r-1}$$

be the sum of the r adjoining spacings starting at $X_{(i)}$. Also let $N_w(i)$ stand for the number of points contained in a window of length w beginning at $X_{(i)}$.

For a fixed window length $0 < w < 1$, the traditional scan statistic is the largest number of points contained in a window of size w scanning over the unit interval. Mathematically, it can be defined as $N_w = \max\{N_w(i): i = 1, \dots, n\}$. For a fixed positive integer r , the r -scan statistic is $A_r = \min\{A_r(i): i = 1, \dots, n-r\}$. In other words, the r -scan statistic A_r is the smallest of the aggregated r -spacings of the n points.

It is not hard to see that if there is a window of length w containing $r+1$ points or more, then there must be r adjoining spacings whose sum is less than w . The converse of this is also true. So N_w and A_r are related by a duality relation

$$\{N_w \geq r+1\} = \{A_r \leq w\}.$$

Consequently, if the distribution function of either one is known, so will the other. The traditional w -scan statistics and the new r -scan statistics can be used interchangeably.

An Application to Molecular Biology

In the early 1990s, advances in biotechnology generated an exponential growth of biomolecular sequence data. Scan statistics have played critical roles in

analyzing these data and extracting useful biological information. They have helped predict important functional sites in the genome and scan markers for disease susceptibility genes. We shall illustrate how the scan statistics were used in a specific example.

DNA is deoxyribonucleic acid, which consists of four different nucleotide bases: adenine (A), thymine (T), cytosine (C), and guanine (G). A large number of these bases are strung together to form a giant sequence with a backbone composed of deoxyribose (a sugar) and phosphate groups. The nucleotide bases A and T form a complementary pair, as do C and G. Because of this pairing, the DNA molecule forms a double helix of two strands with complementary base sequences.

Viral genomes are small, each of them comprising a DNA molecule ranging from a few thousand to several hundred thousand bases. Early studies in molecular virology have reported that the nucleotide sequences around replication origins of certain herpesviruses have a high concentration of palindromes. A DNA palindrome can be defined as a word pattern of the form $b_1 \dots b_L b'_L \dots b'_1$, where b' denotes the complement of base b and L is the half-length of the palindrome. For example, the sequence of bases GCAATATTGC is a palindrome of length 10.

As the central step in the reproduction of herpesviruses, viral DNA replication has been the target for a number of antiherpesvirus drugs (e.g., acyclovir). Understanding the molecular mechanisms involved in DNA replication is of great importance in further developing strategies to control the growth and spread of viruses. Since replication origins are regarded as major sites for regulating genome replication, labor-intensive laboratory procedures have been used to search for replication origins. With the increasing availability of genomic DNA sequence data, one way that may save time and resources would be to scan the viral genome sequence for the expected sequence features by a computer program before an experimental search for replication origins is launched.

The human cytomegalovirus (HCMV) is a member of the herpesvirus family, which includes several well-known viruses, such as herpes simplex and

chicken pox. The HCMV genome is a DNA molecule of 229,354 base pairs. The computerized search for replication origins began by scanning through the genome sequence for palindromes of length 10 or more and located 296 such palindromes. Idealizing the occurrences of these palindromes on the genome sequence as 296 points randomly scattered on the interval of numbers between 0 and 1, scientists have made calculations based on the scan statistics that indicate the presence of a statistically significant (p value < 0.01) cluster of palindromes in the segment from 92,001 to 93,000 bases. Highly sensitive experimental assays performed around this part of the genome confirmed that the segment between 92,210 and 93,175 bases is the OriLyt of HCMV.

In 1994, Leung and coworkers first attempted to formalize the mathematical ideas behind the successful prediction of the OriLyt in HCMV using scan statistics to identify unusual clusters of palindromes and confirmed the feasibility of using palindrome clusters for predicting replication origins in general for the herpesvirus family. In 2005, based on the scan statistics with compound Poisson approximation, Leung and coworkers reported the details of the mathematical theory, suggesting possible ways to improve the reliability of their prediction method of replication origins.

The Assumptions Underlying the Scan Statistics

In the definition of scan statistics, one has to assume that a certain number n of points are sampled independently from the interval of real numbers between 0 and 1 according to a uniform distribution. That is, each point is selected independently and equally likely from anywhere in the interval. It is generally advisable to make a probability plot of the data points against the uniform quantiles to verify that this assumption is satisfied overall to a reasonable degree.

The Research Hypothesis

The scan statistics are used when the researcher suspects that among the observed data points, there is an

unusual cluster that is unlikely to occur by chance. In the test of clustering by the scan statistics, the null hypothesis assumes that all the points are independent and identically distributed according to a uniform distribution. Assuming that the null hypothesis is true, the probability (p value) of observing a value of the scan statistics as high as the value in the data is assessed. If the p value is too small, say, less than 0.05, the null hypothesis will be rejected, and we shall then say that a nonrandom cluster exists among the points.

Computations Involved

Computations involved in the scan statistics are quite complicated. Many different programs based on different approximations of the probability distribution of the scan statistics have been developed. (See, for example, the ones described in *Scan Statistics and Applications*, by Glaz and Balakrishnan.) To fit the different needs of specific applications, it is quite common for researchers to develop their own computer codes. For example, Josephine Hoh and Jurg Ott developed their Scanstat program for gene mapping, available online. Other application codes not online can usually be obtained from the authors directly.

SCATTERGRAM

A scattergram is a visual summary demonstrating the relation between two variables; it illustrates the scores on one variable plotted against scores on another variable. The scattergram is usually drawn before working out a linear correlation coefficient or fitting a regression line. It is used as an aid to interpret the data. For instance, the scattergram can illustrate whether there are any outliers or gaps in the data or whether the data follow a straight or a curved line.

The pattern obtained from the scattergram illustrates the type and strength of the relation between two variables. If the data points make an upward trend going from bottom left to top right (positive slope), then the association is positive (the relation is direct; as one variable increases, so does the other). If the straight line goes down from top left to bottom right (negative slope), then the association is negative (the relation is indirect; as one variable increases, the other decreases). The closer the points follow a straight line, the higher the correlation. No visible trend from the scattergram implies no association; the points are scattered randomly. If the data points form a curved line, then a linear correlation cannot be used to describe the data.

In Figure 1, the scattergram illustrates a negative relation between age and traffic tickets. The scattergram was created using Excel.

When creating a scattergram, observe the following conventions:

1. There are no gridlines for the X or Y axis.
2. The axes are clearly labeled.
3. The points are not connected by a line.

SCREE PLOT

In an explorative data analysis, principal component analysis and factor analysis are often applied for the purposes of data reduction or structure detection or simplification. In these analyses, it is important to decide the number of components or factors to be retained. While there is no set rule, there are a few common conventions. One common practice is to consider only those factors having variance of factors (or eigenvalues) greater than 1. This method is referred to as the *eigenvalue criterion method*. The other common practice is to use a scree plot. In this case, the plot and the eigenvalue criterion method are often used in combination.

A scree plot is a two-dimensional plot with the number of factors on the horizontal axis and eigenvalues on the vertical axis. Its purpose is to provide a useful visual aid for determining an appropriate number of components to retain. The plot shows the fraction of total variance in the data as explained, or represented, by each factor or component. The plot is called a scree plot because it looks like a sloping mass of loose rocks (scree) at the base of a cliff. The scree plot allows one to pick the number of components or factors on the basis of the point at which “elbow,” or separation, is observed or where a plateau begins. The plot in Figure 1 shows eigenvalues versus number of factors with annotation of the first five values of the eigenvalues and their corresponding cumulative percent of variance. The eigenvalues are based on the results from Proc Factor in SAS, and the plot is created by Minitab software.

In this plot, an elbow occurs at the third point and is followed by a plateau. That is, the eigenvalues after the third value are all relatively small. Thus, we see that three principal components should be retained for further use. There is a clear separation between the first two components and the remaining components.

SECONDARY DATA ANALYSIS

If locating a sample on which to conduct research poses problems, it might be worthwhile to consider conducting a secondary data analysis. During the past 25 years, an increasing number of researchers in the United States have turned to secondary data rather than collecting original data for their research. More recently, some researchers have begun to explore uses of secondary data for qualitative research.

At its most basic level, secondary data analysis involves using data collected in previous research to address a different research question. Special considerations in any secondary analysis include differences in operational definitions, unavailability of raw data, and various ethical issues. This entry explores these issues as well as the uses, advantages, and disadvantages of secondary data analysis. To demonstrate how secondary data analysis has been used to address various topics, summaries of some secondary analysis studies have been included at the end of this entry.

Similarities and Distinctions Between Secondary Data Analysis and Meta-Analysis

Graves considered meta-analysis to be a special case of secondary analysis. However, because of differences in the two methods, some researchers do not agree with Graves. A comparison of these two methods reveals both similarities and distinctions. Regarding similarities, both methodologies use data collected by others. Both also offer the temptation to

rely on published findings, which means that each method can be subject to publication bias.

However, at least two distinctions exist between secondary analysis and meta-analysis. First, secondary data analysis uses previously collected data to address problems other than those for which the data were collected. In contrast, meta-analysis combines results from multiple studies with similar hypotheses to clarify findings on the same problem. Second, whereas meta-analysis entails using data from multiple studies, secondary data analysis might use data from a single (usually large) study. Because of these differences between the two methods, some researchers have viewed secondary analysis as distinct from all other types of research.

Practical Basis for Secondary Data Analysis

Governments, businesses, schools, and other organizations have gathered much quantitative information. Therefore, when available information gathered for primary research can serve other research purposes, it has made sense to use that information, rather than repeatedly attempting massive data collection efforts. Researchers have highlighted at least four practical reasons for using secondary data.

Efficiency

Secondary data has been less costly and frequently more easily available than primary data. This has been confirmed by a variety of researchers. Other secondary data analysis scholars concurred that, with research funding shortages, secondary data banks have provided a cost-efficient source of data.

Strengthened Confidence

Both Brannigan and Cowton noted that similar trends found by different sources strengthen confidence in findings. This phenomenon, known as triangulation, often can be achieved efficiently through multiple secondary sources. For triangulation purposes, K. J. Kiecolt and L. E. Nathan also

recommended combining original research with analysis of secondary data.

Special Need for Some Studies

The textual data found in newspaper accounts, letters, and other qualitative sources has been essential for historical research. Katz (in “How satisfied are the self-employed: A secondary analysis approach”; see the last research example in this entry) made the point that secondary data might be less biased than some types of primary data, such as self-report interviews. The reason proposed for reduced bias was that self-report is more subjective than third-party reporting.

Another example of using qualitative data to meet special research needs is found in Lindenmann’s award-winning public health study. Since public health information often is presented to general audiences in qualitative form, Lindenmann chose newspaper articles as the venue for his study. To learn how newspapers reported on matters affecting public health, he studied two national and five regional newspapers’ articles that related to public health issues.

Protection of Research Pool

Finally, secondary data analysis might have particular application for graduate students. Fitzpatrick claimed that by using the analysis from secondary information while learning to do research, potential research participants are protected.

Research Uses of Secondary Data Analysis

Quantitative researchers have found broad applications for secondary analysis because of the availability of summative data in national data banks. These data can help in addressing a host of educational, organizational, medical, environmental, and social problems. Also, as noted elsewhere in this article, graphic and textual secondary data have become widely available to address qualitative research questions. Qualitative data banks include those found in periodicals, newspapers, and other print media.

Quantitative Uses

Trochim and Van Dierendonck, Schaufeli, and Buunk noted that multiple secondary sources were used for some research questions. For example, Trochim noted that a researcher could study crime patterns in different parts of the United States using both census and crime data; likewise, a study reported by Van Dierendonck and colleagues noted use of five sources of secondary data for their examination of causal relationships among the three dimensions of burnout. Similarly, census data could be combined with discipline-specific databases to examine relevant issues in other fields. Some recent examples of uses of quantitative secondary analysis are studies of job satisfaction, work environment, gender, and worker decision making.

Qualitative Uses

Historical studies, obviously, have depended on secondary sources. Common sources for secondary data have included ethnographies, legislation, treaties, annual reports of various agencies, and letters and diaries. These sources have been used to study such topics as trends in social behavior; effects of substance abuse; health care; business; and work, school, and family issues. Also, mixed-methods studies have used both qualitative and quantitative as well as primary and secondary data.

Secondary Data Analysis Process

The process for secondary data analysis, as noted in Figure 1, is similar to that for other types of research except for the methods of gathering and working with the data. For original research, researchers (a) formulate research questions, (b) conduct literature reviews, (c) develop research designs, (d) collect data, (e) analyze data, and (f) report findings. For secondary analyses, they (a) formulate research questions, (b) conduct literature reviews, (c) establish criteria for inclusion, (d) locate summarized data collected by others *or* use their own primary data for a different research purpose, (e) analyze data, and (f) report findings.

Figure 1 Steps in Quantitative Secondary Data Analysis

In the data gathering and recording stages of secondary data analysis, researchers establish size of study, research design, quality controls, and so forth, for the data to be included. Next, they search data archives for data meeting their criteria. These data, frequently subsets of larger data sets, are transported into SPSS or another statistical program. Variables are established, often by combining other variables or by constructing new variables. Once the secondary data have been analyzed, secondary researchers compare their findings with findings of primary researchers and report their findings.

Variations of the Basic Secondary Data Analysis Process

There have been some variations, or modifications, of the basic secondary data analysis process. These process changes have arisen from the unique needs of

research projects. A few of these modifications are discussed in this section, including (a) use of secondary and primary data in the same study, (b) secondary data analysis using one's own data, and (c) studies that include both qualitative and quantitative secondary data.

Using secondary data analysis to complement primary data studies. Heaton ("Children and Families Team") used a combination of primary and secondary data. This approach can strengthen confidence in the findings of secondary data analysis while adding depth to answers to research questions.

Secondary data analysis of researcher's own data. Researchers can also reuse their own data for a new research purpose. Using this variation, researchers could avoid some of the challenges ordinarily involved in secondary data analysis because they would understand the primary research fully and would have access to the complete data set.

Studies using both qualitative and quantitative secondary data. Finally, Janet Heaton, in "Secondary analysis of qualitative data," discussed the option of including both qualitative and quantitative secondary data in studies. For example, a researcher might use secondary data analysis to identify aspects of job satisfaction in middle-management positions in the accounting industry. The researcher might then conduct interviews with several middle managers in selected accounting firms to add another dimension to the study. This variation can reinforce and clarify the findings of primary studies.

Major National Archives

Several large databases have been developed and made available to researchers. These may be classified according to research disciplines or by agency; some examples are included in this discussion. However, Mertens advised that some national databases have limitations relating to ways they can be manipulated. For example, a researcher might find it impossible to disaggregate data according to demographic variables such as gender or race. Also, some demographics that

interested a researcher—such as type of disability, educational level, and so forth—might not even be included in the study.

Nongovernment Databases

ISI Web of Knowledge

Developed by ISI (<http://www.isinet.com/>), this site was introduced in 2001. ISI, which is owned by the Thomson Corporation, has provided resources to researchers since the 1950s. It has become a worldwide organization with offices in the United States, Ireland, Japan, and China. The site contains qualitative and quantitative data banks on a variety of scientific, business, and social topics, and information is available in several languages.

Shuji Kaneko, an employee of Thomson, believes that a major advantage of data on the Web is its direct connection to related information through the link function. ISI, he said, can create links from secondary databases to primary sources. Kaneko also believes that ISI used adequate critical selection criteria to provide reliable and useful information. The criteria he listed were authority, accuracy, currency, navigation and design, applicability and content, scope, audience level, and quality of writing.

General Social Survey

The General Social Survey was one of three databases for social science research recommended by researchers. The General Social Survey is updated every year or so through major national surveys conducted through the University of Chicago. The purpose of the surveys has been to make fresh data available to researchers. Data has included international information as well as that collected in the United States.

Poll Service Databases

The Roper Center for Public Opinion Research, with facilities located at the University of Connecticut, has conducted public opinion polls on a variety of socially relevant issues, including information from the United States as well as 70 other nations. Other well-known opinion poll services include the Gallup

Poll and national news service polls. While sharing agreements for these data vary, interested researchers could find helpful information through these and other poll services.

Commercial Databases

In “Secondary analysis in entrepreneurship: An introduction to databases and data management,” Katz recommended marketing databases for research in appropriate areas. Some of those included Dun and Bradstreet, TriNet, and BRS. Katz also recommended that researchers consider the Interuniversity Consortium for Political and Social Research (<http://www.icpsr.umich.edu/>) Guide to Resources and Services for data-sharing opportunities.

Hard Copy Data Sources

According to Lawrence Neuman, excellent hard copy sources for social and political research include the *Almanac of American Politics*, *America Votes: A Handbook of Contemporary American Election Statistics*, and *Vital Statistics on American Politics*. These sources are available to researchers through their national congressional representatives. The *Almanac of American Politics* publishes congressional voting records, *America Votes* has county voting information for most statewide and national offices, and *Vital Statistics* provides information on campaign spending and a variety of related issues. Information gathered from these databases could be used to amend current practices or to develop policy for new initiatives.

Government Databases

Unlike some of the databases mentioned earlier, government databases can be accessed without charge. Another advantage of government data has been that it may be less biased than other data sources. A description of some government databases follows.

The Data Archive

This is a United Kingdom site. It is a major storage for quantitative computer files and their documentation

in the United Kingdom, according to the University of Southampton. The Data Archive also contains qualitative material—primarily research reports in the broad areas of humanities and social sciences (i.e., education, labor, history, politics, household finance, child development, crime, and public health).

FedWorld

This site (<http://www.fedworld.gov/>) promises to make it easy to locate government information. It has links to countless resources for secondary data analysis. These resources include the census and education databases, discussed next.

Census Databases

The U.S. Bureau of the Census database could be useful to researchers in a variety of disciplines, including business, social science, politics, health, and education. The national census conducted at the beginning of each decade gathers information on population numbers, ages, educational and income levels, housing, employment, and other areas. Inferential statistics can be derived from the vast store of current and past information from the censuses made available through the U.S. Departments of Commerce, Education, and Labor as well as directly through the U.S. Bureau of the Census.

Survey of Income and Program Participation

The Survey of Income and Program Participation database is available through a collaborative effort between the U.S. Census Bureau and the U.S. Social Services Administration. This database contains frequently updated information on income, employment, and participation in various government financial assistance programs.

Education Databases

The National Center for Education Statistics has developed a special database that has been of great assistance to persons preparing grant proposals for educational programs. This database can be found through the U.S. Department of Education Web site

(at <http://www.ed.gov/index.jhtml>). It provides information on demographics according to state, age, level of education, and so forth.

Another valuable resource for education research is the database for the Higher Education Research Institute (<http://www.gseis.ucla.edu/heri/heri.html>). It has information available at a minimal charge.

Advantages of Secondary Data Analysis

Various authors, such as Katz (in “Secondary analysis in entrepreneurship: An introduction to databases and data management”) and Trochim, have discussed advantages of secondary data analysis. This section contains a discussion of some of the most notable reasons for those advantages. Those reasons are efficiency, conservation of participant pools, and the advantage of using unobtrusive measures to obtain the data.

Efficiency

Some authors, including Jean Barclay, A. Dale and colleagues, E. J. Graves, R. Katz (in “Secondary analysis in entrepreneurship: An introduction to databases and data management”), and Kiecolt and Nathan, have stated that conservation of time, effort, and money is the strongest reason for secondary analysis. They pointed out that, especially for studies involving very large populations, individual researchers did not have the necessary money or access to obtain data firsthand. For example, Katz recommended secondary analysis for business studies involving entrepreneurial issues.

Conservation of Participant Pools

J. Fitzpatrick noted that large numbers of graduate students could “wear down” significant pools of potential research participants. Wimmer and Dominick noted that although novice researchers, such as students, can gain benefits from developing and conducting research, this particular type of analysis doesn’t usually produce results that are externally valid.

Unobtrusive Measures

Several researchers noted that, since secondary data analysis involves data collection in an indirect manner, they could avoid some contamination of the data. This observation might apply especially to quantitative data. However, it also could invite some of the challenges of secondary analysis because the burden of selecting high-quality studies would become increasingly important.

Challenges of Secondary Data Analysis

In addition to being a very useful tool, secondary analysis presents challenges to the researcher.

Getting a good fit. Accessing data collected for one research purpose and using it for a different purpose require carefully thought-out criteria for selection to assure the validity of the secondary analysis study. Also, there are limitations on the kinds of research questions and hypotheses that can be used for secondary data analysis purposes. A researcher must adapt the study to questions that can be answered using available data, and the primary study or studies must meet criteria for responsible research.

Loss of control of data collection. Obviously, when a researcher has not been involved in developing the research design or in the collection of data, a loss of control over the process of collecting the data necessarily occurs. In addition, the secondary analyst usually has access only to summarized data.

Ethical issues. Heaton (in “Secondary analysis of qualitative data”) noted that ethical issues could become important in secondary analysis. For example, should participants be contacted for permission to use their information for a different research purpose? Would the new study involve any compromise of either the identity of participants or the integrity of the data?

Establishing new variables. To meet the objectives of a new research purpose, a researcher often must

manipulate the secondary data. This could involve taking subsets of data from databases. It also could require a researcher to collapse information into new variables.

Research Applications of Secondary Data Analysis

Internationally, researchers have used secondary data to study education, business, and social issues. This section contains a review of human resource studies, including decision making at the middle management level, job satisfaction among volunteers, and job satisfaction among entrepreneurs.

Managerial Decision Making

An applied ethics study by Harris examined relationships between courage and middle management decision making. Harris used secondary qualitative data from 610 newspaper items he found in four leading international newspapers. Specifically, the data were examples of courageous behavior and situations in which the virtue of courage was needed for making management decisions. He stated he used reporter accounts because he believed that the data sources were less biased than self-reporting data would have been.

Harris conducted a content analysis of the gathered data. The process involved him in (a) selecting newspaper reports that provided the necessary data, (b) using special software to code the data, and (c) analyzing and evaluating the data. Harris also conducted a check for face validity using the phrases he had coded, noting that the percentage, reliability coefficient, and agreement coefficient were calculated. Reliability coefficients ranged from 77% to 97%; agreement coefficients ranged from 70% to 90%. According to Harris, his validity and reliability results were consistent with or superior to those of other researchers on the variable of courage.

Findings from this study indicated that accounts of courage could be recognized in the descriptions of courage and courageous activity in major newspapers throughout the world. However, Harris found

insufficient data to provide useful information relative to differences in professions or particular ethical values or choices.

Job Satisfaction of Volunteers

Silverberg and his colleagues studied job satisfaction among volunteers in the public parks and recreation industry. The purpose of their study was to check the reliability and the validity of the questionnaire used in a primary study of almost 6,000 volunteers who responded to a “modified employee job satisfaction scale.” Silverberg and colleagues noted that 50% of American adults are volunteers in non-profit organizations and that volunteer effectiveness depended on competence of volunteers and low turnover.

They determined that the instrument was a reliable, valid instrument for making inferences about volunteer job satisfaction in the parks and recreation industry. They also found that volunteer satisfaction was related to job setting and to the psychological needs met through the volunteer job function. Specifically, volunteers in this study wanted to increase their understanding of governmental and organizational operations. Working to benefit others was not seen as a prime motivator.

Recommendations from the study by Silverberg and colleagues included (a) instituting regular meetings between managers and volunteers to gain the feedback necessary to ensure high job satisfaction among volunteers and (b) trying to ensure a good match between volunteer assignments and volunteer motives.

Job Satisfaction Among Entrepreneurs

In “How satisfied are the self-employed: A secondary analysis approach,” Katz used secondary analysis of three previous studies involving more than 1,200 participants to study job satisfaction among the self-employed. He concluded that self-employed workers had higher job satisfaction rates than did salaried workers. Katz also noted that having access to secondary data was insufficient for secondary analysis. Also necessary was detailed information on

(a) how the primary researcher handled missing data, (b) the procedures followed in sample and subsample selection, and (c) coding variations that would affect analysis. Katz recommended that journal editors allow more space so that researchers could report the details needed for secondary analysis. He also suggested that there be changes in research practices in the area of entrepreneurship to enable other researchers to use their data to best effect.

SECTION 504 OF THE REHABILITATION ACT OF 1973

Section 504 of the Rehabilitation Act of 1973, which traces its origins to the wake of World War I, at which time the U.S. government sought to provide vocational rehabilitation to injured soldiers, is the oldest federal law addressing the needs of the disabled. According to Section 504, in language that is similar to that in Title VI of the Civil Rights Act of 1964 and Title IX of the Educational Amendments of 1972: “[n]o otherwise qualified individual with a disability in the United States . . . shall, solely by reason of her or his disability, be excluded from the participation in, be denied the benefits of, or be subjected to discrimination under any program or activity receiving [f]ederal financial assistance . . .” (29 U.S.C.A. § 794(a)).

Section 504 differs significantly from the Individuals with Disabilities Education Act (IDEA). For example, while Section 504 applies to school systems that receive federal financial assistance in the form of money, books, or free lunches, school systems do not receive additional funds under its provisions, as do boards that serve children who qualify for IDEA services. Further, Section 504 protects individuals under the broader notion of impairment rather than the IDEA’s reliance on the statutorily concept of disability, and Section 504 has no age limitation. Moreover, Section 504 covers students, employees, and others, including parents, while the IDEA focuses on the rights of children.

Section 504 defines an individual with a disability as one “who (i) has a physical or mental impairment which substantially limits one or more of such person’s major life activities, (ii) has a record of such an impairment, or (iii) is regarded as having such an impairment” (29 U.S.C.A. § 706(7)(B)). In order to have “a record of impairment,” one must have a history of, or have been identified as having, a mental or physical impairment that substantially limits one or more major life activities, including learning and working (45 C.F.R. § 84.3(j)(2)(i)). Once an individual is identified as having an impairment, educators must consider whether the child is “otherwise qualified.” Unlike the IDEA, Section 504 neither requires that individuals submit to psychological or other examinations nor affords extensive due process protections.

In order to be “otherwise qualified,” persons must be “(i) of an age during which nonhandicapped persons are provided such services, (ii) of any age during which it is mandatory under state law to provide such services to handicapped persons, or (iii) [one] to whom a state is required to provide a free appropriate public education [under the IDEA]” (45 C.F.R. § 84.3(k)(2)). Individuals who are “otherwise qualified” (meaning that, impairment aside, they are eligible to participate in programs or activities) must be permitted to partake as long as they can be provided with “reasonable accommodations.”

Even if one appears to be “otherwise qualified,” educators can rely on three defenses to avoid being charged

with noncompliance with Section 504 (another major difference between Section 504 and the IDEA, which does not recognize defenses). First, educators can be excused from making accommodations that would result in “a fundamental alteration in the nature of [a] program” (*Southeastern Community College v. Davis*). The second defense allows educators to avoid making a modification if it imposes an “undue financial burden” (*Southeastern Community College*). The third defense is that otherwise qualified individuals can be excluded from programs if their presence creates a substantial risk of injury to themselves or others (*School Bd. of Nassau County v. Arline*).

SELF-REPORT

Self-report is one of the most commonly utilized methods of data collection. Surveys, questionnaires, and interviews are all forms of self-report that rely on individuals' subjective evaluations and reports of their thoughts, feelings, behaviors, or experiences. Most often, self-report is used to gather personal

information that cannot be obtained objectively. An individual's self-report may also be of interest in circumstances in which some degree of objective evaluation is possible (e.g., a patient's subjective reports of symptoms). In many settings, such as medicine, policy making, and opinion polls, important decisions are made on the basis of self-report data.

There are two broad categories of self-report data: (a) unstructured, open-ended responses, and (b) structured, fixed-response questions. Open-ended reports have the advantage of soliciting detailed information that may not be captured using closed-response formats. In many cases, this approach is optimal because it provides a wealth of qualitative data. However, such responses do not easily lend themselves to statistical analysis without the use of coding procedures, which can be labor intensive and difficult to develop.

Closed-response formats generate quantitative data much more easily. However, decisions regarding the use of checklists, number scales, or categorical endorsements can have a dramatic impact on response distributions and the subsequent presence or absence of significant statistical effects. Research has demonstrated that by simply altering the response format of a questionnaire, one can generate different responses to the same questions. For instance, decisions regarding whether to anchor a response scale with a midpoint, whether to use a bipolar (–5 to +5) or unipolar (0 to 10) number scale, and whether to label responses with verbal quantifiers like “frequently” or “very often” can influence one's perception of the questions and subsequently the responses one endorses.

A number of cognitive constraints can also interfere with one's ability to generate accurate self-reports. Both the time scale and the regularity of a behavior can alter the memory retrieval strategy used to recall events, while the accessibility of recent experiences may influence more general estimates. Similarly, measures designed to evaluate emotional traits or memories are often biased by the influence of current mood states. Research on such contextual effects has also demonstrated that responses to self-report items may be directly influenced by the content and placement of previous self-report items (i.e., later

answers are influenced by earlier answers). Furthermore, respondents' conscious beliefs regarding the confidentiality of their reports can affect their disclosure of personally sensitive information (especially regarding threatening or stigmatized topics).

Critically evaluating questions to ensure that they are presented clearly, framed in the proper context, and accompanied by appropriate response formats can help prevent self-report data from being compromised by measurement constraints or response biases. Clearly informing respondents as to the intended use, privacy, and protection of self-report information can also reduce self-presentation concerns and facilitate more veridical reporting. A number of innovative self-report methodologies, such as daily diaries and ecological momentary assessment, have addressed some of these concerns by considerably limiting the recall periods (i.e., to a day or even a few minutes) and providing an ecologically valid alternative to lengthy retrospective reporting. By carefully considering these issues, researchers can effectively use self-report as a fast, cheap, and practical method for collecting personal information across a variety of research and applied settings.

SEMANTIC DIFFERENTIAL

Semantic differential is a term used to refer to a method of measuring different dimensions of meaning underlying responses toward an object. This procedure involves presenting individuals with opposing adjective pairs (e.g., good-bad, strong-weak, fast-slow) and asking them to identify where on the scale they feel the object fits in relation to the two adjectives.

Semantic differential scales can be used to capture three broad dimensions of meaning underlying reactions to an object: evaluation, potency, and activity. However, in practice, most researchers use the procedure to assess global attitudes toward an object. Thus, in most situations, researchers focus exclusively on the evaluation dimension.

Development of the Semantic Differential Method

The origins of the semantic differential method can be traced to the pioneering work of Charles Osgood and his colleagues. Osgood was interested in understanding the meaning that people attached to words. He noted that words have both a denotative meaning and a connotative meaning. Denotative meaning refers to the literal dictionary definition of a word. Connotative meaning, on the other hand, refers to the associations of meaning that are attached to a word that are not, strictly speaking, part of its formal definition.

Osgood was interested in identifying the basic dimensions of connotative meaning underlying words. To explore this issue, he constructed pairs of opposing adjectives and then had respondents rate objects on these adjective pairs. Using factor analyses, he found that adjectives seemed to reflect one or more of the three basic underlying dimensions of connotative meaning mentioned above: evaluation, potency, and activity. Evaluation refers to the good-bad continuum of meaning underlying words. Potency reflects the strong-weak continuum. Activity represents the active-passive dimension. These dimensions of meaning have consistently been replicated, and analyses by Osgood and subsequent researchers have identified certain adjective pairs as highly representative of the evaluation (e.g., good-bad, valuable-worthless), potency (e.g., large-small, strong-weak), and activity (e.g., fast-slow, hot-cold) dimensions.

Constructing Semantic Differential Scales

Drawing on this research on connotative meaning, Osgood and others have proposed that semantic

differential items (i.e., adjective pairs) can be used to construct scales assessing people’s attitudes (i.e., evaluations) toward objects, as well as the extent to which people associate activity and potency with an object. A semantic differential scale typically consists of 4 to 10 items selected to assess the dimension of interest. Figure 1 presents an example of a semantic differential scale designed to assess attitudes toward vegetarianism.

When creating such scales, a researcher must keep several issues in mind. For instance, the researcher must ensure that the adjective pairs are strongly reflective of the dimension of interest and do not tap into unintended dimensions. Thus researchers often use published results of factor analyses of adjective pairs as a guide to item selection. Of course, if selections are to be based on past analyses, it is important to carefully consider whether the meaning of word pairings will hold constant across groups and be relevant to the population being sampled.

Item selection also requires the researcher to keep in mind that adjective pairs must be easily related to the object being rated. Some adjective pairs are quite generic and are likely applicable to nearly any object. For example, good-bad could probably be sensibly applied to almost any physical object, person, social group, or concept. Other adjective pairs may reflect somewhat more specific meaning and thus be less easily applied to some objects than others. For instance, beautiful-ugly is highly evaluative in content and could quite sensibly be applied to a person (e.g., one’s spouse) and many physical objects (e.g., a car, a work of art). This pair might be less meaningfully applied to other objects or concepts (e.g., magnetic resonance imaging, social security).

After selecting the items, the researchers must then decide how the items will be presented. Most commonly, these items are presented as 7-point rating scales (although 5-point scales are sometimes used). Participants are asked to identify where on the scale they feel the object is in relation to the two adjectives. For example, the object may be DOG, and items might include good-bad and valuable-worthless. Participants then respond to each item by indicating where on the continuum they would place the object in terms of direction and intensity, with a neutral response being in the middle of the scale. The precise manner in which the response scale is presented varies, with some researchers using spaces to represent the 7-point scale, others numerical values from 1 to 7, and still others numerical values from –3 to +3. Figure 2 illustrates these three common response scale formats.

Some methodologists have also recommended that the positive and negative adjective positions be varied across items such that the left end of the scale is sometimes a positive adjective and other times a negative adjective. This procedure is designed to encourage respondents to consider items more carefully. Of course when varying adjective position, it is important to ensure that the numerical values of the rating scale intuitively fit with the adjectives (e.g., it would be confusing to have the positive adjective associated with –3). For this reason, the physical spacing scale is often more convenient when varying adjective position.

When presenting semantic differential items to assess multiple objects, several strategies can be used. First, an object may be presented and then followed with the items seeking to measure that object. For example, DOG may be presented at the top of a page, and underneath it are the descriptive items such as good-bad, like-dislike, and others. Alternatively, the object and one item that the object is to be rated on can be presented. The object then changes but the item remains the same. For example, DOG is presented with a good-bad scale. This item is followed by CAT, which is also presented with a good-bad scale, and so on. In yet another method of presentation, objects being rated on

different adjective pairs may be presented randomly. Research suggests that results do not vary considerably between these methods, although the first method of presentation allows for easier organization and coding of data.

Once responses to items have been collected, an overall score for ratings of the object on the dimension of interest is computed. For instance, when scoring a semantic differential scale assessing evaluation, researchers usually code responses from 1 to 7 or from -3 to +3, with higher numbers reflecting more positive evaluations. Responses to individual items are then summed or averaged to provide an overall attitude score. Scoring is similar for scales assessing potency and activity, with higher numbers typically reflecting greater potency or activity.

Strengths and Weaknesses of Semantic Differential

The greatest strengths of the semantic differential method are its ease and versatility. Because previous analyses have identified adjective pairs that are highly representative of the dimensions of evaluation, potency, and activity, it is reasonably easy to select items to construct a semantic differential scale. Moreover, many adjective pairs are quite general and thus can be broadly applied to a wide range of objects (e.g., people, groups, concepts, and physical objects). These features make constructing a semantic differential scale a relatively easy process. They also permit reasonably direct comparisons of attitudes toward different objects because the same set of items can be used to assess attitudes toward the objects being compared. Yet another strength of the semantic differential scales is that they have been found to perform well with as few as four items. This efficiency permits quick measurement of attitudes and makes it feasible to

assess attitudes toward numerous topics in a short period of time.

In contrast, other well-known attitude scaling techniques are more cumbersome and less flexible. For example, some of these methods (e.g., Thurstone scales and Guttman scales) require significant item pretesting and evaluation.

These alternative methods also typically produce items that are attitude object specific (i.e., items are applicable to only a single target of judgment, such as a specific social issue, a particular person, or single product). Hence, these alternative methods often require more time and effort for developing a scale, and the scale is usually useful only for a single attitude object or a narrow class of attitude objects. Some of these alternative methods also typically require more items for assessing attitudes. For instance, Thurstone and Likert scales usually involve no less than 10 items and generally as many as 20 or 30 items. Given the practical advantages of the semantic differential method, it is not surprising that semantic differential scales are perhaps the most popular method of attitude measurement.

Formal evaluations of the semantic differential method have suggested that it is a reasonably effective method of attitude measurement. Semantic differential scales are routinely highly correlated with attitude measures constructed using other scaling techniques. Moreover, because of the popularity of the method, semantic differential scales have been used extensively in basic and applied attitude research. In these contexts, they have been found to be sufficiently sensitive for detecting experimental manipulations designed to alter attitudes and for predicting outcomes postulated to be influenced by attitudes.

Although semantic differential scales have proven useful, methodologists also point out potential limitations. For example, respondents who read each item in a strictly literal sense may miss out on the implied meaning within the adjective pairing. For example, if the object were SELF and the item included dirty-clean, the respondent might be confused and not know how to answer. To help remedy this potential problem, participants are often told to go with their first instinct. In addition, careful selection of adjective

pairs can help ensure that very general items are used or that the specific items used are clearly applicable to the object being judged.

A second potential problem is that semantic differential scales are fairly obvious in their objectives. Thus, respondents may figure out what is being measured and may report their attitudes in a self-enhancing light. Of course, such a limitation is true of nearly all self-report measures and can sometimes be reduced with assurances of anonymity.

Another proposed limitation of the method is that semantic differentials allow only for overall analysis of the evaluative dimension of meaning. However, some researchers have explored the possibility of identifying word adjective pairs that are highly affective or cognitive in nature in addition to being highly evaluative. This research suggests that constructing more-specific semantic differential measures of affect and cognition (and perhaps other specific dimensions) is possible.

Finally, it is important to note that the bipolar structure of semantic differentials does present some ambiguity in interpreting scores. Specifically, mid-point responses can reflect one of several reactions to the object. It could imply that a respondent is ambivalent toward the object (i.e., the respondent has strong conflicting positive and negative evaluations), that the respondent truly is neutral (i.e., the respondent's reactions are mostly nonevaluative), or that the respondent has no opinion.

SEMANTIC DIFFERENTIAL SCALE

A semantic differential scale is an efficient method of measuring various dimensions of meaning underlying responses toward an object. This procedure involves presenting individuals with opposing adjective pairs and asking them to locate the object on a rating scale anchored by the opposing adjectives. Semantic differential scales can be used to capture three broad dimensions of meaning underlying reactions to an object: evaluation, potency, and activity. Evaluation represents the good-bad continuum with respect to an object, potency reflects the strong-weak continuum, and activity represents the active-passive continuum. Although the method can be used to assess all three of these dimensions, in practice many researchers choose to measure only the evaluation dimension. When the scale consists only of evaluation items, it can be conceptualized as a measure of attitudes. Indeed, semantic differentials are among the most widely used methods of attitude measurement in the social sciences.

A semantic differential scale usually consists of 4 to 10 items (i.e., adjective pairs). Each descriptive item contains two adjectives, opposite in meaning, on either end of a continuous scale that typically has seven levels of response. Participants are asked to identify where on the scale they feel the object fits in relation to the two adjectives. For example, the object may be DOG, and items might include good-bad and valuable-worthless. Participants then respond to each item by indicating where on the continuum they would place the object in terms of direction and intensity, with a neutral response being in the middle of the scale.

Table 1 Sample of Semantic Differential Evaluation Items

	<i>Vegetarianism</i>													
Dislike	1	–	2	–	3	–	4	–	5	–	6	–	7	Like
Good	1	–	2	–	3	–	4	–	5	–	6	–	7	Bad
Wise	1	–	2	–	3	–	4	–	5	–	6	–	7	Foolish
Pleasant	1	–	2	–	3	–	4	–	5	–	6	–	7	Unpleasant

When scoring a semantic differential scale assessing evaluation, responses are coded from 1 to 7 or from –3 to +3, with higher numbers reflecting more positive evaluations. Responses to individual items are then summed or averaged to provide an overall score. Scoring is similar for scales assessing potency and activity.

When creating a semantic differential scale, researchers should ensure that appropriate adjective pairs have been selected to assess the dimensions of interest. Published factor analyses of word meanings can help determine which dimensions adjective pairs best reflect. In addition, researchers need to consider the appropriateness of word pairs for the specific object of interest. Some adjective pairs are quite general and are probably appropriate for virtually any object. For example, good-bad could probably be meaningfully applied to virtually any physical object, person, social group, or abstract idea. Other adjective pairs may be somewhat more specific and thus perhaps less readily applied to some objects than others. For instance, beautiful-ugly could quite sensibly be applied to a person but less meaningfully applied to an object such as magnetic resonance imaging.

SEMI-INTERQUARTILE RANGE

Briefly, the semi-interquartile range is a measure of the dispersion or spread of a variable; it is the distance between the 1st quartile and the 3rd quartile, halved.

It is common to describe a variable using a measure of central tendency, or average, most commonly the mean or median. However, in order to make sense of a measure of average, we need to have a measure of dispersion. When the mean is used as a measure of average, the standard deviation is usually used as the measure of dispersion. When the median is used, it is more appropriate to use the semi-interquartile range.

The semi-interquartile range is preferred over the range because it is not affected by extreme scores. The range is calculated using only two data points: the highest and the lowest. If one of these values were to change, the range would change dramatically.

Example of the Calculation of the Semi-Interquartile Range

Table 1 shows the data contained in one variable, sorted in order of magnitude and numbered, to make life easier.

There are 21 values, and the middle point, which is the median, is the middle one. This is the 11th point and is equal to 9. To find the exact point, add 1 to the sample size and multiply by 0.5. Thus, the median

point is given by $(21 + 1) \times 0.5 = 11$; it is the 11th point. There are 10 people who score higher than this and 10 who score lower.

For the quartiles, we want the points that are one quarter and three quarters of the way through the distribution. We use a procedure similar to the one we used for the mean, except multiplying by .25 and .75. The points are therefore obtained as follows:

$$\begin{aligned}\text{lower quartile} &= (21 + 1) \times .25 = 5.5; \\ \text{upper quartile} &= (21 + 1) \times .75 = 16.5.\end{aligned}$$

The obvious problem we encounter is that these values do not exist. To solve this problem, as we would with the median, we take the mean of the nearest two values, weighted by their distance from the value that we want. For the 1st quartile, we want the value in the 5.5th position. We therefore find the mean of the fifth and sixth values. The mean of 4 and 5 is 4.5, so the 1st quartile is 4.5. Similarly, for the 3rd quartile, we want the value that is in 16.5th place, and

so we use the mean of the 16th and 17th values. The mean of 13 and 14 is 13.5.

Finally, the semi-interquartile range is the difference between these two values, halved:

$$(13.5 - 4.5) / 2 = 4.5.$$

Additional Notes

The calculation of the quartiles is complicated when the values for the quartiles do not land exactly in between two potential values. For example, if we have a sample of size 32, the 1st quartile will be the 8.25th position. If the 8th value is 4 and the 9th value is 5, the interquartile range should be closer to the 8th value than the 9th and hence will be 4.25, not 4.5.

In a symmetrical distribution, the range given by the median plus or minus the semi-interquartile range will include approximately half of the values. In our case, this would be 11 ± 4.5 , giving a range of 6.5 to 15.5. In our data set, this range includes 13, slightly more than half. (The semi-interquartile range is used instead of the interquartile range because of this property.)

When the data are normally distributed, the sampling distribution of the semi-interquartile range is wider than the sampling distribution of the standard deviation, and hence it is not used when the standard deviation is appropriate.

SHAPIRO-WILK TEST FOR NORMALITY

The most popular nongraphical procedure for testing for fit to the normal distribution is the Shapiro-Wilk test. The test can be obtained easily from leading statistical packages such as R, SAS, and SPSS. This is

fortunate because the Shapiro-Wilk test statistic W is laborious to calculate by hand. The Shapiro-Wilk test statistic is obtained by dividing the square of an appropriate linear combination of the sample order statistics by the sum of squares error. The formula is

$$W = \frac{\left\{ \sum_{i=1}^n a_i (x_{(n-i+1):n} - x_{i:n}) \right\}^2}{\sum_{i=1}^n (x_i - \bar{x})^2},$$

where a_i represents special coefficients obtained from a table in Shapiro and Wilk's 1965 report or a source such as Conover. A computer algorithm given by Royston will also approximate these coefficients. The formulas are also found online in the Wikipedia. After W is calculated, the hypothesis of normality is rejected if W is less than a quantile from a value in another special table.

One major flaw in the original form of the Shapiro-Wilk test was that the table with the necessary coefficients and percentage points was available only for samples of size 50 or less. To deal with this flaw, Shapiro and Francia adapted the W statistic so that the necessary coefficients for the linear combinations depended only on the expected values of the normal order statistics, which are more readily available. Another table of empirically obtained percentage points was given. Royston extended the Shapiro-Wilk test for sample sizes up to 2,000. Royston's method involves an approximate normalizing transformation on the W statistic, which is not asymptotically normal. The calculations are tedious by hand but easily programmed into a computer. In 1989, Royston provided a correction for cases in which ties are present in the data. Royston's version of the Shapiro-Wilk test is available on SAS.

In the Shapiro-Wilk test, the null hypothesis is defined to be that the data are normally distributed (with some unspecified mean and standard deviation), and the alternative hypothesis is that the data are not normal. Therefore, a rejection of the null hypothesis, which will occur when the value of the W statistic is small and the p value is less than the specified level of significance (usually $\alpha = .05$), indicates a significant deviation from normality. A value of W close to its

maximum of 1 indicates a close fit to normality, which is indicated by a p value that is above $\alpha = .05$, and a failure to reject the null.

Unfortunately, the Shapiro-Wilk test shares many of the standard flaws of most goodness-of-fit tests. When the sample is small, the test lacks power, and often the test will fail to reject a sample that arises from a non-normal population. This is troublesome because it is these small sample situations in which most analysts are the most concerned with testing for normality. The usual reason to perform a goodness-of-fit test for normality is to determine whether the assumption of normality is met well enough for the analyst to perform standard parametric tests (e.g., t test, ANOVA). If the assumption is not met, then the researcher may need to make a transformation or pursue alternatives such as nonparametrics, bootstrapping, or Bayesian methods. Also, the Shapiro-Wilk test will almost always reject its null hypothesis when the sample is very large. With a data set of several thousands, even minor deviations present in data generated from a known normal distribution will lead to rejection of normality.

Example

To avoid extreme tedium, we will rely on a computer package to perform the calculations. The examples given here utilize the `shapiro.test` function in the free statistical package R. The Shapiro-Wilk test is also available in virtually all standard statistical software packages, such as SAS and SPSS. SAS users can obtain the Shapiro-Wilk test by adding the normal option to PROC UNIVARIATE.

The first example uses a data set of size 100 randomly generated from a normal distribution of size 100 with mean 100 and standard deviation 15. In this case, $W = 0.9889$ and the p value = 0.5775. We do not have enough evidence to reject normality. Figure 1 is a density plot (or essentially a smoothed histogram) of these data.

The second example (Figure 2) uses a data set of size 100 randomly generated from an exponential distribution of size 100 with mean 1. In this case, $W = 0.8646$, and p value = 4.254×10^{-8} . Notice that the smaller value of the W statistic leads to a p value so small that we will reject the null hypothesis for any

Figure 1 Density ($x = \text{Normal}$)

Figure 2 Density ($x = \text{Exponential}$)

reasonable alpha level and therefore conclude that these data are not normally distributed.

Power

The power of the Shapiro-Wilk test has been compared with several competitors, such as the chi-square, Cramer-von Mises, and Kolmogorov-Smirnov tests and tests based on the standardized third moment (skewness) and fourth moment (kurtosis). It was found to be generally superior to the other tests across a

wide range of possible alternatives. The empirical distribution function tests such as Kolmogorov-Smirnov and Cramer-von Mises, which are based on distance, had lower power. A combination of the skewness and kurtosis tests had more power but was still usually outperformed by the Shapiro-Wilk W statistic.

Recommendations for Testing Univariate Normality

D'Agostino, Belanger, and D'Agostino recommended that the skewness and kurtosis tests should always be calculated as descriptive statistics and that the tests based on $\sqrt{b_1}$ and b_2 should be used, along with Q-Q or normal probability plots. Pearson, D'Agostino, and Bowman compared the $\sqrt{b_1}$ test, the b_2 test, the Shapiro-Wilk W test, the Shapiro-Francia W' test, D'Agostino's Y test, and the D'Agostino-Pearson K^2 test against dozens of alternative distributions. While no test is uniformly the most powerful against all possible distributions, the W test of Shapiro and Wilk was generally the best performer. D'Agostino noted that while the Shapiro-Wilk test is a very sensitive omnibus test against skewed alternatives, one may wish to use a directional test, such as the $\sqrt{b_1}$ test, if the direction of deviation from normality in terms of skewness is known a priori. The b_2 test is more powerful than Shapiro-Wilk's W or D'Agostino's Y if the direction of deviation from normality in terms of kurtosis is known. D'Agostino recommended against the use of chi-square or Kolmogorov-Smirnov tests because of their low power.

SIGNAL DETECTION THEORY

Signal detection theory (SDT) is used to analyze data coming from experiments in which the task is to categorize ambiguous stimuli that can either be generated by a known process (in which case the stimuli are called the *signal*) or be obtained by chance (in which case they are called the *noise* in the SDT framework). For example, radar operators must decide whether what they see on a radar screen indicates the presence of a plane (the signal) or the presence of parasites (the noise). This type of application was the original framework of SDT (see the founding work by Green & Swets). But the notion of signal and noise can be somewhat metaphorical in some experimental contexts. For example, in a memory recognition experiment, participants have to decide whether the stimulus they currently see was presented before. Here the signal corresponds to a familiarity feeling generated by a memorized stimulus whereas the noise corresponds to a familiarity feeling generated by a new stimulus.

The goal of detection theory is to estimate two main parameters from the experimental data. The first parameter, called d' , indicates the strength of the signal (relative to the noise). The second parameter, called C (a variant of which is called β), reflects the strategy of response of the participant (e.g., saying easily Yes

rather than No). SDT is used in disparate domains, from psychology (psychophysics, perception, memory) to medical diagnostics (do the symptoms match a known diagnostic or can they be dismissed as irrelevant?) to statistical decision (do the data indicate that the experiment has an effect or not?).

The Model

It is easier to introduce the model with an example, so suppose we have designed a face memory experiment. In the first part of the experiment, a participant is asked to memorize a list of faces. At test, the participant is presented with a set of faces one at a time. Some faces in the test were seen before (these are *old* faces) and some were not seen before (these are *new* faces). The task is to decide for each face whether this face was seen (response Yes) or not (response No) in the first part of the experiment.

What are the different types of responses? A Yes response given to an old stimulus is a correct response, and it is called a *Hit*, but a Yes response to a new stimulus is a mistake, and it is called a *False Alarm* (abbreviated as FA). A No response given to a new stimulus is a correct response called a *Correct Rejection*, but a No response to an old stimulus is a mistake, called a *Miss*. These four types of response (and their frequency) can be organized as shown in Table 1.

The relative frequency of these four types of response is not all independent. For example, when the signal is present (first row of Table 1), the proportion of Hits and the proportion of Misses add up to 1 (because when the signal is present, the participant can say either Yes or No). Likewise, when the signal is absent, the proportion of FAs and the proportion of Correct Rejections add up to 1. Therefore, all the information in a table such as Table 1 is given by the proportion of Hits and FAs.

Table 1 The Four Possible Types of Response in Signal Detection Theory

Reality	Decision (Participant's Response)	
	Yes	No
Signal present	Hit	Miss
Signal absent	False Alarm	Correct Rejection

Even though the proportions of Hits and FAs provide all the information in the data, these values are hard to interpret because they crucially depend on two parameters. The first parameter is the difficulty of the task: The easier the task, the larger the proportion of Hits and the smaller the proportion of FAs. When the task is easy, we say that the signal and the noise are well separated or that there is a large distance between the signal and the noise. (Conversely, for a hard task, the signal and the noise are close, and the distance between them is small.) The second parameter is the strategy of the participant: A participant who always says No will never commit an FA (and will never get any Hit either); on the other hand, a participant who always says Yes is guaranteed all Hits (but will also have all FAs). A participant who tends to give the response Yes is called liberal, and a participant who tends to give the response No is called conservative.

The SDT Model

So the proportions of Hits and FAs reflect the effect of two underlying parameters: the first one reflects the separation between the signal and the noise, and the second one the strategy of the participant. The goal of SDT is to estimate the value of these two parameters from the experimental data. In order to do so, SDT creates a model of the participant’s response. The SDT model assumes that the participant’s response depends on the intensity of a hidden variable (e.g., familiarity of a face) and that the participant responds Yes when the value of this variable for the stimulus is larger than a predefined threshold.

SDT also assumes that the stimuli generated by the noise condition vary naturally for that hidden variable. As is often the case elsewhere, SDT, in addition, assumes that the hidden variable values for the noise follow a normal distribution. Recall at this point that when a variable x follows a Gaussian (also called normal) distribution, this distribution depends on two parameters: the mean (denoted μ) and the variance (denoted σ^2). It is defined as follows:

$$\mathcal{G}(x, \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{(x - \mu)^2}{2\sigma^2}\right\}. \quad (1)$$

In general, within the SDT framework, the values of μ and σ are arbitrary, and therefore we choose the simpler values of $\mu = 0$ and $\sigma = 1$ (other values will give the same results but with more cumbersome procedures). In this case, Equation 1 reduces to

$$\mathcal{N}(x) = \frac{1}{\sqrt{2\pi}} \exp\left\{-\frac{1}{2}x^2\right\}. \quad (2)$$

Finally, SDT assumes that the signal is *added* to the noise. In other words, the distribution of the values generated by the signal condition has the same shape (and therefore the same variance) as the noise distribution.

Figure 1 illustrates the SDT model. The x -axis shows the intensity of the underlying hidden variable (e.g., familiarity for the face example). As indicated above, the distribution of the noise is centered at zero (i.e., mean of the noise is equal to zero, with a standard deviation of 1). So the standard deviation of the noise is equivalent to the unit of measurement of x . The distribution of the signal is identical to the noise distribution, but it is moved to the right of the noise distribution. The distance between the signal and the noise distributions corresponds to the effect of the signal (this is the quantity that is added to the noise distribution in order to get the signal distribution): This distance is called d' . Because the mean of the noise distribution is 0, d' is equal to the mean of the signal distribution.

Figure 1 The Model of SDT

The strategy of the participant is expressed via the choice of the threshold. There are several ways of expressing the position of this threshold; among the possible candidates, we will mention four of them, denoted B, D, C , and β . The first quantity, B (sometimes called θ), gives the position of the threshold on the x -axis. In the example illustrated in Figure 1, this value is equal to 2, and so the participant corresponding to this figure has decided that any stimulus with a value of x larger than 2 comes from the signal distribution and is given the response Yes. The position of the threshold can also be given relative to the signal distribution (because the noise has zero mean, B is the distance of the threshold relative to the noise distribution); as the mean of the signal is equal to d' , we can compute D as $D = d' - B$ (a value equal to 1 in our example).

The most popular way of expressing the location of the threshold, however, is from neither the distribution of the noise nor the distribution of the signal but relative to what is called the ideal observer. The ideal observer minimizes conjointly the probability of a Miss and of an FA. When each type of error has the same cost, the criterion of the ideal observer is positioned on the average of the means of the signal and the noise distribution. In our example, the threshold of the ideal observer would be equal to $\frac{1}{2}d' = \frac{1}{2} = .5$. The value of C is the distance from the actual threshold to the ideal observer; it can be computed as $C = B - \frac{d'}{2} = 2 - .5 = 1.5$. The sign of C reveals the participant's strategy: when $C = 0$, we have the ideal observer; when C is negative, the participant is liberal (i.e., responds Yes more often than the ideal observer); when C is positive, the participant is conservative (i.e., responds No more often than the ideal observer).

An alternative way of expressing the position of the participant's criterion is given by the quantity called β . It corresponds to the ratio of the height of the signal distribution to the noise distribution for the value of the threshold. Because the distributions of the noise and the signal are normal with variance equal to one, we can compute β from Equation 2 as follows:

$$\beta = \frac{\mathcal{N}(D)}{\mathcal{N}(B)} = \frac{\mathcal{N}(1)}{\mathcal{N}(2)} = \frac{.2420}{.0540} \approx 4.4817. \quad (3)$$

Equation 3 can be rewritten as follows:

$$\beta = \exp\{d' \times C\}. \quad (4)$$

The quantity β has the advantage of being a *likelihood ratio* and can be used to interpret SDT within a statistical framework. For practical reasons, it is often easier to compute the logarithm of β ; for example, from Equation 4, we get

$$\ln \beta = d' \times C = 1 \times 1.5 = 1.5. \quad (5)$$

The model illustrated by Figure 1 generates a specific pattern of response probabilities which can be computed from integrating the normal distribution. So, for example, the probability of an FA is obtained as the probability (i.e., area under the normal distribution) of finding a value larger than 2 with a normal distribution of mean 0 and variance 1 (this can be computed with most statistical packages or from tables such as the ones given in Abdi). This quantity is also called the probability associated with the value 2; in our example, it is equal to .0228. Along the same lines, the probability of a Hit is obtained as the probability (i.e., area under the normal distribution) of finding a value larger than 2 with a normal distribution of mean 1 (i.e., the mean of the signal) and variance 1; this is equivalent to finding the probability (i.e., area under the normal distribution) of finding a value larger than $2 - 1 = 1$ with a normal distribution of mean

Reality	Decision (Participant's Response)		Total
	Yes	No	
Signal present	Hit $Pr \{HIT\} = .1587$	Miss $Pr \{Miss\} = .8413$	1
Signal absent	False Alarm (FA) $Pr \{FA\} = .0228$	Correct Rejection $Pr \{Correct Rejection\} = .9772$	1

$1 - 1 = 0$ and variance 1. This value is equal to .1587.

SDT in Practice

The previous example described the performance of a participant who behaved according to the SDT model. However, in practice we do not know the values of the parameters of SDT, but we want to estimate them from the performance of the participants. In an experimental paradigm, the only observable quantities are the participant’s responses, from which we can derive the number of hits and FAs.

To illustrate this problem, suppose we want to evaluate the performance of a wine taster whose task is to detect whether a wine labeled as made from Pinot Noir has been tempered by the addition of some Gamay (generally considered an inferior grape). Here the signal corresponds to the presence of Gamay. Our wine taster tasted (blindfolded) 20 glasses of Pinot, half of them tempered with some Gamay and half without. The results are reported in Table 3 and show that the proportions of Hits and FAs are .9 and .2, respectively. In order to find the values of d' and the criterion, we need to inverse the formulas given above (i.e., Equations 3–5). We also need one new notation: For a normal distribution with zero mean, we denote by Z_p the value of the normal distribution whose associated probability is equal to P (e.g., $Z_{.025} = 1.96$). We denote Z_H and Z_{FA} the values corresponding to the proportions of Hits and FAs. With these new notations and after some (minor) algebraic manipulations, we find the following set of formulas. The estimation of d' is obtained as

$$d' = Z_H - Z_{FA} = Z_{.9} - Z_{.2} = 1.28 - (-.84) = 2.12. \quad (6)$$

The estimation of C is obtained as

$$C = -\frac{1}{2}[Z_H + Z_{FA}] = -[Z_{.9} + Z_{.2}] = -\frac{1}{2}[1.28 - .84] = -.22, \quad (7)$$

Table 3 The Performance of a Wine Taster Trying to Identify Gamay in a Pinot Noir Wine

Reality	Decision: (Taster's Response)		Σ
	Yes (Gamay)	No (pure Pinot)	
Signal present (Gamay)	Hit # {Hit} = 9 Pr {Hit} = .9	Miss # {Miss} = 1 # {Miss} = .1	10 1
Signal absent (Pure Pinot)	False Alarm (FA) # {FA} = 2 Pr {FA} = .2	Correct Rejection # {Correct Rejection} = 8 Pr {Correct Rejection} = .8	10 1

and $\ln \beta$ is obtained as

$$\ln \beta = d' \times C = 2.12 \times -.22 = -.47 \quad (8)$$

(β is obtained as $\exp\{\ln \beta\} = .63$).

How to interpret these results? The taster is clearly (but not perfectly) discriminating between Pinots and tempered Pinots (as indicated by a d' of 2.12). This taster is also liberal (in case of doubt, the taster would rather say that the wine has been tempered than that it has not).

SIGNIFICANCE LEVEL

An integral part of every quantitative research study is the need to determine an appropriate statistical

significance level, *alpha*, also referred to as p_{critical} . Before data are collected, this level should be selected (a priori) because this level is logical, and the information gleaned from rejecting the null hypothesis is meaningful. In medical studies, it is common to set the significance level to $p < .01$, whereas $p < .05$ is common in the social sciences. For comparison, a $p_{\text{calculated}}$ or *Test Statistic*_{calculated} is used. The decision is the same regardless of whether a $p_{\text{calculated}}$ or *Test Statistic*_{calculated} is used. The $p_{\text{calculated}}$ is now easily obtained from myriad software packages. These probabilities $p_{\text{calculated}}$ and alpha are interesting in and of themselves. First, what do these probabilities mean? What is the interpretation of $p_{\text{calculated}}$ or *Test Statistic*_{calculated}?

The Probabilities: Alpha and $p_{\text{calculated}}$ or *Test Statistic*_{calculated}

Researchers may correctly use statistical significance testing in two general cases: (a) they have a random sample from a population from which an inference is to be drawn, or (b) they believe their sample approximates a random sample. Once this decision is made, the next is to set an alpha level. The setting of the alpha level, a probability ranging between 0 and 1, can be interpreted as the percentage chance of making a sampling error. For instance, an alpha level set at .05 indicates that there is a 5% chance of making an incorrect inference because sampling error creeps into all data without exception, barring collecting data from the entire population. When picking an alpha level, we set a boundary on the probability of making this incorrect inference, called a Type I error. Therefore, alpha is typically set small so that the probability of this error will be low. Thus, this alpha level, also termed p_{critical} , is selected on the basis of judgment regarding Type I error consequences in any given research situation, guided by personal values regarding these consequences.

After the data are collected and analyzed, part of the output is the second probability, often termed $p_{\text{calculated}}$. From this point forward, I treat $p_{\text{calculated}}$ and *Test Statistic*_{calculated} as being the same because the probabilistic interpretations are similar, and the interpretations are exactly the same. This probability, like

the alpha level probability, ranges between 0 and 1 and is calculated based on study parameters. There are two absolutely essential aspects impacting the calculation of the probability $p_{\text{calculated}}$. First is the assumption that the true population parameters are correctly described in the null hypothesis. This assumption is necessary because the actual population parameters are not known. Therefore, we assume that the null hypothesis is true for all calculations. Second, as the sample size approaches the population size, sampling error decreases, and the statistics calculated from them become more representative. It is intuitive that larger samples are more representative. When we think about this in the opposite direction, small samples are more likely to be comprised of less representative data points, and the statistics calculated for them potentially will be less representative of the population. To illustrate this point, if one were to catch two fish from a pond and both were catfish, one might draw the conclusion that the pond contains only catfish. However, with a little more effort and a larger sample, say 100 fish caught, one might learn that the pond ecosystem also consists of bass, perch, gar, and pickerel. So sample size is accounted for in the $p_{\text{calculated}}$ computations. For example, Experiment 1 consists of two groups with 10 members each. The mean for Group 1 is 55 and the mean for Group 2 is 56. The $p_{\text{calculated}}$ will be large and probably exceed the a priori alpha level of $p < .05$. However, Experiment 2 also consists of two groups (Groups 3 and 4), but this time each group contains 110 members. The mean for Group 3 is exactly the same as Group 1, 55, and the mean for Group 4 is exactly the same as for Group 2, 56 (see Table 1). This time $p_{\text{calculated}}$ is probably small and likely to be less than the a priori alpha level $p < .05$. Assuming the sample data were randomly selected from the population where the null hypothesis is true, what is the probability of obtaining the sample statistics from the given sample size(s)? The question in both experiments is, "Are the two means statistically significantly different with alpha = .05?" In Experiment 1, the $p_{\text{calculated}} = .571$, so the means are not statistically different, but in Experiment 2, the $p_{\text{calculated}} = .043$, so the means are statistically significantly different even though the difference in the

means in both experiments is only 1 point (see Table 2). However, the Cohen's *d* effect size does not change from Experiment 1 to Experiment 2. When $p_{\text{calculated}}$ is less than p_{critical} or alpha, we use a decision rule that says we will reject the null hypothesis. The decision to reject the null hypothesis is called a *statistically significant result*. All the decision means is that we believe our sample results are relatively unlikely, given our assumptions, including our assumption that the null hypothesis is exactly true.

Implications

Quantitative results are often misinterpreted because few applied researchers understand the purpose of statistical significance testing. The partial understandings of aspects of statistical significance testing can result in systemic issues that can negatively impact the quality of their research reports. For example, researchers may understand the issue of sample size but worry only about samples that are too small while not considering the implications of extremely large samples or the implications for interpretations based on test statistics of these large samples. It is essential to augment null hypothesis testing with measures of treatment effects.

Statistical Level, Statistical Significance Tests, and Meta-Analytic Thinking

Statistical significance reporting is still an essential component of the newest edition of the *Publication Manual of the American Psychological Association* and a legislative reality and will continue to be reported. However, it is important to understand that given a large enough sample, one would always achieve statistical significance. More than a decade ago, E. N. Pedhazur and L. Schmelkin stated that few methodological issues have generated as much controversy as statistical testing. The $p_{\text{calculated}}$ values in a given study result from specific study characteristics such as sample size and effect size. The result is different studies, composed of varying sample sizes and effect sizes, all possibly having the same $p_{\text{calculated}}$ value. Second, $p_{\text{calculated}}$ does not infer from the sample to the population but from the population to the sample. One possible explanation for the prevalence of these misconceptions is that textbooks and graduate courses have been less than ideal in their treatment of statistical significance testing and its alternatives.

SIMPLE MAIN EFFECT

Table 1 presents hypothetical data from a factorial design. Observations in each cell are averaged to produce a cell mean. Averaging over all levels of one factor produces means for the overall main effect of the other factor. For example, the six values observed with Drug 1 have a mean of 8.0 averaged over both dosage levels. Similarly, the six values from Drug 2 have a mean of 3.0. The difference between 8.0 and 3.0 is the overall main effect of the drug factor.

The two drugs could be compared separately for each dosage level. The difference between Drug 1 and Drug 2 in the 10 mg condition is 3.0 ($= 7.0 - 4.0$). This difference is an example of a simple main effect. That is, we can define a *simple main effect* as a difference in the value of a dependent variable found between two levels of one factor when another factor is held constant. The difference between the two drugs in the 20 mg condition is 7.0 ($= 9.0 - 2.0$).

Simple main effects can also be defined for the other factor. The difference between the two dosage levels for Drug 1 is 2.0 ($= 9.0 - 7.0$). Similarly, the difference between the two dosage levels for Drug 2 is 2.0 ($= 4.0 - 2.0$).

Simple main effects are often tested after finding a significant interaction in a factorial design. However, this practice can be misleading. For example,

Berrin-Wasserman, Winnick, and Borod reported a 2×2 design with a significant interaction and no significant simple main effects. A more complex problem is illustrated by Friedman, Putnam, Ritter, Hamberger, and Berman, who reported a 3×4 factorial design with a significant interaction in which testing simple main effects led to an incorrect interpretation of the reason for the significant interaction.

SIMPSON'S PARADOX

Simpson's paradox arises in the analysis of cross-classified categorical data when contradictory conclusions about the directions of associations

between variables are reached as a result of several groups' being aggregated into one. A well-known example of this phenomenon is the graduate school admissions data from the University of California, Berkeley. During a particular time, 8,442 men applied for graduate school, as did 4,321 women. Each department made its own admissions decisions. In the end, approximately 44% of the male applicants and 35% of the female applicants were admitted. This looks like evidence of sex bias in admissions, and the university administration wished to determine which departments exhibited the most serious bias. Here we explore only a subset of the data, namely the six largest departments. The data, as reported by Freedman and colleagues, are in Table 1.

Looking at each department individually, it is apparent that there is no systematic bias against women; on the contrary, in all six departments, the percentage of women accepted is higher than, or almost equal to, the percentage of men accepted. Indeed, for department A, 82% of female applicants were admitted, compared to only 62% of male applicants. The department that is least favorable to women, department E, shows a discrepancy of only 4%. Yet over all six departments together, 45% of the male applicants were admitted, and only 30% of the female applicants.

Closer examination of the data reveals the source of this seemingly paradoxical situation. Departments A and B were relatively liberal in their admissions policies, accepting two thirds or more of the applicants.

Table 1 UC Berkeley Graduate School Admissions Data

Major	Men		Women	
	Number of Applicants	% Admitted	Number of Applicants	% Admitted
A	825	62	108	82
B	560	63	25	68
C	325	37	593	34
D	417	33	375	35
E	191	28	393	24
F	373	6	341	7

Source: Freedman, Pisani, Purves, & Adhikari (1991).

And most men applied to those two departments. On the other hand, departments C through F were much harder to get into, accepting about a third or less of prospective graduate students. And women applied mostly to those highly competitive departments. The overall effect is that a smaller percentage of women than men were accepted into the graduate programs at Berkeley because they were aiming for more restrictive courses of study. By aggregating over departments, university officials lost vital information.

This is the source of Simpson's paradox, namely, aggregating, or collapsing, over levels in cross-tabulated data when it is inappropriate to do so because of interactions among variables. The presence of interactions means that important and relevant information is lost when the table is collapsed. In the simple example of the graduate admissions data, the problem was easy to spot because the data were subjected to only a two-way classification. As the number of cross-classifications rises, inducing more complex and more numerous types of interactions, detection might not be so immediate. Care should be taken, therefore, when aggregating over levels of classification.

The phenomenon is called paradoxical because it allows researchers to make statements such as "The new treatment is more effective than the old treatment for men. It also works better than the old treatment for women. However, overall, the new treatment is not more effective than the old treatment." While apparently paradoxical, the result is a simple consequence of relationships between positive integers, as we will see in Table 2, a 2 x 2 table that looks at the proportions of males and females who improved with the old treatment versus the new.

Table 2 Mathematical Explanation of Simpson's Paradox

	Improved With Old Treatment	Improved With New Treatment
Men	a/b	c/d
Women	e/f	g/h
Total	(a+e)/(b+f)	(c+g)/(d+h)

In this setting, Simpson's paradox states that it is possible to find numbers such that $alb < cld$ and $elf < glh$ but $(a + e)/(b + f) > (c + g)/(d + h)$. Such values are not hard to find. For example, suppose the old treatment was tried on 200 men, of whom 30 improved, for a success rate of 15%, and on 400 women, of whom 300 improved, a success rate of 75%. On the other hand, the new treatment was tried on 200 men, of whom 40 improved, a success rate of 20%, and on 100 women, of whom 85 improved, a success rate of 85%. For both men and women, the new treatment was more efficacious than the old in terms of proportion who improved. But the old treatment was tried on a total of $200 + 400 = 600$ people, of whom $30 + 300 = 330$ improved, an overall improvement rate of 55%, whereas the new treatment was tried on only $200 + 100 = 300$ people, of whom $40 + 85 = 125$ improved, an overall rate of about 42%. Mathematically, these numbers fit the constraints described above, and similarly any other eight numbers that fit the constraints would result in a Simpson's paradox. Note that it is not the simple ratio that is relevant—substituting 4 for 40 and 20 for 200 for the men who received the new treatment would not meet the constraint, and hence there would be no paradoxical result.

More generally, the values that fit the constraints fall within two extreme conditions. On one end, we have situations in which slightly more units of one type are in a category with much lower probability; for example, see Table 3. Here, men are *much* less likely to improve in response to either treatment than are women, and the new treatment is given to slightly more men. As a result, a higher proportion of both men and women improve with the new treatment, but overall the old treatment is slightly more effective.

Table 3 One Scenario in Which Simpson's Paradox Holds

	<i>Improved With Old Treatment</i>	<i>Improved With New Treatment</i>
Men	1/45	5/55
Women	50/55	45/45
Total	51/100	50/100

At the other extreme are situations in which many more units of one type are in a category with slightly lower probability; for example, see Table 4. Here, both men and women have good rates of improvement, although the rate for the new treatment is slightly better. Men, with the lower probability of improvement, are overwhelmingly given the new treatment, whereas women, with a slightly better chance of improvement, are overwhelmingly given the old treatment. As a result, a higher proportion of both men and women improve with the new treatment, but overall the old treatment is slightly more effective.

Table 4 Another Scenario in Which Simpson's Paradox Holds

	<i>Improved With Old Treatment</i>	<i>Improved With New Treatment</i>
Men	4/5	90/95
Women	94/95	5/5
Total	98/100	95/100

In short, Simpson's paradox is the result of ignoring lurking, or background, variables that contain relevant information. The consequence of ignoring them is that contradictory conclusions may be reached regarding the direction of an association between variables. On an interesting historical note, a case may be made, according to S. E. Fienberg, that the paradox should in fact be named after Yule (and is indeed sometimes called the Yule-Simpson paradox), who apparently discussed it as early as 1903.

SIMPSON'S RULE

In order to estimate the integral of a function of one real variable, f , over a finite interval $[a, b]$, let $h = (b - a)/n$ for a positive even integer $n = 2m$. Then the (composite) Simpson's rule formula is

$$\int_a^b f(x)dx \approx (h/3) (f(a) + 4f(a + h) + 2f(a + 2h) + 4f(a + 3h) + 2f(a + 4h) + \dots + 2f(b - 2h) + 4f(b - h) + f(b)) \quad (1)$$

with error, assuming f'''' exists on (a, b) , given by

$$- (b - a)h^4 f''''(c)/180 \quad (2)$$

for some c in (a, b) . The key features of the error term are the dependence on h^4 and the $f''''(c)$ term. These imply that doubling the number of subintervals (so that h is halved) yields approximately 1/16 the previous error (if the overall interval $[a, b]$ is sufficiently small so that c does not vary too greatly), and the integral will be exact for polynomials of degree 3 or less, since f'''' vanishes identically for such functions.

(Note that a method known as *Richardson extrapolation* can be used to improve Simpson's rule integral estimates even further if two different h values are used.)

As an example, the probability that a standard normal random variable has value between $z = .5$ and $z = 1$ is given by the integral of $f(z) = \exp(-z^2/2)/\sqrt{2\pi}$ from $z = .5$ to $z = 1$. Choosing $n = 10$, Simpson's rule estimates it to be $(.05/3)(f(.5) + 4f(.55) + 2f(.6) + 4f(.65) + \dots + 4f(.95) + f(1))$ or $0.14988228478\dots$ Now $f''''(z)$ is $(z^4 - 6z^2 + 3)f(z)$,

and with c between .5 and 1, the error term is bounded from above by $.6(.56)(.05^4)/180$, that is, by 10^{-8} . (The exact error is, in fact, 1.3×10^{-11} .)

The logic underlying Simpson's rule considers f on $m = n/2$ equally spaced contiguous nonoverlapping subintervals, and on each subinterval of width $2h$, it estimates the integral by using a quadratic interpolation. From the partition $\{a = x_0, x_1, \dots, b = x_{2m}\}$, where $x_{i+1} - x_i = h$, the integral of f on $[x_{2j}, x_{2j+2}]$ for $j = 0$ to $m - 1$ is approximated by the integral of the quadratic function q_j satisfying $q_j(x_{2j}) = f(x_{2j})$, $q_j(x_{2j+1}) = f(x_{2j+1})$, and $q_j(x_{2j+2}) = f(x_{2j+2})$. By elementary calculus, the integral of q_j on $[x_{2j}, x_{2j+2}]$ is exactly $(f(x_{2j}) + 4f(x_{2j+1}) + f(x_{2j+2}))(h/3)$; it is more difficult to deduce that the error incurred on the subinterval is $-f''''(c)h^5/90$ for some c in (x_{2j}, x_{2j+2}) . Summing up estimates from all the subintervals yields Equation 1; collecting the errors and using the intermediate value property for derivatives gives the error term (Equation 2).

In its modern formulation, Simpson's rule is one of an infinite family of what are known as (closed-form) *Newton-Cotes integration methods*. (The trapezoid rule is another, less accurate, closed-form Newton-Cotes method; the midpoint rule is an open-form Newton-Cotes method.) Each estimates integrals by computing the exact integral of an appropriate (piecewise) interpolating polynomial. Using any degree of interpolant, one can quickly deduce any Newton-Cotes weights, such as the $h/3, 4h/3, h/3$ for Simpson's rule, and so deduce ever more accurate integration schemes, as follows. Requiring that the integration method be exact for polynomials of degree d or lower and that the function be evaluated at equally spaced intervals leads quickly to linear conditions for the weights. For instance, in order to achieve exact integration results for polynomial integrands of degree through $d = 2$, consider the monomials $f(x) = 1, x$ and x^2 on the interval $[0, 2h]$: Equating the integral with $w_0f(0) + w_1f(h) + w_2f(2h)$ for these functions yields the system $2h = w_0 + w_1 + w_2, 2h^2 = h w_1 + 2h w_2, 8h^3/3 = h^2 w_1 + 4h^2 w_2$, whose solution is $w_0 = h/3 = w_2, w_1 = 4h/3$. To determine the error term, assuming it has the form $K f''''(c) (b - a)h^k$ for some K, n , and k , apply the estimation to, for instance, $f(x) = x^4$ on $[0, 2h]$; since $f''''(c) = 24$ for any c , and the error

incurred is $-4h^5/15$, the error term must be $-h^4(b-a)f''''(c)/180$. Similarly, considering the related example of exact results for monomial integrands $f(x) = 1, x, x^2$ and x^3 on $[0, 3h]$, one obtains the weights $w_0 = 3h/8, w_1 = 9h/8, w_2 = 9h/8, w_3 = 3h/8$ (known as Simpson's "3/8" rule). Using $f(x) = x^4$, the overall error term is found to be $-h^4(b-a)f''''(c)/80$. (Note that the 3/8 rule, while based on a higher-degree interpolant than Simpson's rule, has a larger coefficient in its error term and ordinarily is not preferred to Simpson's rule. Its advantage is that it allows use of three subintervals. Thus, if data are supplied for an odd number of subintervals, the 3/8 rule can be used for the first three subintervals, and Simpson's rule can be applied to the others.)

Simpson's rule arguably appeared by 1890 B.C. in what is known as the Russian papyrus and was used for measuring volumes of prisms. It was known by Johannes Kepler (1571–1630) as an aid in estimating volumes of barrels. James Gregory (1638–1675) published an algebraic formulation in 1668. As a method developed by Isaac Newton, it appeared in Thomas Simpson's calculus text *A New Treatise on Fluxions* in 1737. Variants of Simpson's rule that have most weights equal to 1 have been found, and Simpson's rule can be used to sum series as well as to estimate integrals.

SIMULATED ANNEALING

Simulated annealing (SA) is an optimization technique that mimics the physical process of thermal cooling. In physics, annealing is the process in which one first heats up a solid to a high enough temperature to liquefy it and then cools the liquid slowly enough

so that the particles arrange themselves in a lattice arrangement having the lowest energy.

Statistical physics describes this cooling process in probabilistic terms by describing the probability that a particle will be in a state with a given energy E and for a fixed temperature T . This probability is given as

$$Pr(\text{Energy} = E) = \frac{1}{Z(T)} \exp\left(-\frac{E}{k_B T}\right),$$

where k_B is the *Boltzmann constant* and $Z(T)$ is a normalizing constant, known as the *partition function*. This distribution is known as the *Boltzmann distribution*.

Looking at this probability, it is clear that as T tends to zero, the distribution concentrates in the minimal energy states. In the limit as $T \rightarrow 0$, we see that the only possible states are the minimal energy states.

The first computer algorithm for simulating the process of thermal cooling was developed by Metropolis and colleagues in 1953. However, not until 1982 was the link between abstract combinatorial optimization and the minimization of energy in thermal cooling explicitly made and exploited.

The idea is to exploit the temperature dependence of the Boltzmann distribution to try to force the current state of our simulation (optimization algorithm) toward one of the globally optimal (minimal energy) states. The key lies in carefully lowering the temperature.

The Metropolis Algorithm

In 1953, N. Metropolis, A. Rosenbluth, M. Rosenbluth, A. Teller, and E. Teller published the paper "Equations of State Calculations by Fast Computing Machines," thereby introducing to the world the highly useful Metropolis simulation algorithm. This algorithm has been cited as among the top 10 algorithms having the greatest influence on the development of science and engineering.

This algorithm will yield the Boltzmann distribution for a given system via simulation.

The basic idea, like many great ideas, is rather simple. Given the energy function E on the state space

Ω , we split the chain into a *proposal* phase and an *acceptance* phase. For the proposal phase, the current state x of the system is subjected to a small perturbation, which generates y , a proposed new state. This proposal process needs to be symmetric (that is, it is just as likely to propose x starting from y as it is to propose y starting from x) and irreducible (it is possible to transition from any state to any other state using only the proposal process). Let $E(x)$ and $E(y)$ denote the energies associated with states x and y . If $E(y) < E(x)$, then we accept the proposed change, and y becomes the new current state. If $E(y) \geq E(x)$, we accept y with probability

$$\exp\left(-\frac{E(x) - E(y)}{k_B T}\right),$$

else we reject the new state y and stay with the original state x .

The Markov chain X_n generated by the Metropolis algorithm will produce many repeated states. In computing using this chain, it is essential to keep these repeated states because this is one way the algorithm corrects the bias from the proposal process, thus allowing it to converge to the Boltzmann distribution.

The separation of the proposal and acceptance phases makes designing a chain much simpler because the proposal process can be virtually any process. The choice of proposal process is often guided by the structure of the state space. The conditions on the proposal process are rarely a problem in practice. For Ω finite, the proposal process is often defined by first giving a local (symmetric) neighborhood structure and then choosing y uniformly from the neighbors of the current x . As long as the neighborhood structure is reasonable, this process will usually work.

We are free to let the structure of the problem guide the neighborhood system (or proposal process) and use the acceptance phase to correct the proposal process in such a way as to ensure the Boltzmann distribution. Heuristically, the neighborhood system defines a type of “topology” on the state space Ω , and along with the energy function, this gives a type of “energy landscape.”

The convergence rate of the Metropolis algorithm is strongly influenced by the proposal process. Thus, any problem-specific information is very useful in designing an efficient Metropolis scheme.

Notice that the Metropolis algorithm does not use the partition function $Z(T)$. This is very important as it is usually impossible to compute this normalizing constant because the state space is usually prohibitively large. The Metropolis algorithm uses only energy differences, so really it uses information about only relative probabilities (under the Boltzmann distribution) and not absolute probabilities.

SA as Time-Varying Metropolis

For a fixed temperature $T > 0$, the Metropolis algorithm gives us a way to simulate a distribution in which better (lower-energy) states are more likely to occur than worse (higher-energy) states. As mentioned above, clearly lowering the temperature will concentrate the Boltzmann distribution more in the low energy states, so the idea behind SA is to lower the temperature in a careful way.

The simplest way to lower the energy would be to have a sequence of temperatures $T_1 > T_2 > T_3 > \dots$ that approaches zero. Start with some state X_0 and run the Metropolis algorithm at temperature T_1 until it has converged to the Boltzmann distribution for temperature T_0 , say some number N_1 of iterations, so that we are in state X_{N_1} . Then using X_{N_1} as the initial state, run the Metropolis algorithm at temperature T_2 for N_2 iterations until it converges. Continuing, we piece together runs of the Metropolis algorithm at each different (but fixed) temperature T_i to get a sequence of states that should converge to a globally minimal state.

Simulated annealing does something like this, but with a temperature that decreases every iteration according to some *cooling schedule*. Thus, an SA process never really reaches an equilibrium distribution because the equilibrium Boltzmann distribution is changing as a function of the current temperature. The idea is that if you decrease the temperature slowly enough, then you track the current Boltzmann distribution closely enough that the overall process will converge.

In general, the *relaxation time* increases as the temperature decreases. As we lower the temperature, the algorithm requires a larger number of iterations to approach the equilibrium distribution. Thus, the convergence of the algorithm slows down considerably for lower temperatures.

If the temperature is lowered too quickly, the system can be “frozen” into a metastable state. In terms of the objective function, this means that we are trapped into a local but not global minimum value of the function. As the algorithm progresses, the current point moves around the state space by taking small steps (the perturbations). If the proposed step is “downhill,” then the step is always taken. If the proposed step is “uphill,” then we sometimes take it. Initially, at high temperatures, many uphill steps are taken. This allows the system to escape from the energy well of a local minimum. As the temperature decreases, the probability of taking an uphill step decreases, so it is more difficult to escape from the basin of a local minimum. If the temperature is decreased too fast, it is possible to get stuck in a local minimum basin, and then the state will converge to the local minimum.

Convergence Results

One of the very nice things about SA is that there are theoretical results that guarantee convergence to a minimal energy state, albeit in the infinite time limit. The 1988 result of Hajek is one such result. Letting T_n denote the temperature at iteration n , a *logarithmic cooling* schedule is of the form

$$T_n = \frac{c}{\log n + 1}.$$

If $c > 0$ is large enough, then Hajek’s result says that using the logarithmic cooling schedule results in $Pr(X_n \text{ is an optimal state}) \rightarrow 0$ as $n \rightarrow \infty$. How large is large enough? Well, if we think of the objective function as defining an energy landscape, then c should be at least as large as the largest “energy barrier” on the surface, that is, the depth of the largest nonoptimal local optimal “valley.”

There are other results that guarantee convergence or give estimates on the convergence rate. However, in

the general situation, all the convergence results essentially require a logarithmic cooling schedule.

This logarithmic cooling schedule can be understood as saying that, in general, the relaxation times grow geometrically as the temperature decreases. Thus, you need something like twice as long at a lower temperature in order to approach the equilibrium.

Example

It is easy to set up an example in which the expected time to convergence is infinite. The following example was given by Shonkwiler and Van Vleck. Let $\Omega = \{0,1,2\}$ with function values $f(0) = -1, f(1) = 1$, and $f(2) = 0$ and proposal matrix

$$\begin{pmatrix} 1/2 & 1/2 & 0 \\ 1/2 & 0 & 1/2 \\ 0 & 1/2 & 1/2 \end{pmatrix}.$$

The Metropolis transition matrix then is

$$P(T) = \begin{pmatrix} 1 - \frac{1}{2}e^{-2/T} & \frac{1}{2}e^{-2/T} & 0 \\ 1/2 & 0 & 1/2 \\ 0 & \frac{1}{2}e^{-1/T} & 1 - \frac{1}{2}e^{-1/T} \end{pmatrix}.$$

Using the logarithmic cooling schedule $T_n = 1/\log(n+1)$, we see that this translates to

$$P(n) = \begin{pmatrix} 1 - \frac{1}{2(n+1)^2} & \frac{1}{2(n+1)^2} & 0 \\ 1/2 & 0 & 1/2 \\ 0 & \frac{1}{2(n+1)} & 1 - \frac{1}{2(n+1)} \end{pmatrix}.$$

Letting h_k be the probability that the first time we are in State 0 is at time k , it can be shown that $h_k \geq \frac{1}{4k(k-1)}$ for $k \geq 2$, and thus the expected hitting time starting from State 2 is at least as large as

$$\sum_{k=2}^{\infty} kh_k \geq \frac{1}{4} \sum_{k=2}^{\infty} \frac{1}{k-1} = \infty,$$

so the expected hitting time for SA is infinite.

Cooling Schedules

While the logarithmic cooling schedule is sufficiently slow to guarantee convergence of SA, it is clearly extremely slow. In fact, using a logarithmic cooling schedule is in effect often the same as performing an exhaustive search (even worse than exhaustive search, in the above simple three-state example). Furthermore, in practice one obviously cannot run an algorithm until the infinite time limit. Thus many other cooling schedules are used. A particularly simple one is geometric cooling, of the form $T_n = T_0\alpha^n$, where $0 < \alpha < 1$.

It might also be desirable to have the temperature decrease adaptively. To do this, one can accumulate statistics about the process (distribution of energy values encountered, number of proposed steps accepted/rejected, etc.) and use this information to derive a model of the energy surface for the problem.

A particularly nice approach to this is one derived from finite-time statistical mechanics. Since the logarithmic cooling schedule and infinite time runs are not practical, we use finite-time and nonequilibrium statistical mechanics to derive “optimal” cooling schedules, such as the *constant thermodynamic speed* cooling schedule. However, these cooling schedules require a fair bit of information about the energy surface. Depending on the optimization problem, it may be better to run many instances of a simpler cooling schedule (or longer runs) than one run of an adaptive cooling schedule.

Application of SA to the Traveling Salesman Problem

The traveling salesman problem (TSP) is a classical combinatorial optimization problem that is NP-hard. The data for the TSP are the geographical locations of N cities and a notion of the “cost” of traveling between any two of these cities. This cost is typically associated with the distance between the cities but does not have to be. Given these N cities, we are to find the tour (list of which cities to visit in order) that minimizes the total cost. For simplicity, we assume that we start and end at the first city (clearly any city on a tour can be thought of as the “first” city on the tour). The N -city TSP has $(N-1)!/2$

distinct tours, so the state space is incredibly huge, even for moderate N .

The first step in designing an SA algorithm for this problem is to decide on the proposal process. This is a crucial step because the convergence rate of the Metropolis algorithm depends very heavily on the design of the proposal process. For our example, we use the 2-opt proposal process for the TSP. To explain this, given the tour

$$c_1c_2c_3 \dots c_{a-1} \underbrace{c_a c_{a+1} \dots c_{b-1} c_b}_{\text{segment}} c_{b+1} \dots c_N$$

we choose two positions, $a, b \in \{1, 2, \dots, N\}$, and “flip” the part of the tour between these positions to get the proposed tour

$$c_1c_2c_3 \dots c_{a-1} \overbrace{c_b c_{b-1} \dots c_{a+1} c_a}^{\text{flipped segment}} c_{b+1} \dots c_N.$$

As a more concrete example, the tour 136425 could be perturbed into the tour 132465 by choosing locations 3 and 5.

This 2-opt proposal process has the feature of breaking two “links” of the tour and replacing them with two other (new) links.

Clearly, the energy for the TSP will be the total cost. Since we are trying to minimize the total cost, this will work as an energy (SA naturally minimizes; a maximization problem needs to be converted to a minimization problem).

Figure 1 shows two typical runs of SA on the TSP. In both figures, the horizontal axis represents iterations and the vertical axis represents energy. The bottom curve is the best energy seen so far, and the top one is the energy of the current state. These figures illustrate that when the temperature is high, the energy of the current state is quite variable, but as the temperature decreases, the energy of the current state tends to settle down and “freeze.” All the runs used a fixed set of 100 cities distributed somewhat randomly in the plane.

Figure 2 shows the results of 10 runs of SA on the TSP. These plots show only the trace of the best so far.

Premature Convergence

An individual run of SA will typically have a short period of rapid decrease followed by long, flat periods

Figure 1 Two Sample Paths From SA on the TSP

in which the best energy stays constant. These flat periods can eat up a majority of the computational effort, especially for very long runs.

There are several different strategies for dealing with this problem. One simple problem is to randomly restart the SA process whenever such a situation occurs. One method that works well is to restart whenever the current state has not changed in some set number of iterations, the idea being that this indicates that a large majority of the “neighbors” of the current state are worse than the current state. Another method, which is also effective, is to run several versions of the algorithm in parallel and do some sort of information sharing.

Figure 2 Ten Runs of SA on the TSP (Best So Far)

SA is a natural candidate for parallelization. In fact, it allows the simplest type of parallelization—multiple independent runs of the identical algorithm, but from randomly chosen starting conditions. Many other types of parallelization involving some amount of information sharing are also possible and effective.

SIMULATION EXPERIMENTS

Simulation experiments are used to mimic a system of interest and are typically, although not necessarily, performed on a computer. A simulation experiment differs from a “simulator” (e.g., a flight simulator), in which an operator is immersed in a virtual environment. In a simulation experiment, the modeler gleans the appropriate information about the system of interest (which may include data gathering), then develops equations and algorithms to simulate the system. These equations and algorithms are then converted to a computational model, which is typically implemented on a digital computer for analysis.

This brief entry provides a description of the mathematical and  computational techniques for modeling, simulating, and analyzing the performance of stochastic systems. By definition, the nature of simulation is that one does not actually experiment with or modify an actual system. Instead, one develops and then works with a mathematical model of the actual system. This model allows the modeler to respond to “what if” questions associated with the model, and these questions, if the model has been developed properly, translate to the associated questions concerning the system.

Model Characterization

A simulation model is typically both stochastic and dynamic, as described in the paragraphs that follow.

A system model is either deterministic or stochastic. A deterministic system model has no stochastic (random) components. For example, provided the conveyor belt and machine never fail, a model of a constant velocity conveyor belt feeding parts to a machine with a constant service time is deterministic.

At some level of detail, however, all systems have some stochastic components: Machines fail, people respond in a random fashion, and so on. One attractive feature of simulation modeling is that stochastic components can be accommodated, usually without a dramatic increase in the complexity of the system model at the computational level.

A system model is static or dynamic. A static system model is one in which time is not a significant variable. Many static models can be analyzed by Monte Carlo simulation, which performs a random experiment repeatedly to estimate, for example, a probability associated with a random event. The passage of time always plays a significant role in dynamic models.

A dynamic system model is continuous or discrete. Most of the traditional dynamic systems studied in classical mechanics have state variables that evolve continuously. A particle moving in a  gravitational field, an oscillating pendulum, and a block sliding down an inclined plane are examples. In each of these cases, the motion is characterized by one or more differential equations that model the continuous time evolution of the system. In contrast, models involving queuing, machine repair, inventory systems, and so forth, are discrete because the state of the system is a piecewise-constant function of time. For example, the number of jobs in a queuing system is a natural state variable that changes value only at those discrete times when a job arrives (to be served) or departs (after being served).

A discrete-event simulation model is defined by three attributes: (a) The model is stochastic—at least some of the system state variables are random; (b) the model is dynamic—the time evolution of the system state variables is significant; and (c) the model has discrete event times—significant changes in the system state variables are associated with events that occur at discrete time instances only.

We focus the balance of this entry on discrete-event simulation because of its utility and popularity as a tool used by practitioners and researchers from several application areas (e.g., operations research, computer science, biomathematics, and statistics).

Simulation Model Development

We present a series of steps that describe, at a high level, how to develop a discrete-event simulation model and then conduct a discrete-event simulation study.

A typical discrete-event simulation model will be developed consistent with the following six steps. Steps 2 through 6 are typically iterated, perhaps many times, until a valid computational model (a computer program) has been developed.

1. Set goals. Once a target system of interest has been identified, determine the goals and objectives of the analysis. These goals and  objectives are often phrased as simple Boolean decisions (e.g., should an additional server be added to a queuing network service node?) or numeric decisions (e.g., how many parallel servers are necessary to provide satisfactory performance in a multiple-server queuing system?). Without specific goals and objectives, the remaining steps lack meaning.

2. Build a conceptual model of the system based on Step 1. What are the state variables, how are they interrelated, and to what extent are they dynamic? How comprehensive should the model be? Which state variables are important? Which have such a negligible effect that they can be ignored? In effect, establish a boundary for what is included in the mathematical model of the system and what is considered part of the external environment.

3. Convert the conceptual model into a specification model. This step typically involves collecting and statistically analyzing data to provide the stochastic “input models” that drive the simulation. In the absence of such data, the input models must be constructed in an ad hoc manner using stochastic models believed to be representative.

4. Turn the specification model into a computational model (a computer program). At this point, a fundamental choice must be made—to use a general-purpose programming language or a special-purpose simulation language.

5. Verify the model. As with all computer programs, the computational model should be consistent with the specification model.

6. Validate the model. Is the computational model consistent with the system being analyzed? Because the purpose of simulation is insight, some would argue that the act of developing the discrete-event simulation model—Steps 2, 3, and 4—is frequently as important as the tangible product. One popular non-statistical technique for model validation is to place actual system output alongside similarly formatted output from the computational model. This output is then examined by an expert familiar with the system. Model validation is indicated if the expert is not able to determine which is the model output and which is the real thing. Interactive computer graphics (animation) can be very valuable during the verification and validation steps.

The actual development of a complex discrete-event simulation model may not be as sequential as the previous steps suggest, particularly if the development is a team activity (in which case some steps will probably be worked on in parallel). The different characteristics of each step should always be kept clearly in mind, avoiding, for example, the natural temptation to merge Steps 5 and 6.

After the successful creation of a computational model (computer program) by means of Steps 1–6, the analysis of that computational model involves the following steps:

7. Design the simulation experiments. If there are a significant number of system parameters, each with several possible values of interest, then the combinatoric possibilities to be studied need to be managed.

8. Make production runs. The simulation runs should be made systematically, recording the value of all initial conditions and input parameters, along with the associated statistical output. Point and confidence-interval estimators of measures of performance of interest are typical discrete-event simulation outputs.

9. Analyze the simulation results. The analysis of the simulation output is statistical in nature because discrete-event simulation models have stochastic (random) components. Common statistical analysis tools (means, standard deviations, percentiles, histograms, confidence intervals, correlations, etc.) are used to draw statistical inferences concerning the model.

10. Make decisions. It is to be hoped that the results of Step 9 will lead to decisions that result in actions. If so, the extent to which the computational model correctly predicted the outcome of these actions is always of great interest, particularly if the model is to be further refined in the future.

11. Document the results. This documentation should include assumptions made concerning the model, details associated with translating the model into computer code, and a summary of insights gained concerning the system. If decisions are made and associated action taken, then the results of that action on the system should be documented.

An important benefit of developing and using a discrete-event simulation model is that valuable insight concerning the system is acquired. As conceptual models are formulated, computational models developed, and simulation output data analyzed, subtle system features and component interactions are often discovered that would not have been noticed otherwise. The systematic application of the 11 steps outlined above can result in better actions taken as a result of insight gained by an increased understanding of how the system operates.

Simulation Programming Languages

There is a continuing debate in the discrete-event simulation community over whether to use a general-purpose programming language or a (special-purpose) simulation programming language. For example, two standard discrete-event simulation textbooks provide the following conflicting advice. Bratley, Fox, and Schrage state, "For any important large-scale real application we would write the programs in a standard general-purpose

language, and avoid all the simulation languages we know." In contrast, Law and Kelton state, "We believe, in general, that a modeler would be prudent to give serious consideration to the use of a simulation package." General-purpose languages are more flexible and familiar; simulation languages allow modelers to build computational models quickly.

Simulation languages have built-in features that provide many of the tools needed to write a discrete-event simulation program. Because of this, simulation languages support rapid prototyping and have the potential of decreasing programming time significantly. Moreover, animation is a particularly important feature now built into most of these simulation languages. This is important because animation can increase the acceptance of discrete-event simulation as a legitimate problem-solving technique. By the use of animation, dynamic graphical images can be created that enhance verification, validation, and the development of insight. (The features and costs of these languages are surveyed by Swain.)

SINGLE-SUBJECT DESIGNS

Single-subject designs involve the intensive study of individual subjects under various conditions, in various environments, or some combination thereof. The subject of interest is often a single organism,

such as a client in a clinical setting, but could also be a group of individuals acting as a single unit, such as a department within an organization or a school within a district. This focus on the individual is reflected in the alternative labels for single-subject designs, including *single-case designs*, *N of 1 designs*, and *within-subject designs*. Although single-subject designs focus on the individual, studies using these designs typically include several participants.

Single-subject designs can be used in correlational or experimental studies, but we will focus on experimental designs. These designs share some basic features with group (or *between-subject*) experimental designs: An independent variable (IV) is manipulated, a dependent variable (DV) is measured, and nuisance variables (NVs) are controlled. Unlike participants in group designs, participants in single-subject designs receive *all levels* of the IV, while the DV is measured repeatedly under those levels. The values of the DV under each level of the IV (e.g., a control condition and one or more treatment conditions, or *interventions*) are compared, and causal inferences regarding the effects of the intervention(s) are then made. In these designs, each participant serves as its own control.

Single-subject designs provide useful and flexible methodological options when (a) one cannot obtain appropriate numbers of participants for group designs (e.g., the population of interest is relatively small, such as persons with a rare medical condition), (b) one seeks to assess treatment effectiveness in particular individuals (e.g., the progress of specific clients is of interest), or (c) one cannot ethically use group designs (e.g., withholding treatment from individuals in a control group is not an option). Practical reasons may also necessitate the use of single-subject designs.

The specific details of single-subject designs vary, but most such designs share two common features. First, the DV is measured repeatedly across time; how often it is measured depends on many factors, including available resources and the nature of the study. Repeated measurement permits the researcher to track changes in the DV and, if

necessary, to modify treatment conditions if the DV does not change in the desired direction. Second, the level of the DV in the absence of treatment is established during a *baseline* (or *A*) *phase*, which typically occurs at the beginning of the study, before treatment is administered, although there are some exceptions.

The baseline phase serves three important functions: (a) It provides information regarding the pre-treatment level of the DV; (b) it provides information on the predicted level of the DV if treatment is not applied; and (c) it provides control data with which treatment data will be compared, with differences in the DV between baseline phase and the treatment (or *B*) phase providing evidence for the effects of the intervention. Figure 1 presents fictitious data to illustrate these functions. The DV is the number of accidents per week at a job site, and the intervention is a program that provides workers with incentives for every day without an accident. Panel A shows that the baseline level of the DV hovers around 15 accidents per week. From these data, we can predict that the number of accidents would probably remain the same if the intervention were not introduced. Panel B depicts a decrease in the number of accidents on introduction of the intervention. The change in the DV from the baseline phase to the treatment phase provides evidence, albeit limited, of the intervention's effectiveness.

To aid the interpretation of an intervention's effectiveness, baseline data should show stability. *Stability* means the data show neither a systematic upward or downward trend (i.e., the data have a slope near zero) nor excessive variability (i.e., the data hover around a consistent value, showing only minor fluctuations from one measurement occasion to the next). Stable baseline data provide a relatively clear benchmark against which to assess the effects of the intervention and information about the steady-state level of the DV. There are no simple rules for deciding when baselines are sufficiently stable, for such a decision depends on several factors, including the nature of the DV, the subject matter, and practical considerations. Notice that Panels A and B of Figure 1 depict stable data. Panels C and D of

Figure 1 Data Illustrating Functions of Baseline Phase

Note: Panel A depicts a two-phase withdrawal design with baseline data and the level of the dependent variable predicted from the baseline data. It is assumed that in the absence of an intervention, the level of the dependent variable will remain similar to that seen in the baseline phase. Panel B depicts the same design with the addition of data demonstrating an effective treatment. The dashed line indicates the predicted level of the dependent variable in the absence of a treatment effect. The difference in the predicted level and the observed level of the dependent variable represents the size of the treatment effect (in this case, approximately 12 points). Panel C depicts a downward trend in the baseline data. Panel D depicts highly variable data.

Figure 1 depict baseline data that are unstable and extremely variable, respectively.

Withdrawal Designs

The example in Figure 1 represents a quasi-experimental single-subject design that consists of two phases, a baseline (A) phase followed by a treatment (B) phase. Such A-B designs are vulnerable to several threats to internal validity. It is possible that some NV, and not the intervention, caused the observed changes in the DV during the B phase. For example, these changes could have resulted from the coincidental occurrence of some external event or from changes in the participants themselves. To increase confidence that the

intervention was responsible for changes in the DV, the researcher could withdraw the intervention and return to baseline conditions, yielding an A-B-A design. Such designs are often termed *withdrawal designs* because the current condition is withdrawn and replaced with another condition.

Withdrawal designs help one rule out the possible effects of NVs on the DV by demonstrating systematic changes in the DV following introduction and withdrawal of the intervention. If the level of the DV in the second baseline phase returns to a level similar to that seen in the first baseline, one can be more confident that the intervention alone caused the observed change during the treatment phase, for it is unlikely that the actions of an NV happened to coincide with

both changes in phases. When changing phases, one should change only one condition at a time. Changing multiple conditions simultaneously makes the determination of the relative influence of each condition on the DV difficult, if not impossible.

One problem with A-B-A designs is that they leave participants in an untreated baseline phase. Thus, one may wish to reinstate the treatment after the second baseline phase, yielding an A-B-A-B design. In addition to leaving participants in a treatment phase, A-B-A-B designs can provide further evidence for treatment effects by demonstrating another change in the DV following the intervention's reintroduction. Two limitations of withdrawal designs are that (a) they cannot be used to study interventions with irreversible effects (e.g., skills training programs, certain medical procedures), and (b) they may require the repeated withdrawal of an effective treatment, which may be impractical, unethical, or impossible. In such situations, other single-subject designs can be used. One such design is the multiple-baseline design.

Multiple-Baseline Designs

As their name implies, multiple-baseline designs assess the effects of the intervention across separate baselines. These baselines can involve (a) different DVs in the same participant in one setting, (b) the same DV in the same participant in different situations, or (c) the same DV in different participants under similar or different conditions. In all three variations, measurements are made simultaneously on all baselines. When the DV on one baseline shows stability, the intervention is introduced (i.e., the treatment phase begins) while measurements continue on the other baselines. If the intervention produces changes only on the DV in the treatment phase and not on DVs in other baseline phases, we can feel more confident that the intervention, and not some other variable, was responsible for the observed change. If this is the case, and if the data are stable in the next baseline, then the intervention is introduced on the next baseline. In this way, the introduction of the intervention is staggered across baselines, and the multiple-baseline design thus comprises a collection of A-B designs. Figure 2

Figure 2 A Multiple-Baseline Design Across Settings

Note: Baseline data are collected on all baselines, and the intervention is introduced in a staggered manner. As with the withdrawal design, the baseline data provide a predicted level of the dependent variable in absence of the treatment. This figure shows an effective intervention in that the level of the dependent variable (the number of accidents) decreases when the treatment is applied. We can rule out coincidental variables as causes for the change because the dependent variable changes only when the intervention is applied and not at other times.

depicts a multiple-baseline design across settings using the same details as in Figure 1. Each baseline represents a different job site.

Unlike withdrawal designs, multiple-baseline designs can be used to study irreversible treatments and treatments that, because of their effectiveness, would be undesirable to withdraw. Nevertheless, multiple-baseline designs have the following shortcomings: (a) They require the withholding of treatment for extended periods of time, which may be undesirable in some cases; (b) they require that the DVs measured across the different baselines be independent of each other; and (c) they may yield ambiguous data regarding treatment effects when changes occur during some treatment phases and not during others.

SINGULAR AND GENERALIZED SINGULAR VALUE DECOMPOSITION

The singular value decomposition (SVD), a generalization of the eigendecomposition, can be used to

analyze rectangular matrices (the eigendecomposition is defined only for squared matrices). By analogy with the eigendecomposition, which decomposes a matrix into two simple matrices, the main idea of the SVD is to decompose a rectangular matrix into three simple matrices: two orthogonal matrices and one diagonal matrix.

Because it gives a least square estimate of a given matrix by a lower rank matrix of the same dimensions, the SVD is equivalent to principal components analysis (PCA) and metric multidimensional scaling and is therefore an essential tool for multivariate analysis. The generalized SVD (GSVD) decomposes a rectangular matrix and takes into account constraints imposed on the rows and the columns of the matrix. The GSVD gives a weighted generalized least square estimate of a given matrix by a lower rank matrix, and therefore, with an adequate choice of the constraints, the GSVD implements all linear multivariate techniques (e.g., canonical correlation, linear discriminant analysis, and correspondence analysis).

Definitions and Notations

Recall that a *positive semidefinite* matrix can be obtained as the product of a matrix by its transpose. This matrix is obviously square and symmetric, and (less obviously) its eigenvalues are all positive or null, and the eigenvectors corresponding to different eigenvalues are pairwise orthogonal. Let \mathbf{X} be a positive semidefinite matrix; then its eigendecomposition is expressed as

$$\mathbf{X} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^T, \quad (1)$$

with \mathbf{U} being an orthonormal matrix (i.e., $\mathbf{U}^T\mathbf{U} = \mathbf{I}$) and $\mathbf{\Lambda}$ being a diagonal matrix containing the eigenvalues of \mathbf{X} .

The SVD uses the eigendecomposition of a positive semidefinite matrix in order to derive a similar decomposition applicable to all rectangular matrices composed of real numbers. The idea here is to decompose any matrix into three simple matrices, two orthonormal matrices and one diagonal matrix. When applied

to a positive semidefinite matrix, the SVD is equivalent to the eigendecomposition.

Formally, if \mathbf{A} is a rectangular matrix, its SVD decomposes it as

$$\mathbf{A} = \mathbf{P}\mathbf{\Delta}\mathbf{Q}^T, \tag{2}$$

with

\mathbf{P} is the (normalized) eigenvectors of the matrix $\mathbf{A}\mathbf{A}^T$ (i.e., $\mathbf{P}^T\mathbf{P} = \mathbf{I}$). The columns of \mathbf{P} are called the *left singular vectors* of \mathbf{A} .

\mathbf{Q} is the (normalized) eigenvectors of the matrix $\mathbf{A}^T\mathbf{A}$ (i.e., $\mathbf{Q}^T\mathbf{Q} = \mathbf{I}$). The columns of \mathbf{Q} are called the *right singular vectors* of \mathbf{A} .

$\mathbf{\Delta}$ is the diagonal matrix of the *singular values*, $\mathbf{\Delta} = \mathbf{\Lambda}^{\frac{1}{2}}$, with $\mathbf{\Lambda}$ being the diagonal matrix of the eigenvalues of matrix $\mathbf{A}\mathbf{A}^T$ and of the matrix $\mathbf{A}^T\mathbf{A}$ (they are the same).

The SVD is a consequence of the eigendecomposition of a positive semidefinite matrix. This can be shown by considering the eigendecomposition of the two positive semidefinite matrices that can be obtained from \mathbf{A} : namely $\mathbf{A}\mathbf{A}^T$ and $\mathbf{A}^T\mathbf{A}$. If we express these matrices in terms of the SVD of \mathbf{A} , we obtain the following equations:

$$\mathbf{A}\mathbf{A}^T = \mathbf{P}\mathbf{\Delta}\mathbf{Q}^T\mathbf{Q}\mathbf{\Delta}\mathbf{P}^T = \mathbf{P}\mathbf{\Delta}^2\mathbf{P}^T = \mathbf{P}\mathbf{\Lambda}\mathbf{P}^T, \tag{3}$$

and

$$\mathbf{A}^T\mathbf{A} = \mathbf{Q}\mathbf{\Delta}\mathbf{P}^T\mathbf{P}\mathbf{\Delta}\mathbf{Q}^T = \mathbf{Q}\mathbf{\Delta}^2\mathbf{Q}^T = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^T. \tag{4}$$

This shows that $\mathbf{\Delta}$ is the square root of $\mathbf{\Lambda}$, that \mathbf{P} are the eigenvectors of $\mathbf{A}\mathbf{A}^T$, and that \mathbf{Q} are the eigenvectors of $\mathbf{A}^T\mathbf{A}$.

For example, the matrix

$$\mathbf{A} = \begin{bmatrix} 1.1547 & -1.1547 \\ -1.0774 & 0.0774 \\ -0.0774 & 1.0774 \end{bmatrix} \tag{5}$$

can be expressed as

$$\begin{aligned} \mathbf{A} &= \mathbf{P}\mathbf{\Delta}\mathbf{Q}^T \\ &= \begin{bmatrix} 0.8165 & 0 \\ -0.4082 & -0.7071 \\ -0.4082 & 0.7071 \end{bmatrix} \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix} \\ &\quad \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & 0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 1.1547 & -1.1547 \\ -1.0774 & 0.0774 \\ -0.0774 & 1.0774 \end{bmatrix}. \end{aligned} \tag{6}$$

We can check that

$$\begin{aligned} \mathbf{A}\mathbf{A}^T &= \begin{bmatrix} 0.8165 & 0 \\ -0.4082 & -0.7071 \\ -0.4082 & 0.7071 \end{bmatrix} \begin{bmatrix} 2^2 & 0 \\ 0 & 1^2 \end{bmatrix} \\ &\quad \begin{bmatrix} 0.8165 & -0.4082 & -0.4082 \\ 0 & -0.7071 & 0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 2.6667 & -1.3333 & -1.3333 \\ -1.3333 & 1.1667 & 0.1667 \\ -1.3333 & 0.1667 & 1.1667 \end{bmatrix} \end{aligned} \tag{7}$$

and that

$$\begin{aligned} \mathbf{A}^T\mathbf{A} &= \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & 0.7071 \end{bmatrix} \begin{bmatrix} 2^2 & 0 \\ 0 & 1^2 \end{bmatrix} \\ &\quad \begin{bmatrix} 0.7071 & -0.7071 \\ 0.7071 & 0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 2.5 & -1.5 \\ -1.5 & 2.5 \end{bmatrix}. \end{aligned} \tag{8}$$

Technical Note: Agreement Between Signs

Singular vectors come in pairs made of one left and one right singular vector corresponding to the same singular value. They could be computed

separately or as a pair. Equation 2 requires computing the eigendecomposition of two matrices. Rewriting this equation shows that it is possible, in fact, to compute only one eigendecomposition. As an additional bonus, computing only one eigendecomposition prevents a problem that can arise when the singular vectors are obtained from two separate eigendecompositions. This problem follows from the fact that the eigenvectors of a matrix are determined up to a multiplication by -1 but that singular vectors, being pairs of eigenvectors, need to have compatible parities. Therefore, when computed as eigenvectors, a pair of singular vectors can fail to reconstruct the original matrix because of this parity problem.

This problem is illustrated by the following example: The matrix

$$\mathbf{A} = \begin{bmatrix} 1.1547 & -1.1547 \\ -1.0774 & 0.0774 \\ -0.0774 & 1.0774 \end{bmatrix} \quad (9)$$

can be decomposed in two equivalent ways:

$$\begin{aligned} \mathbf{A} &= \mathbf{P}\mathbf{\Delta}\mathbf{Q}^T \\ &= \begin{bmatrix} 0.8165 & 0 \\ -0.4083 & -0.7071 \\ -0.4083 & 0.7071 \end{bmatrix} \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix} \\ &\quad \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & 0.7071 \end{bmatrix} \\ &= \begin{bmatrix} -0.8165 & 0 \\ 0.4083 & 0.7071 \\ 0.4083 & 0.7071 \end{bmatrix} \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix} \quad (10) \\ &\quad \begin{bmatrix} -0.7071 & -0.7071 \\ 0.7071 & -0.7071 \end{bmatrix} \\ &= \begin{bmatrix} 1.1547 & -1.1547 \\ -1.0774 & 0.0774 \\ -0.0774 & 1.0774 \end{bmatrix}. \end{aligned}$$

But when the parity of the singular vectors does not match, the SVD will fail to reconstruct the original matrix, as illustrated by

$$\begin{aligned} \mathbf{A} &\neq \begin{bmatrix} -0.8165 & 0 \\ 0.4083 & 0.7071 \\ 0.4083 & 0.7071 \end{bmatrix} \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix} \\ &\quad \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & 0.7071 \end{bmatrix} \quad (11) \\ &= \begin{bmatrix} -1.1547 & -1.1547 \\ 1.0774 & 0.0774 \\ 0.0774 & 1.0774 \end{bmatrix}. \end{aligned}$$

By computing only one matrix of singular vectors, we can rewrite Equation 2 in a manner that expresses that one matrix of singular vectors can be obtained from the other:

$$\mathbf{A} = \mathbf{P}\mathbf{\Delta}\mathbf{Q}^T \iff \mathbf{P} = \mathbf{A}\mathbf{Q}\mathbf{\Delta}^{-1}. \quad (12)$$

For example:

$$\begin{aligned} \mathbf{P} &= \mathbf{A}\mathbf{Q}\mathbf{\Delta}^{-1} \\ &= \begin{bmatrix} 1.1547 & -1.1547 \\ -1.0774 & 0.0774 \\ -0.0774 & 1.0774 \end{bmatrix} \\ &\quad \begin{bmatrix} 0.7071 & 0.7071 \\ -0.7071 & 0.7071 \end{bmatrix} \begin{bmatrix} \frac{1}{2} & 0 \\ 0 & 1 \end{bmatrix} \quad (13) \\ &= \begin{bmatrix} 0.8165 & 0 \\ -0.4082 & -0.7071 \\ -0.4082 & 0.7071 \end{bmatrix}. \end{aligned}$$

Generalized Singular Value Decomposition

For a given $I \times J$ matrix \mathbf{A} , generalizing SVD involves using two positive definite square matrices with sizes $I \times I$ and $J \times J$, respectively. These two

matrices express constraints imposed on the rows and the columns of \mathbf{A} , respectively. Formally, if \mathbf{M} is the $I \times I$ matrix expressing the constraints for the rows of \mathbf{A} and \mathbf{W} the $J \times J$ matrix of the constraints for the columns of \mathbf{A} , then the matrix \mathbf{A} is now decomposed into

$$\mathbf{A} = \tilde{\mathbf{U}}\tilde{\mathbf{\Delta}}\tilde{\mathbf{V}}^T \text{ with: } \tilde{\mathbf{U}}^T\mathbf{M}\tilde{\mathbf{U}} = \tilde{\mathbf{V}}^T\mathbf{W}\tilde{\mathbf{V}} = \mathbf{I}. \quad (14)$$

In other words, the generalized singular vectors are orthogonal under the constraints imposed by \mathbf{M} and \mathbf{W} .

This decomposition is obtained as a result of the standard singular value decomposition. We begin by defining the matrix $\tilde{\mathbf{A}}$ as:

$$\tilde{\mathbf{A}} = \mathbf{M}^{\frac{1}{2}}\mathbf{A}\mathbf{W}^{\frac{1}{2}} \Leftrightarrow \mathbf{A} = \mathbf{M}^{-\frac{1}{2}}\tilde{\mathbf{A}}\mathbf{W}^{-\frac{1}{2}}. \quad (15)$$

We then compute the standard singular value decomposition as $\tilde{\mathbf{A}}$:

$$\tilde{\mathbf{A}} = \mathbf{P}\mathbf{\Delta}\mathbf{Q}^T \text{ with: } \mathbf{P}^T\mathbf{P} = \mathbf{Q}^T\mathbf{Q} = \mathbf{I}. \quad (16)$$

The matrices of the generalized eigenvectors are obtained as

$$\tilde{\mathbf{U}} = \mathbf{M}^{-\frac{1}{2}}\mathbf{P} \text{ and } \tilde{\mathbf{V}} = \mathbf{W}^{-\frac{1}{2}}\mathbf{Q}. \quad (17)$$

The diagonal matrix of singular values is simply equal to the matrix of singular values of $\tilde{\mathbf{A}}$:

$$\tilde{\mathbf{\Delta}} = \mathbf{\Delta} \quad (18)$$

We verify that

$$\mathbf{A} = \tilde{\mathbf{U}}\tilde{\mathbf{\Delta}}\tilde{\mathbf{V}}^T$$

by substitution:

$$\begin{aligned} \mathbf{A} &= \mathbf{M}^{-\frac{1}{2}}\tilde{\mathbf{A}}\mathbf{W}^{-\frac{1}{2}} = \mathbf{M}^{-\frac{1}{2}}\mathbf{P}\mathbf{\Delta}\mathbf{Q}^T\mathbf{W}^{-\frac{1}{2}} \\ &= \tilde{\mathbf{U}}\tilde{\mathbf{\Delta}}\tilde{\mathbf{V}}^T \text{ (from Equation 17).} \end{aligned} \quad (19)$$

To show that Equation 14 holds, suffice it to show that

$$\tilde{\mathbf{U}}^T\mathbf{M}\tilde{\mathbf{U}} = \mathbf{P}^T\mathbf{M}^{-\frac{1}{2}}\mathbf{M}\mathbf{M}^{-\frac{1}{2}}\mathbf{P} = \mathbf{P}^T\mathbf{P} = \mathbf{I} \quad (20)$$

and

$$\tilde{\mathbf{V}}^T\mathbf{W}\tilde{\mathbf{V}} = \mathbf{Q}^T\mathbf{W}^{-\frac{1}{2}}\mathbf{W}\mathbf{W}^{-\frac{1}{2}}\mathbf{Q} = \mathbf{Q}^T\mathbf{Q} = \mathbf{I} \quad (21)$$

Mathematical Properties

It can be shown that the SVD has the important property of giving an optimal approximation of a matrix by another matrix of smaller rank. In particular, the SVD gives the best approximation, in a least square sense, of any rectangular matrix by another rectangular of the same dimensions but smaller rank.

Precisely, if \mathbf{A} is an $I \times J$ matrix of rank L (i.e., \mathbf{A} contains L singular values that are not zero), we denote by $\mathbf{P}_{[K]}$ (respectively $\mathbf{Q}_{[K]}$, $\mathbf{\Delta}_{[K]}$) the matrix made of the first K columns of \mathbf{P} (respectively \mathbf{Q} , $\mathbf{\Delta}$):

$$\mathbf{P}_{[K]} = [\mathbf{p}_1, \dots, \mathbf{p}_k, \dots, \mathbf{p}_K] \quad (22)$$

$$\mathbf{Q}_{[K]} = [\mathbf{q}_1, \dots, \mathbf{q}_k, \dots, \mathbf{q}_K] \quad (23)$$

$$\mathbf{\Delta}_{[K]} = \text{diag}\{\delta_1, \dots, \delta_k, \dots, \delta_K\} \quad (24)$$

The matrix \mathbf{A} reconstructed from the first K eigenvectors is denoted $\mathbf{A}_{[K]}$. It is obtained as

$$\mathbf{A}_{[K]} = \mathbf{P}_{[K]}\mathbf{\Delta}_{[K]}\mathbf{Q}_{[K]}^T = \sum_k^K \delta_k \mathbf{p}_k \mathbf{q}_k^T \quad (25)$$

(with δ_k being the k th singular value).

The reconstructed matrix $\mathbf{A}_{[K]}$ is said to be optimal (in a least square sense) for matrices of rank K because it satisfies the following condition:

$$\begin{aligned} \|\mathbf{A} - \mathbf{A}_{[K]}\|^2 &= \text{trace} \left\{ (\mathbf{A} - \mathbf{A}_{[K]}) (\mathbf{A} - \mathbf{A}_{[K]})^T \right\} \\ &= \min_{\mathbf{X}} \|\mathbf{A} - \mathbf{X}\|^2 \end{aligned} \quad (26)$$

for the set of matrices \mathbf{X} of rank smaller than or equal to K . The quality of the reconstruction is given by the ratio of the first K eigenvalues (i.e., the squared singular values) to the sum of all the eigenvalues. This quantity is interpreted as *the reconstructed proportion* or *the explained variance*; it corresponds to the inverse of the quantity minimized by Equation 26. The quality of reconstruction can also be interpreted as the squared coefficient of correlation (precisely as the R_v coefficient, see entry) between the original matrix and its approximation.

The GSVD minimizes an expression similar to Equation 26, namely,

SIX SIGMA

The term *Six Sigma* may be interpreted in several ways. To some, it represents a metric denoting the level of quality of a product or process, such as the proportion of nonconforming product. This may be expressed as a proportion or percentage (5% nonconforming product, say) or in parts per million (ppm), such as 5,000 defects per million opportunities. To others, such as senior management, Six Sigma conveys a philosophy of continuous quality improvement. This is akin to accepting Six Sigma as the organization motto, with everyone committed to improving products, processes, and services along such dimensions as quality, price, lead time, and on-time delivery. It is interpreted as a business strategy. Finally, Six Sigma is viewed as a methodology for improving quality. In

this context, it represents a structured approach to problem solving using a variety of statistical and interventional tools and techniques.

Perspective on Six Sigma as a Metric

Six Sigma was coined by Motorola in the 1980s. The Greek letter sigma (σ) represents the variability in a process as measured by its standard deviation. The conceptual perspective of the term Six Sigma is that it is desirable for a process to be operating such that the *specification limits*, which govern customer requirements on a selected quality characteristic, are located 6 standard deviations away from the mean value of the characteristic. It is assumed that the probability distribution of the quality characteristic (X) is normal, and its density function is given by

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp(-(x - \mu)^2/2\sigma^2),$$

where μ and σ represent the process mean and standard deviation, respectively. When the assumption of normality of distribution of the quality characteristic can be justified, using standard normal tables, it can be shown that the proportion of nonconforming product is 0.002 ppm. The tail area under the normal curve, above or below the appropriate specification limit, is 0.001 ppm on each side. Figure 1 demonstrates this concept.

The above interpretation of Six Sigma as a metric applies in a static situation. However, Motorola wanted to account for drifts in the process in the long

Figure 1 Process Distribution With Specification Limits at 6 Standard Deviations From Mean

run. An assumption was made that the drift in the process mean would be no more than 1.5 standard deviations from its original location. This assumption implies that a system of statistical process control will be in place for detecting when a process goes “out of control.”

A process could go out of control because of special causes. These special causes are not part of the system as designed but could occur as a result of the use of a wrong tool, an improper raw material, or an operator error. Identification of special causes is typically accomplished through the use of control charts. Special causes could cause a shift in the process mean or an increase in the process standard deviation. Common causes, on the other hand, are inherent to the system. A process can be redesigned to reduce the impact of the common causes, but they can never be eliminated completely. A process with only common causes is said to be in statistical control.

Motorola made the assumption that if a process mean drifted more than 1.5 standard deviations from its initial location, statistical process control methods should be able to detect the drift and bring the process back to a state of control. Thus, at the worst, if the process mean drifts 1.5 standard deviations and the drift is not detected, the process mean would be 4.5 standard deviations from the closer specification limit and 7.5 standard deviations from the farther specification limit. The premise is that the process mean was initially centered between the specification limits, with each limit being 6 standard deviations away from the mean. Under the assumption of normality, it can be shown that the proportion of nonconforming product outside the closer specification limit is about 3.4 ppm, and the proportion nonconforming outside the farther specification limit is negligible. Thus, the total proportion of nonconforming product is 3.4 ppm. Figure 2 demonstrates this concept; it is assumed that the shift in the process mean is 1.5 standard deviations in either direction.

Almost all the Six Sigma literature, when viewed in the context of a metric, highlights this nonconformance rate of 3.4 ppm. As explained in Figure 2, the process mean, in this situation, is really 4.5 standard deviations from the closer specification limit and not 6 standard deviations, as in the original condition. Perhaps an appropriate term to denote this situation

Figure 2 Process Distribution With a Shift of 1.5 Standard Deviations From Mean

would be Four and a Half Sigma, which would be consistent with a nonconformance rate of 3.4 ppm.

Inherent Assumptions and Their Validity

The use of Six Sigma as a metric includes two inherent assumptions. First, it is assumed that the distribution of the quality characteristic, which is being compared to a set of defined specification limits, is normal. There is no guarantee that this assumption will be satisfied for all quality characteristics. The proportion nonconforming will be influenced not only by the location of the process mean and the magnitude of the process variability but also by the shape of the distribution. For example, suppose a product quality characteristic is found to follow an exponential distribution with parameter λ . The probability density function is

$$f(x) = \lambda e^{-\lambda x},$$

where the mean and standard deviation are both $1/\lambda$. Suppose a lower specification limit (LSL) is specified. The proportion nonconforming is

$$P[X < LSL] = 1 - \exp((-1/\lambda) LSL).$$

In practice, λ may be estimated from historical data and replaced by its estimate, $\hat{\lambda}$. If so, the proportion nonconforming found from the above equation will

not necessarily be equal to that obtained using the normal probability distribution. Thus, the metric of 3.4 ppm nonconformance for a Six Sigma process may not necessarily be correct, even if the closest specification limit is 4.5 standard deviations from the process mean.

The second assumption deals with the process shift of 1.5 standard deviations from the original location, assuming that the specifications were initially 6 standard deviations from the process mean. Motorola could have made this assumption. Certainly, for all types of products or services in various industries, there is no guarantee that such a degree of process shift takes place. Nor is there evidence that, as a rule, shifts of 1.5 standard deviations will be detected and the process mean restored through remedial action to its original location. It is assumed that shifts greater than 1.5 standard deviations will not happen, but this level cannot be guaranteed.

Further, there might be instances whereby, based on the criticality of the components or the product quality characteristic, it is not desirable to allow a shift of 1.5 standard deviations; detection might need to take place sooner. In addition, on mathematical grounds, there is no justification that for all processes, shifts of up to 1.5 standard deviations may take place prior to detection.

Six Sigma as a Methodology

One of the major contributions of Six Sigma lies in its application as a structured approach to problem solving and improvements. When applied to improving processes (manufacturing, transactional, or service), Six Sigma provides a road map. There are five main phases in this approach: Define, Measure, Analyze, Improve, and Control.

The Define phase includes problem statement and identification of the scope of the project. It may also include looking at high-level process maps and defining the metrics to be used, as well as selection of baseline and improvement goals. Implementation of Six Sigma is typically accomplished on a project-by-project basis. The person who serves as the promoter of the particular project is called a *champion* and is

also a liaison to senior management. Top management support is enhanced through adequate interaction with the champion, who conveys progress and associated project needs to senior administration.

The Measure phase involves identifying customer needs and documenting the process. Customer requirements are prioritized and measures are established with a tool known as *quality function deployment*. Key process output variables that impact process performance are noted, and associated key process input variables that can be monitored are identified. All steps involved in the process are placed on a process map. Here, for each activity, inputs (controllable and noise), outputs, ownership, and possible reasons for failure are clearly delineated. Metrics for determining process performance levels are also developed. They may include such measures as *defects per million opportunities* or sigma level, which is an indication of the location of the nearest specification limit relative to the process mean. The larger the sigma level, the better. Other measures include short-term process capability indices such as C_p , C_{pk} , CPL , and CPU . C_p is a measure of process potential and should be used when the process mean, μ , is centered between specification limits. It is given by the relation

$$C_p = \frac{USL - LSL}{6\sigma},$$

where USL and LSL denote the upper specification limit and lower specification limit, respectively, and σ represents the process standard deviation. Note that, assuming normality of distribution, the denominator, 6σ , represents the process spread. This is the distance between the *upper natural tolerance limit* and *lower natural tolerance limit*, each of which is 3 standard deviations from the process mean. Hence, C_p can be interpreted as the specification spread divided by the process spread. Desirable values of C_p are greater than or equal to 1. Figure 3 demonstrates a capable process in which $C_p > 1$.

A drawback of C_p is that it does not consider the location of the process. Thus, even if the process mean were to be close to the upper specification limit and the process variability remained the same as that in Figure 3, the C_p index would still be greater than 1, indicating a

Figure 3 A Capable Process With $C_p > 1$

desirable process. However, in this situation, there would be quite a bit of nonconforming product.

In some cases, specifications are one-sided only. For example, the tensile strength of a cable must meet at least a lower specification limit, or the waiting time before being served by a teller in a bank must be less than an upper specification limit. In these instances, the short-term capability indices for one-sided specifications are given by

$$CPL = \frac{\mu - LSL}{3\sigma} \text{ or}$$

$$CPU = \frac{USL - \mu}{3\sigma},$$

respectively. As before, desirable values of CPL or CPU are greater than or equal to 1.

To overcome the drawback of the C_p index, the C_{pk} index, which uses information on both process mean and standard deviation, is used. It is given by

$$\begin{aligned} C_{pk} &= \min \left[\frac{USL - \mu}{3\sigma}, \frac{\mu - LSL}{3\sigma} \right] \\ &= \min [CPU, CPL]. \end{aligned}$$

It is observed that C_{pk} represents the scaled distance, relative to 3 standard deviations, between the process mean and the closest specification limit. Desirable values of C_{pk} are $C_{pk} \geq 1$. Figure 4 shows a

Figure 4 A Process That Is Not Capable, With $C_{pk} < 1$

process that is not capable, with nonconforming product above the upper specification limit. The C_{pk} value for this process is < 1 .

In the long term, because a process can drift, an estimate of the process standard is calculated by using data from subgroups of information collected over a time span. This estimate is denoted by σ_{LT} , as opposed to the estimate of the short-term process standard (σ_{ST}), which is estimated from the variation within subgroups. Thus, there are equivalent long-term versions for all the previous process capability indices. These are denoted P_p , PPL , PPU , and P_{pk} , with the only difference in the computation being that the short-term estimate of the process standard deviation is replaced by a long-term estimate.

Also in the Measure phase, capability analysis of the measurement system is conducted to determine its stability. Such studies are known as *gauge* repeatability and reproducibility studies. Repeatability refers to the inherent variation present in the gage system, implying the variation in measured values when the same part is measured by the same inspector using the same gage, over and over again. Reproducibility, on the other hand, refers to the variability between inspectors or the interaction between inspectors and parts.

The Analyze phase consists of identifying root causes of variation by collecting data from the process and analyzing it with tools such as cause-and-effect or fishbone diagrams. The tools may also include histograms, box plots, scatter diagrams, run charts, multivariable plots, and distribution plots. Distribution

plots, such as the normal probability plot, are used to check the validity of the distributional assumptions. Descriptive statistics on the process-related variables, such as mean, standard deviation, skewness coefficient, and kurtosis coefficient, are commonly used. Inferential statistics is also a focal point of analysis and may include constructing confidence intervals and testing hypotheses on population parameters such as population means, proportions, variances, difference of two means, difference of two proportions, or ratio of two variances. In situations involving comparison of more than two population means, analysis of variance is used. Also, when it is desired to develop a statistical model for a chosen response variable based on certain independent variables or predictors, regression analysis may be used. Software packages can perform all these analyses.

The Improve phase focuses on how process performance may be elevated to reach certain goals not attainable by the current process. Design-of-experiments concepts are used. This phase may start with process characterization, in which key factors or process variables that impact the response variable are identified. Screening designs, such as two-level factorial or two-level fractional experiments, or Plackett-Burman designs may be used in this context. Once the vital factors are identified, the next step is process optimization. Here it is of interest to locate the region in the important factors that leads to the best possible response. The objective is to determine the optimal settings of the factors such that a target value of the response is achieved. Factorial designs or response surface designs are possibilities, with central composite designs or Box-Behnken designs being alternatives to explore when considering polynomial models. Usually, analysis of variance procedures are used for the determination of statistical significance of the factors. The last stage in this phase is the verification or validation step. Experiments are conducted at the identified optimal factor settings, and the observed response variable values are analyzed to determine their proximity to the predicted values.

The final phase of the Six Sigma process is the Control phase. The aim is to sustain the gains identified in the previous phase. Opportunities for standardizing

process steps and mistake proofing the process could be identified. Statistical process control is accomplished with control charts, which detect the presence of special causes in the system and take remedial action as soon as possible. Rules exist for triggering the detection of special causes, the most common one being a single point falling outside the control limits. Control charts exist for variables as well as for attributes; charts for the mean and range, mean and standard deviation, individuals, and moving range are common. Refinements include the exponentially weighted moving average, cumulative sum, and control charts for short production runs. Under attribute charts, charts for proportion nonconforming, number nonconforming, number of defects or nonconformities, and number of nonconformities per unit are commonly used.

Conclusions

While the majority of the statistical or nonstatistical tools used in the Six Sigma approach are not new, there are a few unique features. First, Six Sigma is associated with an approach oriented toward bottom-line results. Financial impact of the project is of major concern, as is retention of top management commitment. Second, Six Sigma identifies a business strategy that may be used for continual improvement to keep abreast of competitors. Third, it utilizes a structured approach to improve a process, product, or services. Such an approach facilitates a better understanding of critical business processes. Fourth, it maintains and improves communication between operations and management through project presentations. Fifth, it demonstrates the value of the various tools in the organizational context, thus creating a win-win situation for everyone.

SIXTEEN PERSONALITY FACTOR QUESTIONNAIRE

The Sixteen Personality Factor (16PF) Questionnaire (published by the Institute of Personality and Ability Testing, www.ipat.com) is a comprehensive self-report inventory of normal personality that takes about 35 minutes to complete. Unlike most test authors, who try to assess a particular psychological construct, Raymond B. Cattell designed the 16PF to measure personality itself. In the 1940s, Cattell defined personality as anything about people that allows us to predict how they will behave in a given situation. He believed that any normal personality trait would be reflected in the English language, as people need adjectives to describe each other. He studied how adjectives clung together statistically as people used them to describe themselves and others. A factor analysis of the results produced the 16 factors; these, in theory, account for most of what is meant by personality.

The 16 factors are Warmth, Reasoning, Emotional Stability, Dominance, Liveliness, Rule-Consciousness, Social Boldness, Sensitivity, Vigilance, Abstractedness, Privatness, Apprehension, Openness to Change, Self-Reliance, Perfectionism, and Tension. Cattell wrote test items to measure these factors. For example, the item “I would rather be a seal in a seal colony than an eagle on a cliff” measured the first factor, Warmth, or sociability. Cattell considered intelligence to be a personality factor because it helps predict behavior, and the 16PF contains some word problems to measure reasoning. The test also has scales that measure the participant’s response style. The latest version of the test, the fifth edition, was published in 1993.

After developing the test and collecting profiles from numerous people, Cattell factor-analyzed 16PF

results. Not counting intelligence, five factors emerged, which the Institute of Personality and Ability Testing has named Extraversion, Anxiety, Self-Control, Independence, and Tough-Mindedness. Thus, Cattell started the Big Five theory, but he always thought that five factors were too few to describe human personality.

As a test of normal personality, the 16PF-5 is well suited to industrial uses, and it can be used under the Americans with Disabilities Act for preemployment screening. With its excellent psychometrics, it has become one of the most widely used personality tests in the world, available in nearly 40 languages. As psychotherapy became destigmatized in the 20th century, and as normal people seek help more than ever before, the 16PF has been increasingly used in the clinic as well.

SKEWNESS

Skewness is a measure of the lack of symmetry, or the lopsidedness, a distribution has. In other words, one tail of the distribution is longer than another. A positively skewed distribution has a longer right tail than left, corresponding to a smaller number of occurrences at the high end of the distribution. This might be the case when you have a test that is very difficult: Few people get scores that are very high, and many more get scores that are relatively low. A negatively

skewed distribution has a shorter right tail than left, corresponding to a larger number of occurrences at the high end of the distribution. This would be the case for an easy test (lots of high scores and relatively few low scores).

Although skewness (and kurtosis) are used mostly as descriptive terms (such as “That distribution is negatively skewed”), mathematical indicators can indicate how skewed or kurtotic a distribution is. For example, skewness is computed by subtracting the value of the median from the mean:

$$Sk = \frac{3(\bar{X} - M)}{s},$$

where

Sk is Pearson measure of skewness,

\bar{X} is the mean,

M is the median, and

s is the standard deviation.

For example, if the mean of a distribution is 100 and the median is 95, the skewness value is $100 - 95 = 5$, and the distribution is positively skewed. If the mean of a distribution is 85 and the median is 90, the skewness value is $85 - 90 = -5$, and the distribution is negatively skewed. The formula takes the standard deviation of the distribution into account so that skewness indicators can be compared with one another.

SMOOTHING

Smoothing methods attempt to capture the underlying structure of data that contain noise. Noise in data may result from measurement imprecision or the effect of

unmeasured variables, and noise tends to mask the structure of a data set or the relationship between two variables. Smoothers aim to eliminate this noise while making very few model assumptions about the distribution of the data.

Common smoothing techniques include density estimation and (nonparametric) regression curve estimation. Density estimation uses sample data for a single variable to estimate the population distribution of that variable. While parametric models (e.g., normal distribution, exponential distribution) can be fit for such data, smoothers typically assume only that the variable is continuous with a smooth density function. Nonparametric regression models the relationship between two (or more) variables without assuming a specific functional form (such as linear or quadratic) for the regression curve.

The smooth curve (whether a density estimate or regression curve) is often determined by “local weighting”—that is, the curve value at any point on the graph is a weighted average of the observed data values near that point, with data closest to the point receiving the greatest weight. Most smoothing methods incorporate some type of tuning parameter that allows the user to control the smoothness of the estimated curve.

This following example (Figure 1) relates the top speed and gas mileage of 82 car models using data from the U.S. Environmental Protection Agency and available online at <http://lib.stat.cmu.edu/DASL/Datafiles/carmpgdat.html>.

The smooth curve shows the negative association between speed and mileage, reflecting that mileage decreases steeply for low top-speed values and more gradually for large top-speed values. The flat region in the middle of the plot is a feature that would probably be invisible on an examination of the raw data. This graph was produced using the “lowess” function (a local regression technique very similar to the loess function) of the free-source statistical software package R.

SOCIAL CLIMATE SCALES

The Social Climate Scales comprise 10 separate scales; each taps the social climate of a different setting. The first group, the Family Environment Scale, Group Environment Scale, and Work Environment Scale,

measure the social climate in community settings. The Classroom Environment Scale and University Residence Environment Scale tap the social climate in educational settings. The Community-Oriented Programs Environment Scale, Ward Atmosphere Scale, and Sheltered Care Environment Scale focus on treatment and residential care settings, and the Correctional Institutions Environment Scale and Military Environment Inventory measure the social climate in these two settings. The Work Environment Scale is published by Consulting Psychologists Press (www.cpp.com), the Sheltered Care Environment Scale is available in a monograph published by Sage (www.sagepub.com), and the other scales are published by Mind Garden (www.mindgarden.com).

Each of the scales measures relationship, personal growth or goal orientation, and system maintenance and change dimensions. Relationship dimensions assess the quality of personal relationships in a setting. They measure how involved people are in a setting, how much they help each other, and how openly they express feelings.

Personal growth or goal orientation dimensions tap how an environment encourages specific goals and directions of change. For example, in the family, these dimensions reflect independence, achievement, intellectual and cultural orientation, participation in recreation, and moral and religious values. In the workplace, they assess employees' autonomy, task orientation, and work pressure.

System maintenance and change dimensions measure order and organization in a setting, how clear it is in its expectations, how much control it maintains, and how responsive it is to change.

Each of the Social Climate Scales has three forms: the Real Form (Form R), the Ideal Form (Form I), and the Expectations Form (Form E). The Real Form asks people how they see a social environment. The Ideal Form asks about a preferred or ideal setting. The Expectations Form asks people to describe what they imagine a new, unfamiliar environment will be like. These forms of the scales measure how people see the settings they are in, what an ideal setting for them would include, and what they expect a new setting they are about to enter will be like.

Each of the scales is based on extensive normative and psychometric data; the subscales have adequate internal consistency, stability, and construct and predictive validity. The scales have many practical applications. They are used to educate clinicians, consultants, and program evaluators about social environments and to help them describe environments, formulate clinical case descriptions, facilitate individual and family counseling, match individuals and environments, and plan interventions to improve environments. With respect to research applications, the scales are used to compare and contrast environments, understand the determinants and impacts of social climate, predict adjustment to life crises, and identify environmental risk factors.

SOCIAL SKILLS RATING SYSTEM

The Social Skills Rating System (SSRS) provides a broad, multirater assessment of student social behaviors that can affect teacher-student relations, peer acceptance, and academic performance. The SSRS documents the perceived frequency and importance of behaviors influencing a student's development of social competence and adaptive functioning at school and at home. The SSRS components include three behavior rating forms (teacher, parent, and student versions) and an integrative assessment and intervention planning record. Teacher and parent forms are available for three developmental levels: preschool, Grades kindergarten through 6, and Grades 7 through 12. The SSRS assesses the domains of social skills, problem behavior, and academic competence.

The Social Skills Scale has five subscales: Cooperation, Assertion, Responsibility, Empathy, and Self-Control. The Problem Behaviors Scale has three subscales that measure Externalizing Problems, Internalizing Problems, and Hyperactivity. The Academic Competence domain concerns student academic functioning and consists of a small, yet critical, sample of relevant behaviors. Items in this domain are rated on a 5-point scale that corresponds to percentage clusters (1 = *lowest 10%*, 5 = *highest 10%*). This domain includes items measuring reading and mathematics performance, motivation, parental support, and general cognitive functioning. The scale appears on the teacher form at the elementary and secondary levels.

Scores are based on the results of 3-point ratings on the Social Skills Scale and the Problem Behaviors Scale (0 = *never occurs*, 1 = *sometimes occurs*, and 2 = *very often occurs*). All social skills items are rated on two dimensions: frequency and importance. The inclusion of the importance dimension allows raters to specify how important each social skill is for classroom success (teacher ratings), for their child's development (parent ratings), and for the student's relationships with others (student ratings).

The SSRS was standardized on a national sample of 4,170 children and used their self-ratings and ratings of them by 1,027 parents and 259 teachers. Internal consistency estimates for the SSRS across all forms and levels yielded a median coefficient alpha for the Social Skills Scale of .90, .84 for the Problem Behaviors Scale, and .95 for the Academic Competence Scale. Overall, these coefficients indicate a relatively high degree of scale homogeneity. The SSRS manual presents a number of studies investigating the construct, criterion-related, and content validity of the scale. For example, the SSRS Social Skills Scale and subscales correlate highly with other measures of social skills, such as the Walker-McConnell Scale of Social Competence and School Adjustment and the Social Behavior Assessment. The SSRS Problem Behaviors Scale and subscales show moderate to high correlations with the Child Behavior Checklist and the Harter Teacher Rating Scale. In addition, the SSRS Social Skills,

Problem Behaviors, and Academic Competence scales reliably differentiate children with mild disabilities (e.g., learning disabilities, behavior disorders, and mild mental or cognitive disabilities) from students without disabilities.

The SSRS has been used in hundreds of studies of children's social behavior. The SSRS has a representative national standardization and extensive evidence for reliability and validity. One of the most attractive features of the SSRS is its utility in selecting target behaviors for intervention purposes, a feature uncommon to most behavior rating scales. An intervention guide that provides a manualized approach to teaching and improving more than 40 social skills coordinates with the SSRS results.

SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT

The Society for Research in Child Development (SRCD) is an organization of more than 6,000 members from various academic disciplines concerned with the study of child development. Disciplines include, but are not limited to, anthropology, home economics, linguistics, neuroscience, nursing, nutrition,

pediatrics, psychiatry, psychology, public health, and sociology. In addition to being multidisciplinary, the society's membership is also international.

The child development movement in the United States began in the 1920s, but its roots reach back much further. It arose from external pressures broadly based on desires for better health, rearing, education, legal rights, and occupational treatment of children. Movements related to child health, child study, and mental hygiene were prominent by the late 19th and early 20th centuries. From these activities came the idea that children were the responsibility of the society at large.

The scientific status of the field of child development received formal recognition in 1923 through the Committee on Child Development, appointed by the National Research Council, a division of the National Academies of Science. Its purpose was to integrate research activities and to stimulate research in child development. In 1927, *Child Development Abstracts and Bibliography*, SRCD's first publication (which continued until 2000), was begun.

In 1933, the Committee on Child Development formed a new, independent organization, and the Society for Research in Child Development emerged. Its mission is to promote multidisciplinary research on infant, child, and adolescent development in diverse contexts and its life-long implications; to foster the exchange of information among scientists and other professionals worldwide; and to encourage applications of research-based knowledge.

The society currently publishes three journals:

1. *Child Development*—contains original articles on development research and theory; six issues a year
2. *Monographs of the Society for Research in Child Development*—consists primarily of comprehensive reports of large-scale research projects or integrated programs of research; four issues a year
3. *Social Policy Report*—focuses each issue on a single topic affecting children, youth, or families and includes analyses of legislation and syntheses of research on issues of social policy and children; four issues a year

The society hosts a biennial meeting with an attendance of more than 5,500. These internationally attended meetings include individual research reports, symposia, invited lectures, and discussion sessions, among other timely and historical programs.

Almost one fifth of SRCD's members come from more than 50 nations other than the United States. Special efforts are made by the society to increase communication and interaction among researchers in human development throughout the world. The society also has a commitment to research and training in diversity. A major goal of SRCD is to increase and disseminate research on children from many racial and ethnic minorities.

The society maintains the Office of Policy and Communications in Washington, D.C. The director supervises the SRCD Fellows Program in Child Development. The goals of this program are to contribute to the effective use of scientific knowledge, to educate the scientific community about public policy, and to establish effective liaisons between scientists and federal and congressional offices. Fellows spend a year in federal agencies or congressional offices working to facilitate the application of research to societal issues regarding children and families. The Office of Policy and Communications also has programs to communicate research to the media and the public.

The society welcomes persons interested in child development. Membership is open to any individual actively engaged in research in human development or any of the related basic sciences, teaching relevant to human development, or activity otherwise furthering the purposes of the society. SRCD is located at 3131 S. State St. Suite 301, Ann Arbor, MI, 48108.

SOCIOLOGICAL ABSTRACTS

Sociological Abstracts, owned by Cambridge Scientific Abstracts (CSA), is an electronic database of bibliographic citations and abstracts that provides access to the world's literature in theoretical and applied sociology and related disciplines in the social and behavioral sciences. Fields covered range from anthropology to gender studies to substance abuse. Containing more than 650,000 records as of July 2005, the database provides citations and abstracts of articles from more than 1,800 journals from 1963 to the present. It also contains abstracts of books, book chapters, book reviews, conference papers, and dissertations, along with book, film, and software review citations. Hard-copy records published in the first 10 years of the database (1952–1963) were digitized and added to the electronic version of Sociological Abstracts in 2005. The database is updated on a monthly basis, with roughly 30,000 records added each year.

The journals presently reviewed for inclusion in the database are divided into three categories—core journals, priority journals, and selective sources—on the basis of the level-of-relevant-coverage rating they receive. Core journals are those produced by dedicated sociological associations, faculties, and so forth, or which include *sociology* in their titles. All significant articles appearing in core journals are fully abstracted and indexed. Priority journals, from disciplines such as anthropology and political science, which frequently address noteworthy sociological issues, are those that regularly feature the work of sociologists. More than half of the significant articles appearing in priority journals are covered in Sociological Abstracts. Serial periodicals that publish the works of sociologists intermittently are considered selective sources; less than half of the significant articles featured in these works are selected for coverage.

Sociological Abstracts contains both limited and comprehensive search tools. The Quick Search option allows users to enter a word or phrase pertaining to a subject of interest and to delimit the search by date.

The Advanced Search option permits even more elaborate search strategies through the use of various parameters. Database users may structure their searches through any number of combinations of fields, such as author, keyword, title, publisher, language, and so forth. They can further refine their searches by restricting their results to year or to journal articles only. In addition, Sociological Abstracts contains a thesaurus function to assist in expanding searches.

On completing a search, the database will display a list of resulting records, each showing the title, author, and source of the item, along with an excerpt from the item abstract. Sociological Abstracts does not provide access to full-text versions of the listed records. Users interested in obtaining sociology-related full-text documents should access an alternate CSA database, *Sociology: A SAGE Full-Text Collection*. CSA sells Sociological Abstracts database licenses to both institutions and individuals. Numerous academic libraries provide access to Sociological Abstracts to faculty, staff, and students.

SPATIAL LEARNING ABILITY TEST

The Spatial Learning Ability Test (SLAT) is a non-verbal measure of complex spatial manipulations (i.e., mental rotation and folding of a two-dimensional item into a three-dimensional item). A cognitive design system approach was applied to develop SLAT so that variations in items reflect variations in spatial processing. Both the level and the cognitive source of SLAT item difficulties are well predicted from a cognitive model that is operationalized by item stimulus

Figure 1 SLAT Cube-Folding Tasks

content. Research has supported SLAT as being a more pure measure of spatial processing than several other spatial tests, even when compared with tests with the same item type. The cognitive design system approach reduces the role of verbal-analytic process strategies in item solution, especially with the design of the distractors.

SLAT consists of cube-folding tasks, as shown in Figure 1. The stem of each SLAT item is a two-dimensional figure consisting of six connected squares with markings on each side. This two-dimensional figure can be folded into a cube. The alternatives show various three-dimensional views of folded cubes. The examinee must choose which alternative shows the correct representation of the markings on the sides of the cube when the cube has been folded.

Three fixed-content test forms and an adaptive form of SLAT are available for use as computerized tests. All SLAT items are calibrated by the Rasch item response theory model. The metric of SLAT scores is defined by the item response theory model. Norms for two samples of young adults are available. SLAT is also available in a dynamic form, which has some support for incremental validity over the static SLAT.

SPATIAL STATISTICS

The terms *spatial statistics* and *spatial analysis* refer broadly to that class of statistical methods used to analyze *spatial data*. Spatial data are observations for which the locations of the observations are an important part of the information carried by the data. It is common to divide the types of spatial data, and the associated analytical tools, into three groups: point pattern data, geostatistical data, and lattice data.

Point Pattern Data

For point pattern data, the locations of the observations constitute the attribute of interest. For example, such data might consist of the locations of all cases of childhood leukemia in a given state. Of interest is whether the data exhibit clustering. That is, do the locations of cases arise in groups more than would be expected from a random distribution of locations in the state? If so, this clustering might suggest an environmental cause associated with the disease.

In other instances, the pattern of locations might be regular. That is, there might be a greater distance between locations than would occur at random. This often occurs in cities, for example, with respect to the locations of elementary schools. Such regularity of the spatial distribution corresponds to policy decisions reflecting the inefficiency of grouping schools close together.

Combinations of patterns can also exist. At one scale, stores often occur in clusters, such as in shopping malls, while at another scale, there is regularity: Malls tend to be distributed across cities rather than tightly concentrated in one subregion of a city.

The statistical tools used to analyze point pattern data range in complexity. Simplest are those that involve dividing the study region into equal-sized subregions and performing a chi-square test to assess whether the counts of locations within the subregions differ significantly from what would be expected under a random (uniform) distribution of observations. If the region of interest is divided into a hierarchy of nested squares, say, the repeated application of such tests can be used to detect spatial patterns at various scales.

While straightforward, the aforementioned approaches require the division of the study region into arbitrary subregions, the choice of which is not without consequence. Thus, there is interest in methods that do not require such subdivision. One example is *Ripley's K function*, based on interpoint distances. In this method, one first calculates the geographic distance between each pair of points, and then the cumulative distribution function of these distances is determined. Finally, by means of Monte Carlo simulations, tests can be constructed to determine whether there is evidence of clustering, randomness, or regularity, and at what scale or scales these patterns occur.

Still more sophisticated methods exist for describing point pattern data. One class of these methods involves the construction of statistical models wherein the observations are assumed to be from a Poisson distribution whose intensity varies across the study area. The focus is then on characterizing the intensity function. This method is typically quite computationally intense, but it has attracted considerable interest recently in the study of spatial clustering of human diseases. More generally, point pattern methods find applications in a variety of biological, environmental, physical, and social science settings.

Geostatistical Data

Like point pattern data, geostatistical data include the locations of the observations, denoted here as

coordinates (x_i, y_i) , representing, for example, longitude and latitude. However, the focus with geostatistical data is less on the locations than on the measurements or observations recorded at the locations, denoted $w(x_i, y_i)$.

Geostatistical data arise often in environmental studies such as the following example. Especially in rural regions, there is interest in measuring the concentration of contaminants such as atrazine in well water. Such data are collected by assaying water sampled from numerous wells located on farms across the region. The concentrations, w , plus the locations of the observations, (x, y) , comprise the geostatistical data. A goal in analyzing such data might involve estimating the population mean concentration for the region and constructing a confidence interval for that mean or testing a hypothesis concerning the mean.

The primary concern for geostatistical data is that the observations w might not be statistically independent. Consequently, the usual statistical tools, t tests, F tests, analysis of variance (ANOVA), and so forth, which rely on such independence, are not applicable in their standard form. Instead, new methods must be used that take into account spatial autocorrelation.

An approach for describing spatial autocorrelation is based on several assumptions, including that of *anisotropy*. Put simply, anisotropy requires the correlation between two w values to depend only on the distance between observations and not on the direction from one to the other. Granting such an assumption, consider the value of w at two locations, (x_1, y_1) and (x_2, y_2) , a distance $h = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$ apart. The *variogram* for observations separated by this distance is defined to be the expected value of the squared difference in w values: $E[w(x_1, y_1) - w(x_2, y_2)]^2$. With appropriate assumptions, it can be shown that this equals $2\sigma^2[1 - \rho(w(x_1, y_1), w(x_2, y_2))]$, where σ^2 represents the variance of a single observation, and ρ represents correlation. The variogram, therefore, can be viewed as a measure of correlation in spatial observations.

It is common to estimate the variogram as a function of the distance h . With such an estimate available, it is possible to adapt standard methods, eventually

yielding the spatial analogs of regression, ANOVA, confidence intervals, and so forth.

The majority of geostatistical tools apply best to Gaussian data. Other forms of continuous data might be approached by making an appropriate transformation of the observations, but the geostatistical analysis of categorical data, for example, is not straightforward, and research into such methods is ongoing.

Lattice Data

Lattice data bear similarities to geostatistical data. Again, greater interest is focused on some measured or observed quantity w , and again there is concern that these observations are spatially correlated, in which case standard statistical methods cannot be used. However, instead of focusing specifically on locations, as for geostatistical data, lattice data are distinguished by a *neighborhood structure*, which forms the basis for modeling spatial autocorrelation.

For example, consider the number of housing units for each county in a state. The numbers of housing units in two neighboring counties might be highly correlated, perhaps as a result of latitude (reflecting climate), amenities (proximity to a sea shore, proximity to a large urban area), and so forth. To formalize this spatial autocorrelation requires the definition of neighboring counties. For example, two counties might be deemed neighbors if they have an adjacent boundary. Alternatively, two (possibly nonadjacent) counties might be declared neighbors if their seats are not separated by more than 50 miles.

Consider the *neighborhood weights matrix* A whose ij th component is 1 if counties i and j are neighbors and 0 otherwise. Also, let W represent the vector of w values for all counties, and let 1 be a vector of 1s. We might postulate the model

$$W = \mu 1 + e,$$

where e represents the correlated error variation in the values of w about μ . One possible model for e takes the form

$$e = \rho A e + \varepsilon.$$

Here, the components of ε are assumed to be independent, Gaussian variables with variance τ^2 , say. Then, this hierarchical combination of models induces a spatial autocorrelation among the w values. Proceeding requires the estimation of μ , ρ , and τ^2 .

Numerous extensions of this model exist. The neighborhood matrix A need not consist only of 0 and 1 values; it is possible to incorporate noninteger and even negative values to reflect partial or inverse neighborhood associations. Alternative models for e can also be used, as can models for W , including regression terms. Moreover, while the resulting model for W is different, it is possible to apply lattice methods to categorical data. In such cases, inferences are usually based on Monte Carlo methods.

The great flexibility of lattice models makes them appealing tools, and they see considerable use in demography, economics, public health, and so on. This flexibility comes at a price, however, because it is not always clear how to define the neighborhood matrix A or how to choose among the many models for e . Perhaps for related reasons, the contrasting geostatistical methods tend to find greater favor in environmental, ecological, and other settings where the definition of a neighborhood structure is less obvious but where the assumption of autocorrelation being a function simply of distance is tenable.

Conclusion

As a subdiscipline, spatial statistics is enjoying considerable growth, fueled by several major changes in the research world. First, the ability to gather spatial data has greatly increased—the network of earth-orbiting satellites is a prime example, providing atmospheric, geographical, biological, and environmental data. Second, the advent of Geographical Information Systems increases our ability to archive and process such data. Both of these advances can be credited in large part to the existence of increased computing power. A third benefit of such power is the advance in statistical analysis tools, such as Monte Carlo simulation, that permit high quality, effective analyses.

Despite these advances, numerous open questions in spatial statistics remain, and the need for additional and more refined tools persists.

SPEARMAN'S RHO

Since its inception more than a century ago, the correlation coefficient has remained one of the most commonly used statistical indices in empirical research. A correlation coefficient provides an index of the relationship between two variables, or bivariate relationship. When both variables are quantitative in nature and either (a) they depart from normality or (b) they represent ordinal scales of measurement, then a researcher can use Spearman's rho (ρ), also known as the Spearman rank correlation coefficient. Charles Spearman introduced the concept of Spearman's rho in his seminal article in 1904, titled "The Proof and Measurement of Association Between Two Things," published in the *American Journal of Psychology*.

Technically speaking, Spearman's rho, a nonparametric measure of association, is appropriate whenever each variable is measured on at least an ordinal scale and both variables are taken from any continuous bivariate distribution. Moreover, Spearman's rho does not require any assumption about the frequency distribution of the variables. However, when the variables are normally distributed, the procedure known as Pearson's r , or the Pearson product-moment correlation, has more statistical power than does Spearman's rho and thus is more appropriate. In fact,

the asymptotic relative efficiency of Spearman's rho with respect to Pearson's r is 91.2%. In other words, Pearson's r is more efficient than Spearman's rho in that for a desired level of statistical significance (i.e., Type I error), Pearson's r has the same power for detecting statistical significance as does Spearman's rho using 91.2% of the sample size needed for Spearman's rho. Alternatively stated, if a sample size of 1,000 is needed for a relationship to be declared statistically significant for a nominal alpha level using Spearman's rho, then a smaller sample size (i.e., 912) is needed to yield the same p value when using Pearson's r . However, when the normality assumption is violated, the Type I error rate is inflated when Pearson's r is used, and thus nonparametric alternatives should be employed.

Spearman's rho is the second-most-popular bivariate correlational technique. Computation of Spearman's rho is as follows: Suppose we have n pairs of continuous data. The first step in computing Spearman's rho is to rank the X scores in the paired sample data from 1 (smallest score) to n (largest score), and independently rank the Y scores in the paired sample data from 1 (smallest score) to n (largest score). Therefore, the original (X_1Y_1) , (X_2Y_2) , \dots , (X_nY_n) pairs of observations will change to $[\text{Rank}(X_1), \text{Rank}(Y_1)]$, $[\text{Rank}(X_2), \text{Rank}(Y_2)]$, \dots , $[\text{Rank}(X_i), \text{Rank}(Y_i)]$. The next step in the process is to calculate a difference d for each pair as the difference between the ranks of the corresponding X and Y variables. The sum of the differences always will equal zero. The test statistic, denoted by r_s , is defined as the sum of squares of these differences³. The formula for this expression is

$$r_s = 1 - \frac{6 \sum d_i^2}{(n^3 - n)}. \quad (1)$$

An examination of the extreme cases helps us see how this formula works. Suppose both X and Y scores represent identical ordered arrays from smallest to largest. In this case, each $d_i = 0$, and thus $\sum d_i^2 = 0$, and substitution in Equation 1 provides an r_s value of +1. Thus, $r_s = 1$ describes a perfect positive relationship between ranks. Conversely, if the ranks of the X scores

are the complete opposite of the ranks of the Y scores, then it can be demonstrated that

$$\sum d_i^2 = \frac{n(n^2 - 1)}{3} = \frac{(n^3 - n)}{3}. \quad (2)$$

Substitution of this value into Equation 1 leads to an r_s value of -1 , which describes a perfect negative relationship. Interestingly, Spearman's rho is equal to Pearson's r with ranks substituted for the original scores.

If two or more scores within the X or the Y set, or both, have the same value (i.e., tied observations), midranks are assigned to these observations. The midrank of a set of tied scores is defined as the average of the ranks to which they would have been assigned if they were not tied. Unfortunately, when one or more ties prevail, it is no longer possible for r_s to take the values -1 or $+1$ even when the association is perfect. As a result, we need to make an adjustment or correction for ties. The formula for r_s then becomes

$$r_s = \frac{n^3 - n - 6 \sum d_i^2 - 6(t' + u')}{\sqrt{n^3 - n - 12t'}\sqrt{n^3 - n - 12u'}}, \quad (3)$$

where $t' = (\sum t^3 - \Sigma t)/12$ for t , which represents the number of tied scores at any given rank in the X set, and the sums Σ are over all the sets of t tied X ranks. Similarly, $u' = (\sum u^3 - \Sigma u)/12$ for ties in the Y set. Again, Spearman's rho in Equation 3 is equal to Pearson's r with ranks substituted for the original scores and with midranks used for ties. It should be noted that if there are no ties in either set, $t' = u' = 0$, then the formula for r_s in Equation 3 reduces to the expression in Equation 1.

Example With Real Data

Spearman's Rho as a Descriptive Statistic

In order to show how r can be computed, we will introduce some real data. Onwuegbuzie was interested in determining a relationship between the total number of points scored (x) by professional National Football League (NFL) teams and their winning

percentages (y) during the 1997–1998 football season. (Both variables are continuous.) All NFL teams were included in the study, yielding a sample size of 30. These data are presented in Table 1. Also, the scatterplot is displayed in Figure 1.

Although the NFL data represented scores that were normally distributed, with small skewness (.67 and .31 for total number of points scored and winning percentage, respectively) and kurtosis (.91 and $-.69$ for total number of points scored and winning percentage, respectively) coefficients, as can be seen from the SPSS output in Figure 2, we will use these data to demonstrate how to use Spearman's rho to assess the relationship between the total number of points scored (x) and winning percentage (y). The first step is to rank the X scores in the paired sample data from 1 (smallest score) to n (largest score), and independently rank the Y scores in the paired sample data from 1 (smallest score) to n (largest score). These ranks are displayed in Table 2.

Once the scores have been ranked and the difference in ranks calculated, squared, and summed, the next step is to compute the correction for ties. There are no ties in the number of points scored (i.e., x set), and so $t = 0$. However, for the winning percentage variable (i.e., y set), there are 11 sets of ties, as shown in Table 3. From Table 3, we have $u' = (281 - 29)/12 = 21.00$.

Notes: *t* = the number of tied scores at any given rank in the *x* set; *U* = the number of tied scores at any given rank in the *y* set; *U*² = the square of the number of tied scores at any given rank in the *y* set. Because there are no ties in the *x* set, *t* = 0.

for the null hypothesis that *x* and *y* are not related (i.e., that *x* and *y* are independent) versus the alternative hypothesis that there is a positive relationship between the total number of points scored and the winning percentage. The sampling distribution of *r_s* is provided in Table 4, for *n* ≤ 30. In this table, the *p* values given are (a) in the right tail if the value of the test statistic (i.e., *r_s*) is positive, and (b) in the left tail if the value of

the test statistic is negative. From Table 4, we can see that the right-tail *p* value is *p* < .001. Thus, we conclude that there is a positive relationship between the total number of points scored and the winning percentage.

For samples larger than 30, Spearman's rho that is uncorrected for ties is approximately normally distributed. Under the null hypothesis, *r_s* has a mean of zero and a standard deviation of

$$\frac{1}{\sqrt{n - 1}} \tag{4}$$

This implies that the *z* statistic for *r_s* is

$$Z = r_s \sqrt{n - 1}, \tag{5}$$

where the *p* values are obtained from the standard normal tables. If there are ties in either sample, then the corrected *r_s* is used with Equation 5. However, when ties prevail, the exact null distribution typically cannot be provided because the *p* values depend on the particular configuration of ties. Therefore, the *p* values obtained from the corrected *r_s* are approximate. For our NFL data, we have

$$Z = .84\sqrt{30 - 1} = 4.52.$$

The approximate *p* value corresponding to this *z* statistic from the standard normal tables is *p* < .0002.

Tail probability on $|r_s|$ for two-sided test

For $n > 30$, the probabilities not found using the normal distribution table by calculating $Z = r_s \sqrt{n-1}$. The left- or right-tail probability for r_s can be approximated by the left- or right-tail probability for Z , respectively.

Source: Adapted from Gibbons (1993).

Note: Entries labeled under the p column represent the cumulative probability, right-tail from the value of r_s to its maximum value of 1, for all $r_s \geq 0, n \leq 10$. The same probability is a cumulative left-tail probability, ranging from -1 to $-r_s$. For $10 < n \leq 30$, the table yields the smallest value of r_s (largest value of $-r_s$) for which the right-tail (left-tail) probability for a one-sided test is less than or equal to selected values, .100, .050, .010, .005, .001, shown in the top row. The same values correspond to $|r_s|$ for a two-sided test with tail probability .200, .100, .020, .010, .002, shown on the bottom row.

Figure 3 SPSS Output for Pearson's r and Spearman's Rho

Comparison With Pearson's r

From the SPSS output in Figure 3, it can be seen that Pearson's r is .87. Thus, the Spearman's rho correlation of .84 represents 96.6% of the Pearson's r correlation, which reflects the loss in relative efficiency as a result of applying Spearman's rho on approximately normal data. Nevertheless, using Cohen's criteria of .1 for a small correlation, .3 for a moderate correlation, and .5 for a large correlation, Spearman's rho correlation still is extremely large.

SPLIT HALF RELIABILITY

All observations and all measurements contain error. The focus of much work in measurement is to minimize and estimate the amount of error in any given measurement. In classical test theory, X is an observed score that is composed of

T , the true score, and E , the error score: $X = T + E$. The true score is never known, but it can be thought of as the long-range average of scores from a single instrument administered to an individual an infinite number of times (the expected value or expected score). The error score is random and may have many sources, including testing conditions, individual characteristics that fluctuate from administration to administration, differences in forms, or instability of an individual's ability or trait over time.

This random error score is quite different from systematic sources of error, such as testwiseness, which may systematically increase an individual's score on each administration. Since testwiseness is systematic or constant, it finds its way into the true score and creates problems regarding validity because the trait being measured inadvertently may be influenced by testwiseness. Random error, since it varies randomly, influences the consistency of scores but not the expected value of a score (the true score) and thus influences reliability, not validity.

Theoretically, we can estimate the amount of error if we know how much of a given score is due to errors of measurement. If we were able to test a single person

repeatedly without the effects of recall and fatigue, variation in their scores would be considered measurement error. If there were no measurement error, they would get the same score on each administration. Since it is not possible to test individuals repeatedly without the interference of recall and fatigue, we employ groups to estimate measurement error variance. This allows us to estimate the standard error of measurement, or the typical amount of measurement error in a set of scores.

If we take the classical test theory model of scores and consider groups of scores and their variances, we see that the variance of the observed scores equals the sum of the variance of true scores and the variance of error scores: $S_X^2 = S_T^2 + S_E^2$ (in sample notation).

This is the long way of introducing the need for reliability: Reliability is a tool used to estimate the standard error of measurement, but it also has some intrinsic benefits in and of itself. Theoretically, reliability is considered the correlation between scores on two parallel forms of a test. The idea is that if there is no measurement error at work, scores from two parallel forms administered to the same group of individuals should be perfectly correlated—each individual should obtain the same score. It can be shown that the correlation between two parallel forms of a test is equal to the ratio of true score variance to observed score variance, or the proportion of variance in observed scores that is due to true individual differences:

$$r_{tt} = \frac{S_T^2}{S_X^2}.$$

This reliability coefficient can then be used in estimation of the standard error of measurement because it tells us the proportion of observed variance that is true variance; the standard error of measurement is a function of the proportion of observed variance that is true variance.

Estimating Reliability

Based on the classical test theory conception of reliability, scores are reliable to the extent that individuals' scores remain constant on repeated measurements. One way to estimate the degree of consistency of scores is on the basis of the idea of internal consistency of

performance. One way to think about internal consistency is to split the test in half and consider each half a parallel form of the test, evaluating the consistency of performance on the two halves.

This form of reliability is best estimated when the actual measurement procedure employs a single form, in which error results from item or content sampling error. This is typically done by administering the single form to each individual and then selecting some method of splitting the test in half to obtain two scores for each individual. The two scores resulting from the two halves are then correlated. This correlation is the split half reliability coefficient.

Formal Conditions for Split Half Reliability

Split half reliability is estimated from the administration of a single form on a single occasion. This is appropriate when the measurement procedure includes only one form or the inference from scores is based on the ability to generalize beyond the items selected for that form. Knowledge of split half reliability allows one to generalize from one sample of items to a larger domain of items. To be a coefficient of reliability, the split halves should be equivalent in terms of content specifications and statistical properties (primarily item difficulties).

There are many methods of splitting a test into halves. One could consider a careful systematic split securing equivalent halves in terms of content and difficulty. A more common approach is to divide items alternately, placing the odd-numbered items into one half test and the even-numbered items into the other half test. Since most tests are organized by content areas and difficulty, this approach provides essentially equivalent halves. Another method would be to simply randomly assign items to each half; however, random sampling could easily lead to nonequivalent halves. Whatever method is used, the correlation of scores from the two halves provides the split half reliability estimate.

Because this method of reliability estimation is based on a single form of a test and the inference regarding score consistency includes generalizing

from performance on a sample of items to performance on the domain of items, sampling error will be impacted by the number of items. All else equal, more items provides more consistent scores. Since we know that test length affects reliability, we need to adjust for the fact that we have a correlation from a test of half the length of the test of interest (the complete form). This is done by employing the Spearman-Brown prophecy formula. An estimate of the complete-form reliability is obtained by taking 2 times the split half reliability divided by 1 plus the split half reliability:

$$\hat{r}_H = \frac{2r_{AB}}{1 + r_{AB}}$$

This form of reliability recognizes that reliability can be estimated from consistent performance within a single test, based on two parallel or equivalent subtests. Note that the use of any one method to split the test in half is at least partially arbitrary—there is no theoretical justification for any given split. If the two halves are not equivalent, the resulting correlation will underestimate the reliability of the full test.

General Issues Regarding Reliability

Because the split half estimate of reliability is based on a correlation, it is not simply a characteristic of the measurement instrument itself. Score variability directly influences correlations, such that all else equal, the more score variance present, the higher the correlation and thus the higher the reliability. Correlational forms of reliability are sample specific and thus not necessarily generalizable to other samples. They do, however, provide an estimate of score consistency for the scores at hand.

In any estimate of reliability, conditions present during the specific administration of the measurement instrument can impact performance and scores in random ways, leading to lower consistency of scores and lower reliability. Each type of reliability estimate (e.g., split half reliability) also captures a specific form of random error. The split half reliability primarily captures measurement error due to sampling items from a domain, a form of sampling error. If this source of error is important to estimate given the measurement

procedure (because a single form is used, and we assume it is a random, representative sample of the domain), then it is an appropriate form of reliability. Technically speaking, an estimate of reliability should be obtained for each set of scores because any one estimate is sample specific, and the argument of generalizability across samples is difficult to make.

Finally, because sampling error is a function of sample size, all else equal, longer forms will yield higher reliability coefficients. Better, larger samples of items from the domain will reduce the likelihood that two forms differ in their ability to cover the domain. Also, because of the arbitrary aspect of methods to split a test form in half, other internal consistency measures are generally thought to be better, including coefficient alpha.

SPREADSHEET FUNCTIONS

A spreadsheet function is a predefined formula. Excel, the most popular spreadsheet, has several categories of functions, including one labeled *statistical*.

One of the most simple of these functions is AVERAGE, which computes the average of a set of values. For example, the following statement averages the numbers in cells A1 through A3:

```
=AVERAGE(A1:A3)
```

The name of the function is AVERAGE, and the argument is A1:A3n.

A similar common function produces the sum of a set of cells:

$$=SUM(A1:A3)$$

In both cases, the results of these calculations are placed in the cell that contains the statement of the function. For example, to use the SUM (or any other) function, follow these steps:

1. Enter the function in the cell where you want the results to appear.

2. Enter the range of cells you want the function to operate on.
3. Press the Enter key, and voila! There you have it. Figure 1 shows the function, the argument, and the result.

Functions can be entered directly when the name of the function and its syntax are known or by means of the Insert command. Some selected Excel functions that perform statistical operations are shown in Table 1.

SPURIOUS CORRELATION

In social science research, the idea of spurious correlation is taken to mean roughly that when two variables correlate, it is not because one is a direct cause of the other but rather because they are brought about by a third variable. This situation presents a major interpretative challenge to social science researchers, a challenge that is heightened by the difficulty of disentangling the various concepts associated with the idea of spurious correlation.

Correlation and Causation

Drawing appropriate causal inferences from correlational data is difficult and fraught with pitfalls. One basic lesson social scientists learn in their undergraduate statistics education is that correlation does not imply causation. This adage is generally taken to mean that correlation *alone* does not imply causation. A correlation between two variables X and Y is not sufficient for inferring the particular causal relationship “ X causes Y ” because a number of alternative causal interpretations must first be ruled out. For example, Y may be the cause of X , or X and Y may be

produced by a third variable, Z , or perhaps X and a third variable, Z , jointly produce Y , and so on.

The statistical practice in the social sciences that is designed to facilitate causal inferences is governed by a popular theory of causation known as the *regularity theory*. This theory maintains that a causal relation is a regularity between different events. More specifically, a relationship between two variables X and Y can properly count as causal only when three conditions obtain: (a) X precedes Y in time; (b) X and Y covary; and (c) no additional factors enter into, and confound, the X - Y relationship.

The third condition requires a check for what social scientists have come to call *nonspuriousness*. A relationship between X and Y is said to be nonspurious when X is a direct cause of Y (or Y is a direct cause of X). A relationship between X and Y is judged nonspurious when we have grounds for thinking that no third variable, Z , enters into and confounds the X - Y relationship. In this regard, researchers typically seek to establish that there is neither a common cause of X and Y nor a cause intervening between X and Y .

Senses of Spurious Correlation

The term *spurious correlation* is ambiguous in the methodological literature. It was introduced by Karl Pearson at the end of the 19th century to describe the situation in which a correlation is found to exist between two ratios or indices even though the original values are random observations on uncorrelated variables. Although this initial sense of a spurious correlation remains a live issue for some social science researchers, it has given way to a quite different sense of spurious correlation. In the 1950s, Herbert Simon redeployed the term to refer to a situation where, in a system of three variables, the existence of a misleading correlation between two variables is produced through the operation of the third causal variable. H. M. Blalock’s extension of Simon’s idea into a testing procedure for more-complex multivariate models has seen this sense of a spurious correlation come to dominate in the social sciences. As a consequence, the social sciences have taken the problem of spuriousness to be equivalent to checking for the existence of third variables.

A Typology of Correlations

In order to understand that this problem of the third variable is not really a matter of spuriousness, it is important to be able to identify different types of correlations in terms of their presumed causes. The following is a typology of such correlations identified in terms of different kinds of presumed causes. These various correlations are sometimes confused when considering the problem of spuriousness.

At the most general level, the typology identifies two kinds of correlation: accidental and genuine. Accidental correlations are those that cannot be given a proper causal interpretation. There are two types of accidental correlation: nonsense and spurious. By contrast, genuine correlations are amenable to a proper causal interpretation. There are two types of genuine correlation: direct and indirect.

Nonsense correlations are those accidental correlations for which no sensible, natural causal interpretations can be provided. Statisticians delight in recounting the more amusing of these cosmic coincidences, such as the high positive correlation between birth rate and number of storks for a period in Britain or the negative correlation between birth rate and road fatalities in Europe over a number of years. In the statistics literature, these are sometimes called *illusory correlations*. These correlations exist, of course, but they cannot be given a plausible causal interpretation.

As characterized here, spurious correlations are accidental correlations that are not brought about by their claimed natural causes. To be true to their name, spurious correlations cannot be genuine correlations because they are false. They are artifacts of method and arise from factors such as sample selection bias; use of an inappropriate correlation coefficient; large sample size; or errors of sampling, measurement, and computation. Karl Pearson's original sense of spurious correlation mentioned above belongs here because the misleading value of ratio correlations depends, not on the relationship between the variables in question, but on their sharing of highly correlated components.

Direct correlations are genuine correlations for which one of the correlates is said to be a direct cause of the other. For example, heavy trucks are a direct

cause of road damage, and frequent and intense sun spots directly cause radio transmission noise. The social sciences are replete with empirical studies that are concerned with establishing direct causal relations. For example, manifest independent variables are examined in outcome studies on the assumption that they impact measured dependent variables in a causally direct way. Just as indirect correlations are often misleadingly called spurious correlations, so direct correlations are sometimes misleadingly called nonspurious correlations.

Indirect correlations are the genuine correlations that are produced by common or intervening causes and that we misleadingly call spurious correlations. However, there is nothing spurious about them at all. So-called spurious correlations are really genuine correlations, so their existence can hardly be denied by claiming that they are brought about by some underlying third variable. For example, if general intelligence is the common cause of correlated IQ performance on the verbal and numerical subtests of an intelligence test, then those subtest performances are indirectly and genuinely correlated. Clearly, this correlated IQ performance is not spurious because general intelligence explains why the correlation obtains; it does not render the correlation nonexistent or give us grounds for thinking that this is so.

From this analysis, it is clear that spurious correlations, properly named, must be regarded as a class of accidental correlations; otherwise we cannot sensibly deny the causal relations they are mistakenly thought to express.

Generative Causation

Tests for so-called spurious correlations are generally carried out to determine whether causal relations are empirical regularities. For this task, the regularity theory of causation is adequate, but only up to a point. Its requirements of temporal priority and covariation capture the idea of regular succession, but in order to properly understand the so-called problem of spuriousness, it is necessary to go beyond the restrictions of the regularity theory. A theory that allows us to do this is the generative theory of causation. The generative

theory depicts causation as a relation where, under appropriate conditions, a causal mechanism *produces* its effect. For this to happen, the causal mechanism must connect to its effect and have the power to generate that effect, usually when stimulated by the appropriate causal condition. It should be noted that it is the productivity of a generative mechanism that makes it a causal mechanism, and for this to be possible, there must be a naturally necessary connection that allows for a transmission of power from a cause to its effect. This causal power exists irrespective of whether it is currently being exercised. As such, it is properly viewed as a *tendency*, that is, an existing state of an object which, if unimpeded, will produce its effect. When it is unimpeded, we are able to diagnose the presence of the causal mechanism on the basis of the triggering condition(s) or its presumed effect(s) or both.

Unlike the regularity theory of causation, the generative theory is able to accommodate explanatory theories that are concerned with illuminating unobserved causal mechanisms. We need a theory of causation that affords us the conceptual space to do this because many of the world's causal mechanisms are not open to direct inspection. This is certainly true of the social sciences, where many of the postulated causal mechanisms are internal states. Intellectual abilities, personality traits, and emotional states are obvious cases in point.

Causation and Spuriousness

Simon's influential analysis of spurious correlation reveals a commitment to something like the regularity theory of causation. He notes that in order to distinguish true from spurious correlation, the term *cause* must be defined in an empiricist manner, with no reference to necessary connections between events, as the generative theory of causation makes.

Simon believes that a commitment to empiricist thinking about causality enables him to distinguish true from spurious correlations as he understands them. Ironically, however, this commitment actually prevents him from drawing his distinction properly. Recall that, for Simon, correlations are spurious if

they are brought about by common or intervening causes. Now, given that many of these causes will be latent or unobserved, it follows from a commitment to the regularity theory of causation that for a methodologically acceptable treatment of these variables to be possible, Simon and fellow empiricists must focus on altogether different variables at the manifest level. But this cavalier ontological attitude threatens to wreck our efforts to obtain genuine causal knowledge because the manifest replacement variables cannot act as surrogates for their latent variables, which are common and intervening causes. They are ontologically distinct from such causes and, although as causal conditions they may trigger their latent counterparts, they do not function as major causal mechanisms that determine so-called spurious correlations. Clearly, a coherent perspective on third variables that are latent variables requires a generative theory of causation.

Conclusion

When addressing the third variable problem, methodologists and researchers employ the misleading term *spurious correlation* to speak about genuine, indirect correlations. This practice only muddies the waters. Drawing causal inferences from correlational information is as difficult as it is important, and being clear about our key concepts can only facilitate such an undertaking. Not only is the terminology confusing, and thereby an impediment to understanding, but it also encourages a misleading view about the relation between causation and spuriousness that has the potential to misguide our causal modeling practices.

STANDARD DEVIATION

The standard deviation (abbreviated as *s* or *SD*) represents the average amount of variability in a set of scores as the average distance from the mean. The larger the standard deviation, the larger the average distance each data point is from the mean of the distribution.

The formula for computing the standard deviation is as follows:

$$s = \sqrt{\frac{\sum (X - \bar{X})^2}{n - 1}}$$

where

s is the standard deviation,

Σ is sigma, which tells you to find the sum of what follows,

X is each individual score,

\bar{X} is the mean of all the scores, and

n is the sample size.

This formula finds the difference between each individual score and the mean $X - \bar{X}$, squares each difference, and sums them all together. Then it divides the sum by the size of the sample (minus 1) and takes the square root of the result. As is apparent, the standard deviation is an average deviation from the mean.

Here is a sample data set for the manual computation of the standard deviation:

5, 4, 6, 7, 8, 6, 5, 7, 9, 5

Table 1 Computing the Standard Deviation

<i>X</i>	$(X - \bar{X})$	$(X - \bar{X})^2$
5	-1.2	1.44
4	-2.2	4.84
6	-.2	.04
7	.8	.64

5	-1.2	1.44
7	.8	.64
9	2.8	7.84
5	-1.2	1.44
Sum	0	21.6

To compute the standard deviation, follow these steps:

1. List each score. It doesn't matter whether the scores are in any particular order.
2. Compute the mean of the group.
3. Subtract the mean from each score.
4. Square each individual difference. The result is the column marked $(X - \bar{X})^2$ in Table 1.
5. Sum all the squared deviations about the mean. As you can see in Table 1, the total is 21.6.
6. Divide the sum by $n - 1$, or $10 - 1 = 9$, so then $21.6/9 = 2.40$.
7. Compute the square root of 2.4, which is 1.55. That is the standard deviation for this set of 10 scores.

What we now know from these results is that each score in this distribution differs from the mean by an average of 1.55 points.

The deviations about the mean are squared to eliminate the negative signs. The square root of the entire value is taken to return the computation to the original units.

Every statistical package available computes the standard deviation. In Figure 1, Excel's Data Analysis ToolPak was used to compute a set of descriptive statistics, including the standard deviation.

Summary

- The standard deviation is computed as the average distance from the mean.
- The larger the standard deviation, the more spread out the values are, and the more different they are from one another.
- Just like the mean, the standard deviation is sensitive to extreme scores.
- If $s = 0$, there is absolutely no variability in the set of scores, and they are essentially identical in value. This will rarely happen.

STANDARD ERROR OF THE MEAN

The standard error of the mean (or *standard error*, for short) is a measure of how representative a sample is of the population from which it was drawn. Using information about how people vary within a sample and how big that sample is, we can estimate how

much variation we would expect to see if we drew multiple samples from a given population.

The concept of the standard error of the mean is similar to the standard deviation. Just as the standard deviation allows us to see how much individuals vary within a sample, so the standard error allows us to estimate how much samples will vary within a population. This is important because in research, it is seldom possible to observe the whole population we are interested in. We nearly always observe a smaller sample and make inferences from it to the population. For example, if we were interested in finding out whether Americans, on average, have a higher body mass index (BMI) than Europeans do, then we would take a sample of Americans and a sample of Europeans and find out the average BMI of both samples. It would be unfeasible to get this information for all members of both populations, but using the information we get from our sample, we can build up a picture about what the distribution of all possible samples would look like.

Take a look at Figure 1a. This shows a normal distribution of BMI scores in a sample of 50 Americans using some hypothetical data. The mean BMI score for this sample is 24.35. Based on the nature of normal distributions, the standard deviation of 3.31 tells us that 68% of all individuals in this sample have a

Figure 1a A Normal Distribution of Body Mass Index Scores From a Hypothetical Sample of 50 Americans

score between 21.04 and 27.66 (± 1 standard deviation) and that 95% have a score between 17.73 and 30.97 (± 2 standard deviations).

Now take a look at Figure 1b. This also shows a normal distribution, but this time it is for all possible sample means from the population of Americans (again using hypothetical data). Undoubtedly there will be some variation between the different possible samples we could have selected. We may have selected a particularly overweight group of Americans, for instance. Imagine we *could* take all possible samples. Each one would have a different makeup of people and thus would have a slightly different average BMI. The standard error tells us the degree to which sample means drawn from the same population are likely to differ.

Notice that the mean score of samples is the same as the mean score of the sample of 50 individuals. Notice also that the distribution of all sample means is narrower. This makes sense when we realize that we are less likely to observe extreme means than we are to observe extreme individuals. What is really important, though, is that we are now able to estimate the upper and lower boundaries of the mean that we expect to see if the sample has been drawn from this population. Using the standard error of .47,

Figure 1b A Normal Distribution of Hypothetical Mean Body Mass Index Sample Scores From an American Population

we see that 68% of all sample means will be between 23.88 and 24.82, and 95% will be between 23.41 and 25.29. If we find a sample that has a mean score outside those limits, then we can assume that it is not from the same population (using 95% confidence intervals).

The concept of the standard error of the mean was first introduced by Ronald Fisher in 1925 in his book *Statistical Methods for Research Workers*. It is a concept that really underpins the frequentist philosophy of statistics that dominates the social sciences. Because if we can estimate the distribution of all possible sample means, then we can also estimate the probability of observing the mean we have observed in a given population and thus test hypotheses.

Assumptions of the Standard Error of Mean

1. The data are normally distributed.
2. The data occur at an interval or ratio level.

An Example

Let's take the example given earlier regarding BMI and nationality. Let's say we took 50 Americans and 50 Europeans and took their height and weight and then calculated a BMI for each person. The means and standard deviations appear in Table 1.

We find that the average BMI is 24.35 for the Americans and 20.69 for the Europeans in our study. Now let's calculate the standard error associated with each of these means. To do this, we need to know how wide the variability is between the scores in each

Table 1 A Comparison of Hypothetical Average Body Mass Index Scores for Americans and Europeans

Nationality	<i>N</i>	Mean	<i>SD</i>
American	50	24.35	3.31
European	50	20.69	1.47
Total	100	22.52	3.14

sample (the standard deviation, or σ) and how large the samples are (N).

$$\text{Standard error} = \sigma/\sqrt{N}.$$

You can see that the standard error will increase as the variability in the data (σ) increases and will decrease as the sample size (N) increases. So for Americans,

$$\text{standard error} = 3.31/7.07 = .47.$$

And for Europeans,

$$\text{standard error} = 1.47/7.07 = .21.$$

According to the principles underlying normal distributions, the standard error shows us that we can be 95% confident that the population BMI score for Americans is somewhere between 23.41 (mean – 2 standard errors) and 25.29 (mean + 2 standard errors) and that for Europeans, the population mean is somewhere between 20.27 and 21.11. Since the boundaries between the two groups do not cross, we can be 95% confident that the two samples are from different populations.

Calculating Standard Error Using SPSS

SPSS will calculate the standard error of a mean through the DESCRIPTIVES option or through the COMPARE MEANS option. As we have a grouping variable in this example, we will go through the COMPARE MEANS option.

1. Go to ANALYZE, COMPARE MEANS, and then MEANS. A command box will appear with all your variables on the left-hand side.
2. Select the variable of interest and arrow it into the *Dependent list* box.
3. Select the grouping variable and arrow it into the *Independent list* box.
4. Click on OPTIONS, find Std. Error of Mean in the left-hand box, and arrow it into the right-hand box.
5. Now click CONTINUE and OK. In the output, you will get a table that shows the standard error, along with the other descriptive statistics (see Table 2).

Table 2 The Standard Error and Other Descriptive Statistics

		Report		
BMI				
<i>Nationality</i>	<i>Mean</i>	<i>N</i>	<i>Std. Deviation</i>	<i>Std. Error of Mean</i>
American	24.3520	50	3.31073	.46821
European	20.6900	50	1.47250	.20824
Total	22.5210	100	3.14400	.31440

If you wanted to look at the standard errors associated with each mean graphically, you could select the ERROR-BAR option in GRAPHS. For this example, we want to create a simple error bar graph for summaries of separate variables. Highlight the variables of interest and put them into the ERROR-BAR box. Figure 2 shows the resulting bar graph.

STANDARD ERROR OF MEASUREMENT

In order for the scores produced by a measure (referred to hereinafter as scores) to prove useful for the purpose of basic or applied research, it is critical that the measure be reliable. Reliability can be viewed from the perspective of systematic versus nonsystematic sources of variability in scores. To the degree that scores are systematic, they lead to measurement that is precise. Thus, if the level of an attribute (e.g., verbal ability) of a measured entity (e.g., person) remains unchanged, then repeated measurement of the attribute should produce scores that do not vary from one measurement occasion to the next. The greater the degree to which the variability in scores is a function of systematic variance, the more reliable the measure.

Scores are nonsystematic to the extent that they contain error variance that is random in nature. The greater the degree of error variance, the more scores will vary from one measurement occasion to the next. Error in the scores will cause them to vary across occasions even though the level of the measured attribute remains constant.

Ways of Viewing the Reliability of a Measure

There are two basic ways of characterizing the reliability of a measure. One is the *reliability coefficient* (r_{xx}), which varies between 0 (totally unreliable) and 1 (totally reliable).

Conceptually, it is the proportion of variance in scores that is systematic. It can be estimated through three general strategies. The *test-retest strategy* requires that a number (N) of entities be measured on two occasions with the same k -item measure. The *alternative forms strategy* involves measuring the N entities at approximately the same time using two forms of a measure that are designed to assess the same underlying construct but that have different items. The *internal consistency method* relies on measuring the N entities on a single occasion with a measure having multiple (k) items.

The reliability of a measure can also be characterized in terms of the *standard error of measurement*, denoted herein as σ_{meas} , which should not be confused with the standard error of the mean (σ_M). Assuming that an attribute of an entity was measured a large number of times with a specific measure of the variable x and that its level remained constant over time, the σ_{meas} would be the standard deviation of scores produced by the measure. Alternatively, the σ_{meas} can be thought of in terms of the standard deviation of scores resulting from measuring a given entity with j measures of x that meet the classical test theory requirements of being mutually parallel. In practice, the estimation of σ_{meas} requires neither (a) the repeated measurement of the entity with a single measure of x nor (b) the measurement of the entity with j parallel measures of x .

Assuming the measurement of x across N measured entities, an estimate of σ_{meas} (denoted hereinafter as $\hat{\sigma}_{\text{meas}}$) can be obtained using estimates of the reliability of the measure (r_{xx}) and the standard deviation of scores produced by the measure (s_x):

$$\hat{\sigma}_{\text{meas}} = s_x \sqrt{1 - r_{xx}}$$

For example, assume that a researcher measured the quantitative ability of 30 individuals using a 25-item test and that the resulting scores had a mean of 18, standard deviation of 5, and an internal consistency-based estimate of reliability of .80. In this case, $\hat{\sigma}_{\text{meas}}$ would be

$$\begin{aligned} \hat{\sigma}_{\text{meas}} &= s_x \sqrt{1 - r_{xx}} \\ &= 5 \sqrt{1 - .80} \\ &= 2.24. \end{aligned}$$

As should be apparent from the formula for the $\hat{\sigma}_{\text{meas}}$, it can vary between the values of 0 (when $r_{xx} = 1$) and s_x (when $r_{xx} = 0$).

Uses of the Standard Error of Measurement

Assuming that the value of r_{xx} is known, the $\hat{\sigma}_{\text{meas}}$ can be used to establish a confidence interval around an

individual's true (x_t), as opposed to the individual's observed (x_o) score. The estimated value of x_t is given by

$$\hat{x}_t = x_o r_{xx}$$

For example, assume that a person took the above-described quantitative ability test and obtained a score of 15. The individual's estimated true score would be

$$\begin{aligned}\hat{x}_t &= x_o r_{xx} \\ &= 15(.80) \\ &= 12.\end{aligned}$$

Having this estimate, a 95% confidence interval about it can be established by use of

$$\hat{x}_t \pm 1.96\sigma_{\text{meas}}$$

Thus, the individual's true score would fall in an interval having a lower limit of $7.61 = 12 - 1.96(2.24)$ and an upper limit of $16.39 = 12 + 1.96(2.24)$. In view of the width of the interval, the test would not be very useful for applied purposes, especially if scores on the test were used for important decision-making purposes (e.g., employee hiring). Note, however, that if the same test had a reliability of .90, the confidence interval would extend from 8.90 to 15.10. The general notion here is that the smaller the $\hat{\sigma}_{\text{meas}}$, the narrower the confidence interval.

Importance of Narrow Confidence Intervals

Narrow confidence intervals are important when scores on one variable (e.g., x) are used to predict scores on another (e.g., y). For example, GRE scores are used by most universities to predict success in graduate school. In this and other prediction contexts, the narrower the confidence interval, the greater the degree to which the scores will predict other variables accurately. The reason for this is that nonsystematic variance in scores leads to the attenuation of relations between predictor scores and scores on a predicted variable.

In practice, $\hat{\sigma}_{\text{meas}}$ can be decreased by increasing the reliability of a measure. There are several ways of doing this. In the case of a multi-item measure, two strategies are (a) increasing the number of items in the measure, and (b) including items that have a high degree of correlation with one another.

STANDARD SCORES

A standard score is a score that uses the same metric as other standard scores so that they can be compared to one another easily. Any standard score can be defined as a converted score (based on the raw score) with a set mean and standard deviation. Popular examples are scores on IQ tests and the two types that we will cover here, are called z scores and T scores.

What both of these, as well as other standard scores, have in common is that they share the same mean and standard deviation. It is because of this that standard scores from different distributions can be compared to one another. However, the one restriction is that only the same type of standard scores can be compared. One can compare z scores from one distribution with z scores from another, but one cannot compare z scores from one distribution with T scores from another.

For example, here is a list of 10 raw scores and their corresponding z scores. All the information needed to compute the z scores is contained in Table 1.

Table 1 Raw Scores and Standard Scores

	Raw Score	<i>z</i> Score
	87	0.66
	78	-0.07
	93	1.15
	69	-0.81
	95	1.31
	57	-1.79
	87	0.66
	71	-0.64
	69	-0.81
	68	-0.89
Mean	77.40	
<i>s</i>	12.58	

Note: *s* = standard deviation.

The *z* scores are standard scores with a mean of 0 and a standard deviation of 1. The formula for computing a *z* score is

$$z = \frac{(X - \bar{X})}{s},$$

where

z is the standard *z* score,

X is the raw score,

\bar{X} is the mean of the distribution, and

s is the standard deviation for the distribution.

For example, where the mean is 77.4 and the standard deviation is 12.58, the *z* score for a corresponding raw score of 69 is $-.81$ (almost one standard score below the mean). Here's the formula:

$$z = \frac{(69 - 77.4)}{12.58}.$$

Another popular type of standard score is the *T* score. *T* scores are standard scores with a mean of 50 and a standard deviation of 10. The formula for computing a *T* score is

$$T = 50 + 10z,$$

Table 2 Raw Scores, *z* Scores, and *T* Scores

<i>s</i>	12.58		

Note: *s* = standard deviation.

where

T is the standard *T* score and

z is the standard *z* score.

Table 2 shows the listing of *T* scores and *z* scores for the raw scores shown earlier.

For example, when the mean is 77.4 and the standard deviation is 12.58, the *T* score for a corresponding raw score of 69 is 41.92 (almost one standard score below the mean):

$$T = 50 + 10z \text{ or } 50 - 8.1 \text{ or } 41.9.$$

STANDARDS FOR EDUCATIONAL AND PSYCHOLOGICAL TESTING

The current revision of the *Standards for Educational and Psychological Testing* is the third version of the *Standards* and, like its predecessors, it is the collaborative effort of three prominent national associations

interested in educational and psychological tests: the American Educational Research Association (AERA), the American Psychological Association (APA), and the National Council on Measurement in Education (NCME). The first edition of the *Standards* appeared in 1974. It replaced a document published by APA in 1966 and prepared by a committee representing the APA, AERA, and NCME titled *Standards for Educational and Psychological Tests and Manuals*. The 1974 *Standards* was revised in 1985.

To identify revisions needed for the *Standards*, a rigorous and diligent effort to obtain input from the broad measurement community was undertaken. In 1993, the presidents of APA, AERA, and NCME appointed a 15-member Joint Committee with diverse backgrounds in testing and assessment in a variety of settings. The Joint Committee completed the revision during 6 years. Three extended periods of public review and comment provided the Joint Committee with more than 8,000 pages of comments from upwards of 200 organizations and individuals. The Joint Committee considered all this input and developed a draft document. An extensive legal review of this draft was then conducted to explore potential liability issues and to ensure compliance with existing federal law. The revised *Standards* represents a consensus of the Committee and has the endorsement of each of its three sponsoring organizations.

Purpose of the *Standards*

The intent of the third edition of the *Standards* is to promote sound and ethical use of tests and to provide a basis for evaluating the quality of testing practices by providing a frame of reference to assure that all relevant issues are addressed. Like its predecessors, the third edition attempts to reflect professional consensus regarding expectations for the development, validation, and use of educational and psychological tests. The *Standards* is intended to speak broadly to individuals (e.g., students, parents, teachers, administrators, job applicants, employees, clients, patients, supervisors, executives, and evaluators, among others), institutions (e.g., schools, colleges, businesses, industry, clinics, and government agencies), and society as a

whole about tests and testing. The *Standards* can be used to help test publishers decide how to develop, validate, and present tests. The *Standards* can also be used by test users (those who administer tests) to select, use, and evaluate tests. The *Standards* does not attempt to provide psychometric answers to public policy issues that involve testing. Instead, the *Standards* encourages making relevant technical information about tests and testing available so that those involved in policy development may be fully informed.

Organization of the *Standards*

The current revision of the *Standards* contains three parts. Part I addresses test construction, evaluation, and documentation; Part II discusses fairness in testing; and Part III covers testing applications. The standards that apply to the development of tests and those that are of interest to test publishers appear primarily in Part I. The standards identified in Part II and Part III apply primarily, but not exclusively, to test users.

Part I includes the following chapters:

1. Validity
2. Reliability and Errors of Measurement
3. Test Development and Revision
4. Scales, Norms, and Score Comparability
5. Test Administration, Scoring, and Reporting
6. Supporting Documentation for Tests

Part II includes the following chapters:

7. Fairness in Testing and Test Use
8. The Rights and Responsibilities of Test Takers
9. Testing Individuals of Diverse Linguistic Backgrounds
10. Testing Individuals with Disabilities

Part III includes the following chapters:

11. The Responsibilities of Test Users
12. Psychological Testing and Assessment

13. Educational Testing and Assessment
14. Testing in Employment and Credentialing
15. Testing in Program Evaluation and Public Policy

Each chapter begins with contextual background intended to facilitate interpretation and application of the standards in that chapter. An index and a glossary that defines terms as they are used in the *Standards* also are provided.

Major Differences Between the Second and Third Editions of the *Standards*

The overall number of standards has increased from the 1985 edition for three reasons. First, new types of tests and uses for tests evolved after the 1985 revision. Several of the new standards apply only to these new developments, unlike the broad applicability that is characteristic of many of the continuing standards. Second, some standards are repeated, with context-relevant wording changes, in multiple chapters to accommodate users who refer only to those chapters that have direct relevance to their particular setting or purpose for testing. The wording changes enable standards to align with the content of the chapter. Third, standards addressing issues such as conflict of interest and equitable treatment of test takers have been added. According to the *Standards*, “The increase in the number of standards does not per se signal an increase in the obligations placed on test developers and test users.”

The 1985 *Standards* categorized each standard as either primary (to be met by all tests before they are used), secondary (desirable but not feasible in all situations), or conditional (importance varies with application). This distinction was eliminated for the third edition of the *Standards* because it was recognized that the various standards are not absolutes. The applicability of the standards can vary in relevance and importance based on the intended use(s) of a test and the role of the person(s) participating in the testing process (e.g., test taker, test administrator, test developer, test marketer, and those who make decisions

based on test results). The third edition also clarifies that some standards are broad and encompassing in their applicability and others are narrower in scope. Therefore, the standards should not be applied in a literal, rigid, or cookbook fashion. Instead, whether a test or use is judged acceptable may depend on several interrelated and interacting factors. These can include (a) the extent to which the test developer has met relevant standards, (b) the degree to which the test user has met relevant standards, (c) the availability of alternative, equally promising measures, (d) the extent of empirical research that supports the intended use of the measure, and (e) professional judgment. The *Standards* advises that before a test is operationally used for a particular purpose, “each standard should be carefully considered to determine its applicability to the testing context under consideration.”

Each chapter in the third edition contains more introductory material than did the second edition. The purpose of this additional information is to provide background for the standards specific to the chapter so that users can more easily interpret and apply the standards. The language, although prescriptive at times, “should not be interpreted as imposing additional standards.”

The third edition defines and clarifies several important terms. For example, the term *test* is defined as an “evaluative device or procedure in which a sample of an examinee’s behavior in a specified domain is obtained and subsequently evaluated and scored using a standardized process.” Thus the term *test* is broad, including both instruments that are evaluated for quality or correctness and instruments that are measures of attitudes, interests, traits, and dispositions, often referred to as scales or inventories rather than tests. Assessment is considered to be a broader concept than testing, but testing is part of assessment. *Assessment* refers to a process that integrates test information with background and contextual information, whereas *testing* refers to the results obtained from a specific instrument or instruments.

The new *Standards* broadens the meaning of the term *construct*. In previous editions, *construct* meant unobservable characteristics that must be inferred from multiple, related observations, a definition that

proved confusing and controversial. The third edition broadens the term to mean the “concept or characteristic that a test is designed to measure.” This change requires test professionals to specify the interpretation of the construct that will be made on the basis of a score or pattern of scores. This change also reflects a shift in the third edition of the *Standards* from discussing types of validity to discussing various *lines of validity evidence* that serve to enhance interpretation of a score relative to the construct the test is designed to measure.

Lines of Validity Evidence

Formerly, the *Standards* described three types of validity that a test may demonstrate: content, criterion-related (predictive and concurrent), and construct. The new *Standards* considers validity to be the extent to which multiple lines of evidence and theory “support the interpretations of test scores entailed by the proposed uses of tests.” According to the new *Standards*, then, validity is a function of the extent to which theory and empirical evidence support the assumption that a test score reflects the construct the test purports to measure. Five sources of such evidence of validity are identified in the *Standards*: test content, response processes, internal structure, relations to other variables, and consequences of testing.

Of these five sources of validity, three reflect historical conceptions of validity that have appeared in previous editions of the *Standards*. These are test content (equivalent to content validity), internal structure (equivalent to construct validity), and relations to other variables (equivalent to criterion-related validity). The two new sources of validity evidence are response process and consequences of testing. Evidence of response process validity indicates whether the test taker used the processes intended by the test developer, rather than an unintended process, to respond to a problem. For example, in responding to a mathematics problem, did the test taker apply the intended cognitive-mathematical process or an alternative process, such as guessing? Validity evidence related to the consequences of testing emerges when

the outcome and interpretation of the test fulfill the claims made for the test. For example, if a measure purports to predict those who will benefit from a particular psychological treatment, how well does it actually do so?

A number of advances and developments have occurred in testing since the *Standards* was released in 1999. Thus, this edition of the *Standards* should be considered a work in progress. AERA, APA, and NCME have already begun the revision process for the fourth edition. Although an exact publication date cannot be determined, it is expected to come early in the next decade.

STANFORD ACHIEVEMENT TEST

The Stanford Achievement Test Series (publisher: Harcourt Assessment) is a set of 13 norm-referenced grade-level assessments of academic achievement in mathematics, reading, language, spelling, science, social science, and listening. The Stanford Early School Achievement Test levels are designed to assess initial school learning across kindergarten and the first half of first grade. The Stanford Achievement Test (Primary 1–3, Intermediate 1–3, and Advanced 1–2) spans the second half of first grade through ninth grade. Finally, the three-level Stanford Test of

Academic Skills assesses performance on curricula in Grades 9 through 12.

This typically group-administered test is available in a number of formats, including general and secure forms, full-length and abbreviated batteries of multiple choice items, and large-print and Braille editions. Also, special screening procedures for assigning deaf and hard of hearing students to test levels have been developed by the Gallaudet Research Institute.

The test score metrics available to assist with the interpretation of student test performance include individual percentile rank, normal curve equivalent, stanine, grade equivalent, content cluster and process cluster performance category, and scaled score. The scaled score, derived from the vertical equating of test levels, is particularly useful for monitoring individual student achievement test results from year to year.

The design and materials for the latest (10th) edition of the Stanford were developed to conform to the 1999 AERA, APA, and NCME *Standards for Educational and Psychological Testing*. The design strategy emphasized universal design principles and visual characteristics that are appealing and resemble everyday instructional materials. Such features include full color “lifelike” illustrations, visually distinct framing of each question, placement of response bubbles on answer sheets to correspond with page and subtest location in the test booklet, and the absence of time constraints (although suggested testing times are given). Item development was responsive to widely promulgated national curriculum standards. To satisfy individual state academic standards, a core subset of items from the Stanford is augmented with specifically developed items on a state-by-state contract basis.

The Stanford was first published in 1923 by the World Book Company and is now published by Harcourt Assessment, the testing division of Reed Elsevier, which acquired Harcourt in 2001. The Stanford was developed for a longitudinal study of gifted children under the direction of Lewis M. Terman (1877–1956) and was first offered at only two elementary grade levels. The most recent update, the 10th edition, was normed in the spring and fall of 2002 and published in 2003. Regarded as the first standardized academic achievement test, the Stanford

has remained a highly respected assessment instrument with excellent psychometric characteristics.

STANFORD-BINET INTELLIGENCE SCALES

The Stanford-Binet Intelligence Scales is one of the most popularly used measures of intelligence. Around 1905, Parisian Theophilus Simon, in his work with developmental psychologist Jean Piaget, speculated about the successes and failures of elementary school children. As Piaget was becoming increasingly intrigued by the nature of some normal children’s failures to read, Simon was working with Alfred Binet to develop a test (for the school children of Paris) to predict and distinguish between those who would do well in school and those who would not.

The result of Simon and Binet’s efforts was the first intelligence scale (1905) used to identify children who were mentally retarded (or those who were thought not to be able to succeed in school). The items were arranged by difficulty at first and later on by age level, so by 1916, the test results yielded a *mental age* (MA) for test takers, and a ratio of chronological age (CA) and mental age provided a measure of whether a child was behind, even with, or ahead of his or her chronological age. For example, someone who is chronologically 120 months (10 years) old may have a mental age of 126 months and therefore be advanced in mental age, compared with chronological age.

The Simon-Binet scale became the Stanford-Binet scale in the early 20th century, when Lewis Terman

(then at Stanford University) authored the authoritative book on the administration and scoring of the test. Also, the IQ score, a ratio of mental age to chronological age, was first used. For the 120-month-old with a mental age of 126 months,

$$IQ = \frac{MA}{CA} \times 100 = \frac{126}{120} \times 100 = 105.$$

If one's mental and chronological ages are equal, then one's IQ score is 100, just about what we expect if someone is average.

It was convenient to have one number, a simple ratio of MA to CA, to express one's theoretical intelligence quotient. But this approach was never really embraced because the upper limit depends on the upper age limit for the test. For example, if the items go up only to an age level of 21 years, anyone with a CA greater than 21 years has to have an IQ less than 100. This is in part why we no longer think of intelligence as IQ but use more descriptive and informative terms for describing someone's level of intelligence.

The fourth edition of the Stanford-Binet is now the standard, and it is the result of many revisions over the past 100 years. The test, based on the *g* theory of intelligence, assesses three different general areas or types of intelligence: crystallized intelligence, fluid intelligence, and short-term memory. In theory, these types are independent of one another.

Crystallized intelligence reflects knowledge that is acquired or learned, such as the number of elements on the periodical table or the author of *Moby Dick*. Fluid intelligence is that general ability that Charles Spearman talked about, including such activities as problem solving, remembering, and learning. A test item that evaluates fluid intelligence might ask the test taker to copy a pattern created by the test administrator.

Today's Stanford-Binet assesses five different factors, fluid reasoning, knowledge, quantitative reasoning, visual-spatial processing, and working memory—outgrowths of the fluid, crystallized, and memory typology. Each of these areas is assessed verbally and nonverbally, resulting in 10 subtests. In the end, each individual test taker has a score for verbal and nonverbal performance and a full-scale intelligence score.

The Stanford-Binet assesses intelligence by beginning with those items that are the easiest and then finding out which items become so difficult that there is no need to test further. This range of difficulty helps define the starting and ending points in the scoring of performances.

The basal age is the lowest point on the test at which the test taker can pass two consecutive items that are of equal difficulty. The examiner can feel confident that the test taker is on firm ground at this point and could pass all the items that are less difficult. Ceiling age is the point at which at least three out of four items are missed in succession and is the place to stop testing.

The number correct on the test is then used to compute a raw score, which is converted to a standardized score and then compared with other scores from test takers in the same age group. Because the Stanford-Binet is a standardized test and has been normed extensively, such comparisons are easy to make and very useful.

STANINE

The term *stanine* comes from the field of measurement, for a person's performance on a test can be (and often is) converted into a stanine score. An examinee's stanine score shows the examinee's position relative to other test takers' positions. Because of this focus on relative performance, stanines are similar to percentile ranks, *T* scores, or normal curve equivalent (NCE) scores. Though like these other kinds of standard scores in purpose, stanines have many characteristics that make them unique and quite different from the others.

A person's stanine score will be a single-digit number, and it could be as high as 9, as low as 1, or equal

to any whole number in between. In the group of test takers that serves as the *reference group*, fewer individuals receive the higher and lower stanine scores, and most people earn stanine scores at or near the middle of the 9-point scale. Table 1 shows what percentage of individuals in the reference group receives each stanine score.

Although stanine scores are fairly easy to understand from the information in Table 1, they can be made even easier to understand by attaching verbal descriptors to the individual stanine scores or to groups of adjacent stanine scores. Some people recommend dividing the stanine scale into three parts and using the terms *above average*, *average*, and *below average* to describe those whose test scores position them in any of the top three, middle three, or bottom three stanine categories, respectively. Others

recommend using these descriptors: *outstanding* for stanine 9, *above average* for stanines 7 and 8, *average* for stanines 4, 5, and 6, *below average* for stanines 2 and 3, and *poor* for stanine 1. A few people recommend using a different label for each stanine category, as indicated in Table 2.

The Meaning and Origin of the Word *Stanine*

The word *stanine* is an abbreviation of the phrase *standard of nine*. With stanines, there is a standard of nine because the reference group is always divided into nine categories, or levels, with the specific percentages set equal to 4, 7, 12, 17, 20, 17, 12, 7, and 4. It doesn't matter whether the reference group is bright or dull, hard-working or lazy; the reference group's top 4% will end up getting a stanine score of 9, the next best 7% will receive a stanine score of 8, and so forth. Thus, the percentages in the various stanine categories are constant regardless of the characteristics of the reference group.

The term *stanine* was first used by the U.S. Army Air Force during World War II. Recruits were given a battery of placement tests, and each examinee's performance (on each portion of the test battery) was converted into a stanine score. At the time, having test scores converted into single-digit numbers was especially helpful, for each examinee's data were entered into a computer. Back then, however, data were typed on Hollerith punch cards, and it was far more efficient during data entry to use one column per score (without the need for any decimal points or negative signs).

Advantages of Stanines Over Raw Scores

After a test is administered and the examinees' work is scored, each test taker usually earns a raw score based on the number of questions answered correctly. Raw scores are useless by themselves. For example, if Johnny gets a 43 on a math test, there is no way to know from this raw score how well (or poorly) Johnny performed. If Johnny's raw score is converted into a percentage-correct score or compared to a cut-score

for passing the test, we get a better feel for how Johnny did. However, simply knowing Johnny’s percentage-correct score or whether he did or did not pass the test provides no information whatsoever as to how Johnny’s performance compares with that of others who took the same test.

When an examinee’s raw score is converted into a stanine score, we learn how that particular test taker compares with other test takers. There are different ways to convert a raw score into some other score that indicates, in a relative sense, how well or poorly a person has done when taking a test. Later in this entry, stanines will be compared with percentile ranks, *T* scores, and NCE scores.

Stanines, Norm-Referenced Tests, and Criterion-Referenced Tests

As indicated earlier, stanines provide information as to how a test taker performs relative to others in a reference group. Because of this inherent feature of stanine scores, they are used exclusively with norm-referenced tests. They are *not* to be used with criterion-referenced tests. With this latter kind of test, comparisons against others are of little or no interest to those who deal with the scores examinees earn.

Converting Raw Scores Into Stanine Scores

There are two ways to convert an examinee’s raw score into a stanine score. One of these methods can

be called the *ranking* procedure. The other method involves reference to a normal distribution, so this second method might be called the *normal distribution* procedure.

The ranking method for determining stanine scores is quite simple and straightforward. After the examinees’ raw scores are determined, those scores are ranked from high to low. Then, the top 4% are given a stanine score of 9, the next highest 7% are given a stanine score of 8, and so on. Note that this method of creating stanine scores makes no assumption as to the distributional shape of the raw scores.

The second procedure for determining stanine scores is used with tests that have been normed on a large group of individuals who have already taken the test and whose scores have been normalized. A normal distribution is divided into nine sections, with the upper and lower boundaries of each stanine section set equal to the *z* scores shown in Table 3.

Except for stanines 1 and 9, each stanine section has a width equal to one half of a standard deviation. Because a normal distribution is considered to have no upper or lower scores, stanine 9 has a boundary of $z = +1.75$ on the left but no boundary on the right. Similarly, stanine 1 has a boundary on the right of $z = -1.75$ but no boundary on the left.

Because of the known properties of a normal distribution, it is possible to define the boundary lines between adjacent stanine categories in terms of percentiles rather than *z* scores. Rounded to whole numbers, these percentile boundaries are shown in Table 4.

Table 3 Stanines *z* Scores

Stanines Located on the Left Side of the Normal Distribution			The Middle Stanine (i.e., Stanine 5)		Stanines Located on the Right Side of the Normal Distribution		
<i>Stanine section</i>	<i>Lower boundary</i>	<i>Upper boundary</i>	<i>Lower boundary</i>	<i>Upper boundary</i>	<i>Stanine section</i>	<i>Lower boundary</i>	<i>Upper boundary</i>
4	$z = -.75$	$z = -.25$	$z = -.25$	$z = +.25$	6	$z = +.25$	$z = +.75$
3	$z = -1.25$	$z = -.75$			7	$z = +.75$	$z = +1.25$
2	$z = -1.75$	$z = -1.25$			8	$z = +1.25$	$z = +1.75$
1	No lower boundary	$z = -1.75$			9	$z = +1.75$	No upper boundary

Table 4 Percentile Boundaries

<i>Adjacent stanines</i>	1 and 2	2 and 3	3 and 4	4 and 5	5 and 6	6 and 7	7 and 8	8 and 9
<i>Percentile of boundary</i>	4	11	23	40	60	77	89	96

Each of these percentiles, of course, can be determined by adding together the stanine percentages for those stanines located to the left of the boundary line being considered. For example, the percentile boundary separating stanines 5 and 6 can be determined by adding 4, 7, 12, 17, and 20.

How Stanines Are Used

Stanines are used in school settings to accomplish three different goals. In two of these uses, the focus is on the individual test taker. When stanines are used to accomplish the third goal, the focus is a group of test takers rather than a single person.

If a test yields just one score or a “total” score based on several parts of the test, that score often is converted into a stanine to show how the test taker performed relative to others in the reference group. For example, if the examinee’s stanine score is 8, that examinee would be thought of as having a relatively high position within the reference group. On the other hand, a stanine of 1 would indicate that an examinee was positioned quite low compared to others who took the same test. Stanine scores such as these are often used to place students into homogeneous learning groups.

If a test yields multiple scores, each for a different skill or competency being measured, a test taker’s resulting scores can each be converted into a stanine. Then, the individual’s various stanine scores can be examined so as to identify areas of strength and areas of weakness. For example, if a pupil earns a stanine score of 8 in reading, a score of 7 in writing, a score of 9 in spelling, and a score of 4 in arithmetic, such scores can be used to tailor instruction to the places where the pupil is “ahead” or “behind.”

Stanine scores are also used within statements of instructional goals. For example, a magnet elementary school recently articulated this goal for its third-grade

teachers: “In the area of math, the percentage of students scoring in the high stanines will be 65% or higher and no more than 5% scoring in the low stanines as measured on the [Iowa Test of Basic Skills].” In this third use of stanine scores, the focus is on a group of students rather than on individual pupils.

Stanines Versus Other Kinds of Standard Scores

Stanine scores are easier to understand than other kinds of standard scores, such as z scores, T scores, or NCE scores. This is because (a) there are only nine stanine scores, (b) no decimals or negative values are involved, and (c) people have little difficulty “catching on” to the fact that most examinees end up in stanines 4, 5, or 6; that fewer test takers end up in stanines 3 and 4 (or stanines 7 and 8); and that only a very small percentage of examinees end up in stanines 1 or 9. Thus, it is not surprising that stanine scores are used in parent-teacher conferences and in reports that summarize students’ test performance.

Although stanines have certain distinct advantages over other standard scores, they have one main limitation. Simply stated, the difference between two people can be completely hidden when their test performance is reported via stanines, or conversely, two people who are very similar may end up “looking dissimilar” because of their stanine scores. To illustrate this disadvantage of stanines, suppose four individuals take a test and perform such that their percentile ranks are 41, 59, 76, and 78. The first two of these test takers would both have a stanine score of 5 despite the difference in how they performed on the test. The third and fourth test takers would end up in different stanines despite the similarity in how they performed. These two undesirable situations would not occur if the performance of these four test takers is converted into z scores, T scores, or NCE scores.

Warnings About Stanine Scores

For those who use stanine scores, it is important to keep four things in mind. First, we should always know who formed the reference group when we attempt to interpret an examinee's stanine score. If the reference group was quite bright or highly skilled, an examinee thought to be average (or even above average) in ability could end up with a low stanine score. Second, stanine scores should not be averaged. Third, a comparison of two stanine scores can be misleading because of the way test scores are converted into stanines. This third warning applies to the comparison of two different examinees or to the comparison of one examinee's standing at two different times.

Finally, those who use stanine scores should always be concerned about issues of reliability and validity. Without much difficulty, one could create a test, administer that test to a large reference group, and then create a conversion table that allows test scores to be easily transformed into stanine scores. Yet we must ask the critical question whether a new test taker's stanine score can be trusted to mean what we are tempted to think it does. As with other ways of reporting test performance (such as percentile ranks or T scores), stanine scores should be interpreted only if they are tied to a measuring instrument that has known (and respectable) psychometric properties.

STATIS

STATIS is a generalization of principal component analysis (PCA), and its goal is to analyze several sets of variables collected on the same set of observations. It is attributed to Escouffier and L'Hermier des Plantes. A related approach is known as *procrustes matching by congruence coefficients* in the English-speaking community. The goal of STATIS is (a) to compare and analyze the relationship between the different data sets, (b) to combine them into a common structure called a *compromise*, which is then analyzed via PCA to reveal the common structure between the observations, and finally (c) to project each of the original data sets onto the compromise to analyze communalities and discrepancies. STATIS is used in very different domains, such as sensory evaluation, molecular imaging, brain imaging, ecology, and chemometrics.

The number or nature of the variables used to describe the observations can vary from one data set to the other, but the observations should be the same in all the data sets.

For example, the data sets can be measurements taken on the same observations (individuals or objects) at different occasions. In this case, the first data set corresponds to the data collected at time $t = 1$, the second to the data collected at time $t = 2$, and so on. The goal of the analysis, then, is to evaluate whether the position of the observations is stable over time.

As another example, the data sets can be measurements taken on the same observations by different participants or groups of participants. In this case, the first data set corresponds to the first participant, the second to the second participant, and so on. The goal of the analysis, then, is to evaluate whether there is an agreement between the participants or groups of participants.

The general idea behind STATIS is to analyze the structure of the individual data sets (i.e., the relation between the individual data sets) and to derive from this structure an optimal set of weights for computing a common representation of the observations, called the *compromise*. The weights used to compute the compromise are chosen to make it as representative of

all the data sets as possible. The PCA of the compromise gives, then, the position of the observations in the compromise space. The position of the observations for each data set can be represented in the compromise space as supplementary points. Finally, as a by-product of the weight computation, the data sets can be represented as points in a multidimensional space.

An Example

A typical example of using STATIS is the description of a set of products by a group of experts. This type of data can be analyzed using a standard PCA after the data have been averaged across experts. However, this approach neglects the inter-expert differences. STATIS has the advantages of providing a compromise space for the products as well as evaluating the differences among experts. We illustrate the method with an example from wine tasting.

Red wines often spend several months in oak barrels before being bottled because oak adds interesting components to the wine. However, only certain species of oaks seem to work well. Suppose we wanted to evaluate the effect of the oak species on barrel-aged red burgundy wines. First, we selected six wines coming from the same harvest of pinot noir and aged in six different barrels made with one of two different types of oak. Wines 1, 5, and 6 were aged with the first type of oak, whereas wines 2, 3, and 4 were aged with the second. Next, we asked each of three wine experts to choose from two to five variables to describe the six wines. For each wine, each expert was asked to rate the intensity of the variables on a 9-point scale. The results are presented in Table 1. The goal of

the analysis is twofold. First, we want to obtain a typology of the wines, and second, we want to know whether there is agreement among the experts.

Notations

The raw data consist of T data sets. For convenience, we will refer to each data set as a study. Each study is an $I \times J_{[t]}$ rectangular data matrix denoted $\mathbf{Y}_{[t]}$, where I is the number of observations and $J_{[t]}$ the number of variables collected on the observations for the t th study. Each data matrix is, in general, pre-processed (e.g., centered, normalized), and the pre-processed data matrices actually used in the analysis are denoted $\mathbf{X}_{[t]}$.

For our example, the data consist of $T = 3$ studies. The data were centered by column (i.e., the mean of each column is zero), and the starting point of the analysis consists of three matrices $\mathbf{X}_{[t]}$:

$$\mathbf{X}_{[1]} = \begin{bmatrix} -3.00 & 2.67 & 3.67 \\ 1.00 & -0.33 & -1.33 \\ 2.00 & -2.33 & -2.33 \\ 3.00 & -2.33 & -1.33 \\ -2.00 & 1.67 & 0.67 \\ -1.00 & 0.67 & 0.67 \end{bmatrix}, \tag{1}$$

$$\mathbf{X}_{[2]} = \begin{bmatrix} -2.00 & 1.17 & 3.17 & 2.50 \\ 0.00 & 0.17 & 0.17 & -1.50 \\ 1.00 & -1.83 & -2.83 & -2.50 \\ 3.00 & -1.83 & -2.83 & -1.50 \\ -1.00 & 1.17 & 2.17 & 1.50 \\ -1.00 & 1.17 & 0.17 & 1.50 \end{bmatrix},$$

Each of the $\mathbf{X}_{[i]}$ matrices is then transformed into an $I \times I$ scalar product matrix denoted $\mathbf{S}_{[i]}$ and computed as

$$\mathbf{S}_{[i]} = \mathbf{X}_{[i]} \mathbf{X}_{[i]}^T. \tag{2}$$

For example, the 6×6 between-wine scalar product matrix for the first wine expert is denoted $\mathbf{S}_{[1]}$. It is obtained as

$$\mathbf{S}_{[1]} = \mathbf{X}_{[1]} \mathbf{X}_{[1]}^T = \begin{bmatrix} 29.56 & -8.78 & -20.78 & -20.11 & 12.89 & 7.22 \\ -8.78 & 2.89 & 5.89 & 5.56 & -3.44 & -2.11 \\ -20.78 & 5.89 & 14.89 & 14.56 & -9.44 & -5.11 \\ -20.11 & 5.56 & 14.56 & 16.22 & -10.78 & -5.44 \\ 12.89 & -3.44 & -9.44 & -10.78 & 7.22 & 3.56 \\ 7.22 & -2.11 & -5.11 & -5.44 & 3.56 & 1.89 \end{bmatrix}. \tag{3}$$

The scalar product matrices for the second and third wine experts are equal to

$$\mathbf{S}_{[2]} = \begin{bmatrix} 21.64 & -3.03 & -19.36 & -20.86 & 13.97 & 7.24 \\ -3.03 & 2.31 & 2.97 & 1.47 & -1.69 & -2.03 \\ -19.36 & 2.97 & 18.64 & 18.14 & -13.03 & -7.36 \\ -20.86 & 1.47 & 18.14 & 22.64 & -13.53 & -7.86 \\ 13.97 & -1.69 & -13.03 & -13.53 & 9.31 & 4.97 \\ 7.64 & -2.03 & -7.36 & -7.86 & 4.97 & 4.64 \end{bmatrix}. \tag{4}$$

and

$$\mathbf{S}_{[3]} = \begin{bmatrix} 11.81 & -3.69 & -15.19 & -9.69 & 8.97 & 7.81 \\ -3.69 & 1.81 & 7.31 & 1.81 & -3.53 & -3.69 \\ -15.19 & 7.31 & 34.81 & 9.31 & -16.03 & -20.19 \\ -9.69 & 1.81 & 9.31 & 10.81 & -6.53 & -5.69 \\ 8.97 & -3.53 & -16.03 & -6.53 & 8.14 & 8.97 \\ 7.81 & -3.69 & -20.19 & -5.69 & 8.97 & 12.81 \end{bmatrix}. \tag{5}$$

Computing the Compromise Matrix

The *compromise matrix* is a scalar product matrix that gives the best compromise (hence its name) of the scalar product matrices representing each study. It is obtained as a weighted average of the study scalar product matrices. The weights are chosen so that studies agreeing the most with other studies will have the larger weights. To find these weights, we

need to analyze the relationships between the studies.

Comparing the Studies

To analyze the similarity structure of the studies, we start by creating a *between study cosine matrix* denoted \mathbf{C} . This is a $T \times T$ matrix whose generic term

$c_{t,t'}$ gives the cosine between studies. This cosine, also known as the R_V coefficient, is defined as

$$R_V = [c_{t,t'}] = \frac{\text{trace} \{ \mathbf{S}_{[t]}^T \mathbf{S}_{[t']} \}}{\sqrt{\text{trace} \{ \mathbf{S}_{[t]}^T \mathbf{S}_{[t]} \} \times \text{trace} \{ \mathbf{S}_{[t']}^T \mathbf{S}_{[t']} \}}}. \quad (6)$$

Using this formula we get the following matrix \mathbf{C} :

$$\mathbf{C} = \begin{bmatrix} 1.00 & .95 & .77 \\ .95 & 1.00 & .82 \\ .77 & .82 & 1.00 \end{bmatrix}. \quad (7)$$

PCA of the Cosine Matrix

The eigendecomposition of the cosine matrix reveals the structure between the studies. This amounts to performing a *noncentered* PCA of \mathbf{C} . Formally, this matrix has the following eigendecomposition:

$$\mathbf{C} = \mathbf{P}\mathbf{\Theta}\mathbf{P}^T \text{ with } \mathbf{P}^T\mathbf{P} = \mathbf{I}, \quad (8)$$

where \mathbf{P} is the matrix of eigenvectors of \mathbf{C} and $\mathbf{\Theta}$ the diagonal matrix of eigenvalues. An element of a given eigenvector represents the projection of one study on this eigenvector. Thus the studies can be represented as points in the eigenspace and their similarities visually analyzed. In this case, the projections are computed as

$$\mathbf{G} = \mathbf{P}\mathbf{\Theta}^{\frac{1}{2}}. \quad (9)$$

For our example, we find that

$$\mathbf{P} = \begin{bmatrix} 0.58 & -0.49 & 0.65 \\ 0.59 & -0.29 & -0.75 \\ 0.55 & 0.82 & 0.12 \end{bmatrix} \quad (10)$$

and
$$\mathbf{\Theta} = \begin{bmatrix} 2.70 & 0.00 & 0.00 \\ 0.00 & 0.26 & 0.00 \\ 0.00 & 0.00 & 0.04 \end{bmatrix}$$

and
$$\mathbf{G} = \begin{bmatrix} 0.96 & 0.25 & 0.14 \\ 0.98 & 0.14 & -0.16 \\ 0.91 & -0.42 & 0.03 \end{bmatrix}. \quad (11)$$

As an illustration, Figure 1 displays the projections of the experts onto the first and second components. It shows that the three studies are positively correlated with the first component (this is because all the elements of the cosine matrix are positive).

Computing the Compromise

The weights used for computing the compromise are obtained from the PCA of the cosine matrix. Because this matrix is not centered, the first eigenvector of \mathbf{C} represents what is common to the different studies. Thus studies with larger values on the first eigenvector are more similar to the other studies and therefore will have a larger weight. Practically, the weights are obtained by rescaling the elements of the first eigenvector of \mathbf{C} so that their sum is equal to 1. We call the weight vector α . For our example, we find that

$$\alpha = [.337 \ .344 \ .319]^T. \quad (12)$$

So with α_t denoting the weight for the t th study, the compromise matrix, denoted $\mathbf{S}_{[+]}$, is computed as

$$\mathbf{S}_{[+]} = \sum_t^T \alpha_t \mathbf{S}_{[t]}. \quad (13)$$

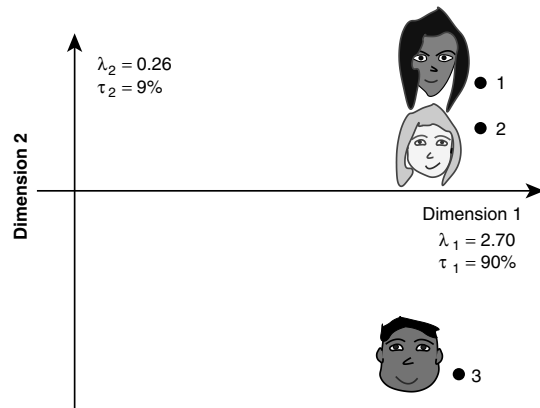

Figure 1 The Expert Space

In our example, the compromise is obtained as and

$$S_{[+]} = \begin{bmatrix} 22.15 & -5.42 & -19.37 & -17.83 & 12.57 & 7.90 \\ -5.42 & 2.45 & 5.59 & 3.09 & -3.01 & -2.71 \\ -19.37 & 5.59 & 23.61 & 14.76 & -13.38 & -11.21 \\ -17.83 & 3.09 & 14.76 & 17.47 & -10.84 & -6.65 \\ 12.57 & -3.01 & -13.38 & -10.84 & 8.61 & 6.05 \\ 7.90 & -2.71 & -11.21 & -6.65 & 6.05 & 6.62 \end{bmatrix}. \quad (14)$$

$$\text{diag}\{\Lambda\} = \begin{bmatrix} 69.70 \\ 7.35 \\ 2.52 \\ 1.03 \\ 0.32 \end{bmatrix}. \quad (18)$$

From Equations 17 and 18, we can compute the compromise factor scores for the wines as

$$F = QA^{\frac{1}{2}} \quad (19)$$

How Representative Is the Compromise?

The compromise is the best aggregate of the original scalar product matrices. But how good is this “best”? An index of the quality of the compromise is given by the ratio of the first eigenvalue of **C** to the sum of the eigenvalues of **C**:

$$\text{Quality of compromise} = \frac{\vartheta_1}{\sum_{\ell} \vartheta_{\ell}} = \frac{\vartheta_1}{\text{trace}\{\Theta\}}. \quad (15)$$

$$= \begin{bmatrix} 4.52 & -0.92 & -0.91 & -0.03 & 0.17(36) \\ -1.13 & -0.42 & 0.78 & 0.54 & 0.29(37) \\ -4.59 & -1.53 & 0.01 & -0.40 & -0.13(38) \\ -3.77 & 1.61 & -0.78 & 0.19 & 0.01(39) \\ 2.87 & 0.08 & 0.27 & 0.34 & -0.43(40) \\ 2.10 & 1.18 & 0.63 & -0.64 & 0.09(41) \end{bmatrix}. \quad (20)$$

For our example, the quality of the compromise is evaluated as $\frac{2.74}{3} \approx .91$. So we can say that the compromise “explains” 91% of the inertia of the original set of data tables.

In the **F** matrix, each row represents an observation (i.e., a wine), and each column is a component. Figure 2 displays the wines in the space of the first two principal components. The first component has an eigenvalue equal to $\lambda_1 = 69.70$, which corresponds to 85% of the inertia because

Analyzing the Compromise

The compromise matrix is a scalar product matrix, and therefore its eigendecomposition amounts to a PCA. From this analysis, we can explore the structure of the set of observations. The eigendecomposition of the compromise gives

$$\frac{69.70}{69.70 + 7.35 + 2.52 + 1.03 + 0.32} = \frac{69.70}{80.91} \approx .85.$$

$$S_{[+]} = QAQ^T \quad (16)$$

The second component, with an eigenvalue of 7.35, explains almost 10% of the inertia. The first

with

$$Q = \begin{bmatrix} 0.54 & -0.34 & -0.57 & -0.03 & 0.31 \\ -0.14 & -0.15 & 0.49 & 0.54 & 0.51 \\ -0.55 & -0.57 & 0.00 & -0.40 & -0.23 \\ -0.45 & 0.59 & -0.49 & 0.19 & 0.01 \\ 0.34 & 0.03 & 0.17 & 0.34 & -0.75 \\ 0.25 & 0.43 & 0.39 & -0.63 & 0.16 \end{bmatrix} \quad (17)$$

component is easily interpreted as the opposition of the wines aged with the first type of oak (wines 1, 5, and 6) to the wines aged with the second type of oak (wines 2, 3, and 4).

Projecting the Studies Into the Compromise Space

The analysis of the compromise reveals the structure of the wine space common to the experts. In addition, we want to see how each expert “interprets” this space. This is achieved by projecting the scalar product matrix of each expert onto the compromise. This operation is performed by computing a projection matrix that transforms the scalar product matrix into loadings. The projection matrix is deduced

from the combination of Equations 16 and 19, which gives

$$F = S_{[+]} Q \Lambda^{-\frac{1}{2}}. \tag{21}$$

This shows that the projection matrix is equal to $(Q \Lambda^{-\frac{1}{2}})$. It is used to project the scalar product matrix of each expert onto the common space. For example, the coordinates of the projections for the first expert are obtained by first computing the matrix

$$Q \Lambda^{-\frac{1}{2}} = \begin{bmatrix} 0.06 & -0.12 & -0.36 & -0.03 & 0.55 \\ -0.02 & -0.06 & 0.31 & 0.53 & 0.90 \\ -0.07 & -0.21 & 0.00 & -0.39 & -0.41 \\ -0.05 & 0.22 & -0.31 & 0.18 & 0.02 \\ 0.04 & 0.01 & 0.11 & 0.34 & -1.34 \\ 0.03 & 0.16 & 0.25 & -0.63 & 0.28 \end{bmatrix}, \tag{22}$$

Figure 3 shows the first two principal components of the compromise space, along with the projections of wines for each expert. Note that the position of each wine in the compromise is the barycenter of the positions of this wine for the three experts. In order to make this relation clear and also to facilitate the interpretation, we have drawn lines linking the position of each wine for each expert to the compromise position. This picture confirms a conclusion obtained from the analysis of the C matrix: Expert 3 tends to be at variance with the other two experts.

The Original Variables and the Compromise

The analysis of the compromise reveals the structure of the set of observations, but the original data tables

were rectangular tables (i.e., each expert was using several scales to evaluate the wines). And we want to be able to relate these specific scales to the analysis of the compromise.

The original variables can be integrated into the analysis by adapting the standard approach that PCA uses to relate original variables and components, namely, computing loadings (i.e., correlation between the original variables and the factor scores). This approach is illustrated in Table 2, which gives the loadings between the original variables and the factors of the compromise. Figure 4 shows the circle of correlation obtained for each expert (these loadings could have been drawn on the same picture). Here we see, once again, that Expert 3 differs from the other experts and is mostly responsible for the second component of the compromise.

STATISTICAL SIGNIFICANCE

Before accepting the theoretical importance or real-life impact of their research findings, psychologists have to be sure that their findings are statistically significant (i.e., that the data are not the result of happenstance). Psychologists use the *null hypothesis significance test procedure* (NHSTP) to test for statistical significance, which may be explained by exploring (a) the uncertainty inherent in empirical data, (b) the nature of inferential statistics, (c) the test statistic that represents a research outcome, and (d) the nature of the binary decision about chance effects.

Chance Effects on Empirical Data

The *substantive population* of a research effort consists of all individuals to whom the research conclusions apply. It may consist of all hyperactive boys in a

study of hyperactivity. Any of its characteristics (e.g., the mean attention span of all hyperactive boys, u) is a *parameter*. Suppose that a psychologist collects data from a randomly selected *sample* of 100 hyperactive boys. A characteristic of the sample is a *statistic* (e.g., the sample's mean attention span, \bar{X}).

The sample mean is unlikely to be identical to the population mean because of chance influences. For example, chance factors during data collection (a) determine who are included in the sample and (b) render some boys more attentive than usual while other boys are being distracted more than usual. Consequently, different samples of 100 hyperactive boys selected and tested in exactly the same way produce different mean attention spans.

Suppose that the psychologist selects randomly 100 hyperactive boys and assigns randomly 50 to Group 1 and 50 to Group 2. The random selection and random assignment procedures warrant the suggestion that Groups 1 and 2 are the respective samples of two substantive populations with the same mean (i.e., $u_{\text{spanI}} = u_{\text{spanII}}$). Be that as it may, the means of Groups 1 and 2 (\bar{X}_{spanI} and \bar{X}_{spanII} , respectively) are not expected to be literally the same by virtue of happenstance.

Statistical Populations and Research Manipulation

To test whether Drug D affects the attention span of hyperactive boys, the psychologist gives Group 1 Drug D and Group 2 a placebo. The two substantive populations now become two methodologically defined statistical populations, namely, (a) hyperactive boys given Drug D and (b) hyperactive boys given a placebo. Their means are u_{DrugD} and u_{Placebo} , respectively. The means of Groups 1 and 2 are \bar{X}_{DrugD} and \bar{X}_{Placebo} , respectively.

If Drug D is not efficacious, $u_{\text{DrugD}} = u_{\text{Placebo}}$ because the distinction between the two methodologically defined populations becomes mute. This equality implies that $\bar{X}_{\text{DrugD}} = \bar{X}_{\text{Placebo}}$. However, because of the aforementioned chance effects, $(\bar{X}_{\text{DrugD}} - \bar{X}_{\text{Placebo}})$ is not expected to be exactly zero.

An efficacious Drug D would change the attention span, thereby leading to $u_{\text{DrugD}} \neq u_{\text{Placebo}}$. It follows that $(\bar{X}_{\text{DrugD}} - \bar{X}_{\text{Placebo}})$ is not zero. Thus arises the following conundrum: A nonzero $(\bar{X}_{\text{DrugD}} - \bar{X}_{\text{Placebo}})$ is expected

regardless of the efficacy of Drug *D*. Psychologists use statistical significance to handle the dilemma.

Inferential Statistics

Psychologists use *NHSTP* to learn something about population parameters (e.g., $u_{DrugD} - u_{Placebo}$) on the basis of the statistical significance of their corresponding sample statistics ($\bar{X}_{DrugD} - \bar{X}_{Placebo}$). This is achieved by using the standardized form of an appropriate theoretical distribution to make a binary decision regarding chance effects on the data in probabilistic terms.

The Theoretical Distribution

The statistical question is whether or not the observed $\bar{X}_{DrugD} - \bar{X}_{Placebo}$ warrants the conclusion that $u_{DrugD} \neq u_{Placebo}$. Psychologists answer this question by appealing to an appropriate *random sampling distribution of differences* that describes the probabilities of all possible values of $\bar{X}_{DrugD} - \bar{X}_{Placebo}$.

A random sampling distribution of differences is a theoretical probability density function defined by its mean (called *mean difference*) and standard deviation (called *standard error*). The two parameters are mathematically related to the means and standard deviations of the two underlying statistical populations, respectively. Specifically, the mean difference ($u_{DrugD} - u_{Placebo}$) equals $(u_{DrugD} - u_{Placebo})$, and the *standard error of differences* is a function of the two population standard deviations. The latter function depends, moreover, on sample size.

The Test Statistic

Consequently, a different random sampling distribution is implicated when there is a change in the sample sizes. This gives rise to an infinite number of probability density functions. The situation is made less daunting by standardizing the random sampling distribution, using its standard error as the unit of measure. The result is a distribution of the *t* statistic for every combination of two sample sizes. The *t* statistic is given by Equation 1:

$$t = \frac{\text{Sample statistic} - \text{Population parameter}}{\text{Standard error of the random sampling distribution}} \quad (1)$$

Specifically, for the hyperactivity example,

$$t = \frac{(\bar{X}_1 - \bar{X}_2)(u_1 - u_2)}{\text{Standard error of differences}}$$

The *t* statistic is an example of a *test statistic*, namely, the statistic used in making the statistical decision about chance.

A Binary Decision Task

The rationale of tests of statistical significance may now be illustrated with a binary decision task. The decision maker is confronted with two sets of 50 scores each. Set *Null* is depicted in Table 1. The probability of every possible score-value is also shown. Nothing is known about the other set, Set *Alternative*, except that (a) its scores overlap with those of the Set *Null* to an unknown extent, (b) a score, *X*, is selected on any occasion from either set with an unknown probability, and (c) all scores within the chosen set have an equal chance of being selected. The decision maker has to indicate from which set the score is chosen.

The decision is made solely on the basis of Set *Null* because nothing is known about Set *Alternative*. A rational rule is to consider Set *Null* too unlikely as the source of Score *X* if its associated probability (i.e., the probability of obtaining a value that is equal to, or more extreme than, *X*) is smaller than a predetermined value (e.g., 0.04). Specifically, the decision maker rejects Set *Null* as the source when 12 or 2 is chosen because the associated

probability of either of them is 0.04. The value 12 or 2 is a criterion value for the decision (hence called a *critical value*).

The Statistical Hypotheses

A test of statistical significance is a binary decision task. Analogous to Score X in the binary decision task is the result of a research effort, such as $(\bar{X}_{DrugD} - \bar{X}_{Placebo})$. Analogous to Set *Null* is the appropriate chance-dependent t distribution chosen with reference to the degrees of freedom (df ; viz. $n_1 + n_2 - 2$ in the present example). *NHSTP* begins with two statistical hypotheses, H_0 and H_1 .

H_0 : An Implication of Chance Effects

Accepting the inevitability of chance effects, the psychologist allows for a nonzero $(\bar{X}_{DrugD} - \bar{X}_{Placebo})$ even though $(u_{DrugD} = u_{Placebo})$ is envisaged when Drug D is inefficacious. Encapsulating this methodological frame of reference are the conditional propositions [CP1-a] and [CP1-b].

[CP1-a]: If the chance effects assumption is true, then $H_0: u_{DrugD} = u_{Placebo}$.

[CP1-b]: If H_0 is true, then the random sampling distribution of differences has a mean difference of zero (i.e., $u_{DrugD} - u_{Placebo} = 0$).

[CP1-a] shows that the *statistical null hypothesis* (H_0) is an implication of the chance effects assumption. [CP1-b] makes explicit that H_0 stipulates the to-be-used random sampling distribution of differences linking $(\bar{X}_{DrugD} - \bar{X}_{Placebo})$ to $(u_{DrugD} - u_{Placebo})$. The statistical decision about chance effects is made with the standardized form of this random sampling distribution (see “The Test Statistic” section above).

The Complement of Chance Effects, H_1

The complement of the chance effects assumption is the stance that influences

other than happenstance determine $(\bar{X}_{DrugD} - \bar{X}_{Placebo})$. Its implication is the statistical alternative hypothesis (H_1), as may be seen from [CP2-a] or [CP2-b] or [CP2-c].

[CP2-a]: If there is more than chance effects, then $H_1: u_{DrugD} \neq u_{Placebo}$.

[CP2-b]: If there is more than chance effects, then $H_1: u_{DrugD} > u_{Placebo}$.

[CP2-c]: If there is more than chance effects, then $H_1: u_{DrugD} < u_{Placebo}$.

The consequent of [CP2-a] is a two-tailed H_1 , in which the direction of $(u_{DrugD} - u_{Placebo})$ is not specified. The consequent of [CP2-b] or [CP2-c] is a one-tailed H_1 , in which the direction of $(u_{DrugD} - u_{Placebo})$ is specified (see Table 2 for the exact relationship).

Researchers carry out research such as this because they do not know the magnitude of $(u_{DrugD} - u_{Placebo})$. This situation is analogous to knowing nothing about Set *Alternative*. That is, H_1 does not stipulate a usable random sampling distribution of differences because $(u_{DrugD} - u_{Placebo})$ is not known. It is for this reason that H_1 plays no part in the statistical-significance decision.

Some psychologists suggest that the ill-defined sampling distribution implied by H_1 serves to inform the psychologist of the probability of obtaining statistical significance (viz., *statistical power*). Be that as it may, by virtue of the theoretical implication or pragmatic objective of the research, H_1 informs (a) whether the significance test is directional and (b) the direction of the difference if it is a directional test. At the same time, there are reasons to question the validity of statistical power.

Table 2 The Pairing of H_0 and H_1

	<i>If the chance effects assumption is true, then</i>	<i>If there is more than chance effects, then</i>
Nondirectional test	$H_0: u_{DrugD} = u_{Placebo}$	$H_1: u_{DrugD} \neq u_{Placebo}$
Directional test	$H_0: u_{DrugD} \leq u_{Placebo}$	$H_1: u_{DrugD} > u_{Placebo}$
	$H_0: u_{DrugD} \geq u_{Placebo}$	$H_1: u_{DrugD} < u_{Placebo}$

The Statistical Decision About Chance Effects

The psychologist adopts a predetermined criterion (called α , which is by convention 0.05) for rejecting the chance-effects explanation of the data. The α level is also known as the *level of significance*. H_0 is rejected if the computed t equals to, or exceeds, a critical t (viz., a t whose associated probability is 0.05). The result is deemed statistically significant at the 0.05 level in such an event. The critical value of t is analogous to the critical 12 or 2 in the binary decision task.

Two Types of Errors

It is clear that a statistically significant result is one that is deemed too unlikely to be due to happenstance. The “too unlikely” characterization sets in high relief that the binary decision is liable to be mistaken. There are two types of errors. A Type I error is committed if H_0 is rejected when H_0 is true. A Type II error is made if H_0 is not rejected when H_1 is true.

Although psychologists do not know the probability of the Type II error (because the implication of H_1 is unknown), they can (and do) set the probability of the Type I error (called α). To say that a research result is significant at the 0.05 level is to say that it might be brought about by chance fewer than five times out of 100 *in the long run*. It says, at the same time, that the psychologist would be wrong five times out of 100 in the long run if H_0 is rejected.

Summary and Conclusions

Statistically significant results are outcomes that are deemed too unlikely to be due to chance event. The decision is based on a well-defined random sampling distribution. The practical value or theoretical importance of the result is not informed by statistical significance because statistical decision, value judgment, and theoretical analysis belong to different domains.

STEM-AND-LEAF DISPLAY

The stem-and-leaf display is an exploratory data analysis technique developed by John Tukey to summarize graphically the characteristics of a distribution. It is especially easy to produce by hand, and it is effective for examining distributions for small sample sizes. (All major statistical packages provide point-and-click routines that can be used readily to examine the distributions in the case of large sample sizes.) At the top of the next page are side-by-side stem-and-leaf displays for 100 randomly selected IQ scores and the subset of all scores greater than 99.

To construct a stem-and-leaf display, we place the data in ascending order and break each score into two parts, a stem (the leading digit[s], which contains the most salient information) and a leaf (the trailing digit[s], which contains less salient information). Two common line depths (i.e., “stem widths”) are created by forming stems that include the digits 0–4 and 5–9 (see Random IQ display) or by forming stems that include the digits 0–1, 2–3, 4–5, 6–7, and 8–9 (see IQ>99 display).

In the stem-and-leaf display for the variable Random IQ, the first line (1 6 4) indicates there is one score in the line (“line depth”), the IQ score 64, which is partitioned into a stem (6) and a leaf (4). For scores below the median, line depths are calculated by counting the total number of scores from the bottom (lowest score) of the distribution up to, and including, the scores in that line. For scores above the median, line

depths are calculated by counting the total number of scores from the top (highest score) of the distribution down to, and including, the scores in that line. For the line that contains the median (IQ score 104), the depth of the line is reported in parentheses (20). Note that the center three depths (31, 20, 49) add to $N = 100$ since they account for all the scores within the distribution. Note also that some computer programs report leaf frequency instead of depths for all lines.

We can locate the center of the distribution (i.e., find the median) by eye or by counting in from either end until half of the observations are counted. We can examine the range of the data by locating the minimum and maximum values. We can locate the quartiles of the distribution either by eye or by counting. Turned on its side, the stem-and-leaf display forms a “digital histogram” that can be used to examine distribution shape, locate peaks and gaps, and identify unusual observations.

For the variable Random IQ, the distribution is approximately normal. There is a gap in the distribution and a possible outlier (64). For the variable IQ>99, the distribution is positively skewed, with a gap and two possible outliers. If the line depths (stem widths) were identical in the two displays, the

stem-and-leaf display for variable IQ>99 would be identical to the bottom half of the stem-and-leaf display for variable Random IQ.

STRATIFIED RANDOM SAMPLING

Stratified random sampling is a sampling technique in which the population is divided into groups called

strata. The idea behind stratified sampling is that the groupings are made so that the population units within a group are similar. The variance of the sample estimator is the weighted sum of the within-stratum variances. Because the groupings have been made so that units within a stratum are similar, strata should be less variable than the population as a whole. The variance of the sample estimator is a measure of how different the sample estimates are from all the theoretically possible samples that could be taken (given the sample design) and is therefore a measure of precision of the sample. A sample design with low variance is more desirable than a design with high variance. With a stratified random sample in which each stratum is surveyed using simple random sampling, provided the population has been divided into homogeneous strata, the weighted sum of the within-stratum variances will be less than the variance from simple random sampling with no stratification. Stratified random sampling is therefore considered a more precise sampling technique than simple random sampling.

Example

The data set in Table 1 is the number of possums caught in traps in a study area in New Zealand. The area was divided into three strata based on a map of the area. By looking at the map and studying the mapped hill slope and aspect, the researcher divided the study area into three contiguous strata roughly corresponding to hillside easterly aspect, valley floor, and hillside westerly aspect.

The mean for stratum h is calculated as

$$\bar{X}_h = \sum_{i=1}^h \frac{X_{hi}}{n_h},$$

where n_h is the number of units selected from the h th stratum and x_{ih} is the value of the i th sample unit in the h th stratum.

The sample mean from stratified sampling is the weighted sum of the stratum means, calculated as

Table 1 Different Strata for Random Sampling

Stratum 1	Stratum 2	Stratum 3
2	2	0
0	4	1
1	2	2
4	0	3
1	2	0
0	0	0
4	4	1
2	0	2
0	6	4
6	1	1

$$\bar{X}_{st} = \frac{1}{N} \sum_{h=1}^H N_h \bar{X}_h,$$

where N is the size of the population and N_h is the size of the h th stratum.

The estimated variance of the sample mean is calculated as

$$\hat{\text{var}}(\bar{X}_{st}) = \frac{1}{N^2} \sum_{h=1}^H N_h^2 \left(1 - \frac{n_h}{N_h}\right) \frac{s_h^2}{n_h},$$

where s_h^2 is the sample variance for the h th stratum.

In this example, the stratum means were $\bar{X}_1 = 2.00$, $\bar{X}_2 = 3.50$, and $\bar{X}_3 = 1.40$, and $N_1 = 200$ hectares, $N_2 = 150$ hectares, and $N_3 = 450$ hectares. The data show some differences in possum numbers among the strata, with half again as many possums caught in stratum 2 as in stratum 3. The sample variances were $s_1^2 = 3.80$, $s_2^2 = 5.65$, and $s_3^2 = 1.64$. With these stratum statistics, the stratified sample mean and estimated variance of the sample mean are calculated as

$$\begin{aligned} \bar{X}_{st} &= \frac{1}{800} (200 \times 2.00 + 150 \times 3.50 + 450 \times 1.40) \\ &= 1.94 \end{aligned}$$

and

$$\begin{aligned} \widehat{\text{var}}(\bar{X}_{st}) &= \frac{1}{800^2} \left(200^2 \times \left(1 - \frac{10}{200} \right) \frac{3.80}{10} \right. \\ &\quad \left. + 150^2 \times \left(1 - \frac{10}{150} \right) \frac{5.65}{10} \right. \\ &\quad \left. + 450^2 \times \left(1 - \frac{10}{450} \right) \frac{1.64}{10} \right) \\ &= 0.09. \end{aligned}$$

If stratified sampling had not been used and instead the population had been surveyed by simple random sampling and the resultant sample had the same 30 values, the sample mean would have been 2.30 and the estimated variance of the sample mean 0.15. The stratified sample has a lower variance than the equivalent simple random sample and is estimated to be more precise.

Allocation of Survey Effort Among Strata

Further gains in sample precision (measured by the reduction in estimated variance of the sample mean) could be made by changing how much sample effort is expended within each stratum. In the possum example, stratum 3 had the lowest sample variance. Reducing the sample size within this stratum could mean that the strata with the higher variances could have a higher sample size. This should reduce the variance of the stratified sample. Conversely, stratum 3 is the largest-size stratum, and a large sample within this stratum could be warranted on this ground.

Optimal allocation of survey effort among strata to achieve the lowest variance for a given sample size incorporates both stratum variance and size. Differential sample costs among strata can also be included as a parameter in optimal allocation:

$$n_h = n \times \left(\frac{N_h \sigma_h}{\sqrt{c_h}} / \sum_{h=1}^H \frac{N_h \sigma_h}{\sqrt{c_h}} \right),$$

where c_h is the cost of sampling a unit in the h th stratum.

The result of optimal allocation is that strata that are variable, large, and proportionally cheap to survey are allocated larger sample sizes compared with strata that have low variance, are small, and are expensive to survey.

With the example data set, assuming the cost of surveying a unit was the same for all strata and that the within-stratum variances were $\sigma_1^2 = 3.80$, $\sigma_2^2 = 5.65$, and $\sigma_3^2 = 1.64$, the optimal allocation for $n = 30$ among the three strata can be estimated. Optimal allocation when the costs of sampling are assumed to be equal among the strata is called *Neyman allocation*.

For stratum 1,

$$\begin{aligned} n_1 &= 30 \times \left(\frac{200\sqrt{3.80}}{200\sqrt{3.80} + 150\sqrt{5.65} + 450\sqrt{1.64}} \right) \\ &= 8.84 \\ &= 9 \text{ (rounded)}. \end{aligned}$$

For stratum 2,

$$\begin{aligned} n_2 &= 30 \times \left(\frac{150\sqrt{5.65}}{200\sqrt{3.80} + 150\sqrt{5.65} + 450\sqrt{1.64}} \right) \\ &= 8.09 \\ &= 8 \text{ (rounded)}. \end{aligned}$$

For stratum 3,

$$\begin{aligned} n_3 &= 30 \times \left(\frac{450\sqrt{1.64}}{200\sqrt{3.80} + 150\sqrt{5.65} + 450\sqrt{1.64}} \right) \\ &= 13.07 \\ &= 13 \text{ (rounded)}. \end{aligned}$$

Optimal allocation would mean that stratum 1 has a sample size of 9, stratum 2 has a sample size of 8, and stratum 3 has a sample size of 13.

A simpler method of allocating survey effort among strata is to use proportional allocation, in which effort is allocated according to the relative size of the strata:

$$n_h = n \times \left(\frac{N_h}{\sum_{h=1}^H N_h} \right)$$

If sample effort had been allocated only on the proportional sizes of the strata, then stratum 1 would have been allocated a sample size of $n_1 = 7$, stratum 2 a sample size of $n_2 = 6$, and stratum 3 a sample size of $n_3 = 17$:

$$\begin{aligned} n_1 &= 30 \times \left(\frac{200}{800} \right) \\ &= 7.50 \\ &= 7 \text{ (rounded),} \end{aligned}$$

$$\begin{aligned} n_2 &= 30 \times \left(\frac{150}{800} \right) \\ &= 5.63 \\ &= 6 \text{ (rounded),} \end{aligned}$$

and

$$\begin{aligned} n_3 &= 30 \times \left(\frac{450}{800} \right) \\ &= 16.88 \\ &= 17 \text{ (rounded).} \end{aligned}$$

The sample size for stratum 1 was rounded to $n_1 = 7$ rather than 8 to ensure the total sample size was 30 (if it were rounded to 8, then the total sample size would have been 31).

Proportional allocation is simpler in that estimates of within-stratum variances and sample costs are not needed. However, assuming the estimates of within-stratum variances and sample costs are accurate, optimal allocation will result in smaller variance of the stratified sample estimate than proportional allocation will.

With optimal allocation, in the example data set, stratum 3 was allocated the largest sample size. Stratum 3 was the largest stratum ($N_3 = 450$, compared with $N_1 = 200$ and $N_2 = 150$) but was also the least variable stratum ($s_3^2 = 1.64$, compared with $s_1^2 = 3.8$ and $s_2^2 = 5.65$). Optimal allocation resulted in a smaller sample size for stratum 3 than the proportional allocation sample size, reflecting the fact that optimal

allocation incorporates stratum variance (and cost) along with stratum size in allocating survey effort.

Advantages of Stratified Sampling

Other than improved survey precision, stratified sampling offers the advantage that it is often logistically easier to divide a population into strata and then plan to survey within each stratum. For example, in a field survey for a particular species of plant, if the study area is very large, it may be convenient to divide the study area into strata. Separate survey teams can then survey within each stratum. A further advantage of stratified sampling is that surveying each stratum separately allows separate estimates of the mean or total to be calculated for each stratum. In the field study example, it may be very useful to know the estimated total number of plants in the separate strata so that stratum-specific decisions about how to manage the plants can be made.

Defining Strata

Stratum boundaries can be defined on the basis of any criteria and any number of criteria. The idea behind stratified sampling is that units within strata should be as similar as possible, so it is sensible to have stratum boundaries that relate in some way to the experimental unit. In the possum survey, the strata were defined on geographical information and with the knowledge that possum densities vary among hillsides with an easterly aspect, valley floors, and hillsides with a westerly aspect. Stratified random sampling may be used to estimate how much money commercial businesses spend on staff training (per staff member), and in this application, it would be sensible to stratify on business size. Large and small businesses are likely to spend different amounts per staff member, whereas it seems reasonable that most large businesses spend roughly similar amounts.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Lakhani, R. (2004). Occupational health of women construction workers in the unorganized sector. *Journal of Health Management*, 6(2), 187–200.

This study assessed the occupational health status of women workers in the construction industry by evaluating incidences of occupational health disorders. In all, 1,052 workers were selected by **stratified random sampling**; medically examined; and subjected to relevant interviews, examinations, and investigations. More than three fourths of the women and almost all the men reported working 10 to 12 hours daily. A majority of the women reported headaches and backaches, as well as pain in the limbs. As much as 56% of women and 16% of men reported injuries resulting in work loss and had no social security or other workers' benefits. Respiratory, eye, and skin disorders and noise-induced hearing loss were found to be prevalent among workers exposed to hazards like dust, noise, heat, cold, nonionizing radiation, dry cement, glass, adhesives, tar, and paint. About 76% of the women reported gender-specific work stress factors, such as sex discrimination and balancing work and family demands, above and beyond the impact of general job stressors such as job overload and skill underutilization.

STRONG INTEREST INVENTORY

The Strong Interest Inventory (SII; publisher: Consulting Psychologists Press, www.cpp.com) first was published by Edward K. Strong, Jr., in 1927. Over the decades, this measure of vocational interests has been updated and expanded appreciably. By virtue of its long history, the SII is one of the most well-documented instruments available for use by assessment experts. Clients find SII scores useful for making vocational and educational decisions, confirming occupational choices, suggesting new directions within a career, understanding job dissatisfaction,

and developing plans for retirement. The questionnaire, which takes about 30 minutes to complete, includes 291 items. The profile reports five types of scales—General Occupational Themes, Basic Interest Scales, Occupational Scales, Personal Style Scales, and Administrative Indexes.

The General Occupational Themes are designed to measure John Holland's vocational types—Realistic (building, working with machines), Investigative (researching, analyzing data), Artistic (creating, writing, performing), Social (helping others, teaching), Enterprising (selling, leading), and Conventional (paying attention to detail, organizing). The Basic Interest Scales (BIS) cover 30 content areas, each of which is clustered according to its strongest relation with Holland's vocational types. For example, Realistic BIS includes mechanics and construction, Investigative BIS includes medical science, Artistic BIS includes visual arts and design, Social BIS includes counseling and helping, Enterprising BIS includes entrepreneurship, and Conventional BIS includes office management. The General Occupational Themes and the BIS are normed on a large sample of employed women and men.

The Occupational Scales measure the interests of 122 occupations, drawn from a wide array of professional, technical, and nonprofessional jobs, with separate sex-normed scales reported for each occupation (i.e., a total of 244 Occupational Scales). The scores for these scales reflect the similarity of a client's interests to those of people in the occupation.

The Personal Style Scales measure an individual's work and learning style. Work Style is designed to distinguish between people who like working with others (e.g., school counselors) and those who prefer working with data, things, and ideas (e.g., mathematicians). Learning Environment identifies people who prefer academic environments (e.g., sociologists) versus those who prefer hands-on environments (e.g., auto mechanics). Leadership Style differentiates people who like to take charge (e.g., school administrators) and those who prefer to follow (e.g., production workers). Risk Taking identifies people who like risky activities (e.g., firefighters) and those who are cautious (e.g., librarians). Team Orientation contrasts

those who prefer team-based activities (e.g., nursing home administrators) and those who prefer working alone (e.g., medical illustrators).

Studies have demonstrated the reliability of SII scale scores over short and relatively long periods of time. An extensive body of literature also reports evidence of validity for SII scores for use with clients who vary in age, ability, ethnicity, and interest orientation.

STROOP COLOR AND WORD TEST

The Stroop Color and Word Test developed from the observation by early experimental psychologists that the naming of color hues is always slower than the reading of color names in literate adults. The earliest published report of this phenomenon was offered by Cattell in 1886. J. Ridley Stroop suggested in 1935 that the difference in color naming and word reading was due to colors' being associated with a variety of behavioral responses while words were associated with only one behavioral response: reading. In order to further study the relationship between color naming and word reading, Stroop devised the test that has come to be called the Stroop Color and Word Test.

The earliest version of the Stroop consisted of the words *red, green, brown, blue, and purple* printed on a page consisting of ten rows and ten columns. Each word was printed in colored ink, but never in the color it represented by the word (e.g., *red* could be printed in blue ink but never in red ink). Another page of the test consisted of colored ink printed as small rectangles. The final page consisted of the color words listed above, this time printed in black ink.

Since Stroop's original studies, several hundred studies have been published on the Stroop test. The Stroop has attracted such attention because of its high reliability in identifying individual differences and because of its somewhat paradoxical nature. The research has examined the use of the Stroop in cognitive and personality research, in experimental psychopathology, and in the diagnosis and understanding of organic brain dysfunction.

Neuropsychological studies have suggested that Stroop interference occurs not at the response stage or in the confusion of the participant but as a result of interference in verbal processing. The Stroop stimuli appear to activate an automatic verbal processing response that interferes with the consciously instructed color naming. The participant completes the task either by completing both responses sequentially (reading the word, followed by naming the color) or by suppressing the automatic, word-reading response through volitional control.

Current versions of the Stroop test consist of three pages and generally use only three colors. Page 1 consists only of color word names (e.g., *red, green, and blue*) while page 2 uses XXXX's printed in red, green, and blue ink. The third page (interference) consists of the color words on page 1 printed in nonmatching ink (e.g., the word *red* printed in blue ink). The participant must name the color of the ink rather than the word. The Stroop may be scored as the total number of items finished in a set time (usually between 30 and 60 seconds) or the time to complete an entire page. The former version has the advantage of limiting the time the test takes without apparently limiting the information that is gathered. It is used widely as a neuropsychological instrument, primarily as a measure of possible reading disorders (when there is no interference effect) and as a measure of complex executive functions (when the interference effect is unusually large).

STRUCTURAL EQUATION MODELING

Structural equation modeling (SEM) is a general term that describes a large number of statistical models used to evaluate the consistency of substantive theories with empirical data. It represents an extension of general linear modeling procedures such as analysis of variance and multiple regression. In addition, SEM can be used to study the relationships among latent constructs that are indicated by multiple measures and is applicable to experimental or nonexperimental data and to cross-sectional or longitudinal data.

SEM has a number of synonyms or special cases in the literature, including *path analysis*, *causal modeling*, and *covariance structure analysis*, or some variations of these terms. Path analysis is an extension of multiple regression in that various multiple regression models or equations can be estimated simultaneously; it provides a more effective and direct way of modeling mediation effects. Path analysis can be considered an early form and a special case of SEM in which structural relations among only observed variables are modeled. Structural relations are hypotheses about how independent variables affect dependent variables. Hence, the earlier path analysis or the later SEM is sometimes referred to as causal modeling. Because analyzing interrelations among variables is a major part of SEM and these interrelations are supposed to generate the observed covariance or correlation patterns among the variables, SEM is also sometimes called covariance structure analysis.

The measurement of latent variables originated from psychometric theories. Unobserved latent variables cannot be measured directly but are indicated or inferred by responses to a number of observable variables (indicators). Latent constructs such as intelligence or reading ability are often gauged by responses to a battery of items that are designed to tap those constructs. Responses of a participant are supposed to reflect where the participant stands on the scale of the latent variable. Factor analyses have been widely used to examine the number of latent constructs underlying the observed responses and to evaluate the adequacy of individual items or variables as indicators for the latent constructs they are supposed to measure. The merger of confirmatory factor analysis models (sometimes called *measurement models*) with structural path models on the latent constructs became a general SEM framework in analyzing covariance structures. Today's advancement of SEM includes the modeling of mean structures in addition to covariance structures, the modeling of growth or changes over time (growth models), and the modeling of data having nesting structures (e.g., students are nested within classes, which in turn are nested within schools; multilevel models).

How Does SEM Work?

SEM is a complex and growing collection of techniques. This discussion will focus on only the basic logic and mechanism of the way SEM works. Interested readers should consult additional references for the specific type of model and data involved. In general, however, every SEM analysis goes through steps of model specification, data collection, model estimation, evaluation, and modification. Issues pertaining to each of these steps are discussed briefly below.

Model Specification

A sound model is theory based. According to theories, findings in the literature, knowledge in the field, or one's educated guesses, causes and effects among variables of interest can be specified. In SEM, a variable can serve both as a source (i.e., cause) variable and

a result (i.e., effect) variable in a chain of causal hypotheses. This kind of variable is often called a mediator. Suppose that social status has a direct impact on learning motivation, which in turn is supposed to affect achievement. Motivation, then, is a mediator between social status and achievement; it is the source variable for achievement and the result variable for social status. Furthermore, feedback loops among variables (e.g., achievement, in the example proposed above, can in turn affect social status) are permissible in SEM, as are reciprocal loops (e.g., learning motivation and achievement affect each other).

Models can be more easily conceptualized and communicated in graphical forms. Many specialized SEM software programs, such as LISREL and EQS, can translate graphical specification of a model into computer syntax for analysis. A directional arrow is universally used to indicate a hypothesized causal direction. For the mediation example above, the model can be expressed as social status \rightarrow learning motivation \rightarrow achievement. The variables to the right of the arrow heads are commonly termed *endogenous variables*, and the variables having no arrows pointing to them are called *exogenous variables*.

Given the flexibility in model specification, a variety of models can be conceived. However, not all specified models can be identified and estimated. Just as in algebra, where equations cannot have more unknowns than knowns, a basic principle of identification is that a model cannot have a larger number of unknown parameters to be estimated than the number of unique pieces of information provided by the data (variances and covariances of observed variables in conventional SEM). Another basic principle is that all latent variables must be scaled so that their values can be interpreted. These are called necessary conditions for identification, but they are not sufficient. The issue of model identification is complex. Fortunately, there are some established rules that can help researchers decide whether a particular model of interest is identified. When a model is identified, every model parameter can be uniquely estimated. When a model fails to be identified, on the other hand, either some model parameters cannot be estimated or numerous sets of parameter values can produce the same level of model

fit. In any event, results of such (unidentified) models are not interpretable, and the models require respecification (often by the addition of constraints).

Data Collection

Data collection should come, if possible, after models of interest are specified, such that sample size can be determined a priori. The sample size required to provide accurate parameter estimates and model fit information depends on the model size as well as the score scale and distribution of the measured variables. For example, larger models require larger samples to provide stable parameter estimates, and larger samples are required for categorical or nonnormally distributed variables than for continuous or normally distributed variables.

SEM is a *large-sample technique*. That is, model estimation and statistical inference or hypothesis testing regarding the specified model and individual parameters are appropriate only if sample size is not too small for the estimation method chosen. A general rule of thumb is that the minimum sample size should be no less than 200 (preferably no less than 400, especially when observed variables are not multivariate normally distributed) or 5 to 20 times the number of parameters to be estimated, whichever is larger. Larger models often contain a larger number of model parameters and hence demand larger sample sizes.

Model Estimation

A properly specified structural equation model often has some fixed parameters (e.g., missing or omitted paths have path coefficients of zero) and some free parameters to be estimated from the data. Free parameters are estimated through iterative procedures to minimize a certain discrepancy function between the observed covariance matrix (data) and the model-implied covariance matrix (model). Definitions of the discrepancy function depend on specific methods used to estimate the model parameters. A commonly used normal theory discrepancy function is derived from the *maximum likelihood method*. This estimation method assumes that the observed variables are

multivariate normally distributed or that there is no excessive kurtosis of the variables.

When this distributional assumption is violated, parameter estimates may be unbiased (if the proper covariance or correlation matrix is analyzed; i.e., Pearson for continuous variables, polychoric or polyserial correlation when categorical variables are involved), but their estimated standard errors will likely be underestimated, and the model chi-square statistic will be inflated. In other words, when distributional assumptions are violated, statistical inference may be incorrect. Other estimation methods that do not make distributional assumptions are available, but they often require unrealistically large sample sizes to work satisfactorily ($N > 1,000$). When sample size is not that large, a viable alternative is to request robust estimation from some SEM software programs (e.g., LISREL, EQS, Mplus), which provides some adjustment based on the severity of nonnormality to the chi-square statistic and standard error estimates. Statistical inference based on adjusted statistics has been found to work quite satisfactorily, provided sample size is not too small.

The estimation of a model may fail to converge, or the solutions provided may be improper. In the former case, SEM software programs generally stop the estimation process and issue an error message or warning. In the latter, parameter estimates are provided, but they are not interpretable because some estimates are out of range (e.g., correlation greater than 1, negative variance). These problems may result if a model is ill specified (e.g., the model is not identified), the data are problematic (e.g., the sample size is too small, the variables are highly correlated), or both.

Model Evaluation

Once model parameters have been estimated, one would like to make a dichotomous decision: either retain or reject the model. This is essentially a statistical hypothesis-testing problem, with the null hypothesis being that the model under consideration fits the data. The overall goodness-of-fit test statistic has a chi-square distribution (i.e., it is a chi-square test). Unfortunately, this test statistic has been found to be

extremely sensitive to sample size. That is, the model may fit the data reasonably well, but the chi-square test may reject the model because of large sample size. In reaction to this sample size sensitivity problem, a variety of alternative goodness-of-fit indices, such as *goodness of fit index*, *normed fit index*, and *comparative fit index*, have been developed to supplement the chi-square statistic. Higher values of these indices indicate better model-data fit. Values in the .90s (or more recently $\geq .95$) are generally acceptable as indications of good fit. Another popular index is the *root mean square error of approximation* (RMSEA). Unlike the other fit indices, a smaller value of RMSEA indicates better model-data fit ($\leq .05$ indicates close fit, $\leq .08$ indicates acceptable fit, $\geq .10$ indicates bad fit). SEM software programs routinely report a handful of goodness-of-fit indices. Some of these indices work better than the others under certain conditions. It is generally recommended that multiple indices be considered simultaneously when overall model fit is evaluated.

Because some solutions may be improper, it is prudent for researchers to examine individual parameter estimates as well as their estimated standard errors. Unreasonable magnitude or direction of parameter estimates or large standard error estimates are some indications of plausible improper solutions.

Model Modification

When the goodness of fit of the hypothesized model is rejected (by the chi-square model fit test and other fit indices), SEM researchers are often interested in finding an alternative model that fits the data. Post hoc modifications of the model are often based on modification indices, sometimes in conjunction with the expected parameter change statistics (which approximate the expected sizes of misspecification for individual fixed parameters). Large modification indices suggest large improvement in model fit as measured by chi-square if certain fixed parameter(s) were free to be estimated (it is less likely due to chance fluctuation if a large modification index is accompanied by a large expected parameter change value). The suggested modifications, however, may or may not be supported

on theoretical grounds. Researchers are urged not to make too many changes based on modification indices, even if such modifications seem sensible on theoretical grounds. Note that SEM takes a confirmatory approach to model testing; one does not try to find the best model or theory via data using SEM. Rather than data-driven post hoc modifications (which may be very inconsistent over repeated samples), it is often more defensible to consider multiple alternative models a priori. That is, multiple models (e.g., based on competing theories or different sides of an argument) should be specified prior to model fitting, and the best-fitting model should be selected among the alternatives. Because a more complex model, assuming it is identified, will generally produce better fit, and different models can produce the same fit, theory is imperative in model testing.

In conclusion, it is worth noting that although SEM allows the testing of causal hypotheses, a well-fitting SEM model does not and cannot prove causal relations without satisfying the necessary conditions for causal inference (e.g., time precedence, robust relationship in the presence or absence of other variables). A selected well-fitting model in SEM is like a retained null hypothesis in conventional hypothesis testing; it remains plausible among perhaps many other models that are not tested but may produce the same or better level of fit. SEM users are cautioned not to make unwarranted causal claims. Replications of findings with independent samples are recommended, especially if the models are obtained with post hoc modifications.

STRUCTURED CLINICAL INTERVIEW FOR *DSM-IV*

The Structured Clinical Interview for *DSM-IV* (SCID) disorders is a semistructured standardized diagnostic interview commonly used for clinical and research applications. (*DSM-IV* is the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition.) Several versions of the SCID are available, including standard face-to-face interview, computerized interviewer-entered data, and computerized patient-entered self-report. The SCID was developed at the New York Psychiatric Institute Biometrics Research Lab in a comprehensive effort to standardize *DSM-IV* diagnostic interviewing procedures including uniform phrasing of interview questions. Standardized interview procedures were greatly needed to enhance interrater DSM diagnostic reliability, particularly when interviewers differed significantly in education, training, and clinical experience.

When *DSM-IV* Axis I disorders are under consideration, the SCID-I interview is appropriate. The SCID-I interview is comprised of sequential modules that assess for mood disorders, psychotic symptoms, psychotic disorders, substance use disorders, anxiety, and other Axis I disorders commonly found in adults. Each module begins with screening questions. When negative responses are provided for all the screening questions, the interviewer is directed to the next module by means of a branching system. When some positive responses are provided for the screening questions, the interviewer is directed to a more comprehensive review of symptoms for that module. The SCID-II should be used when Axis II personality disorders are under consideration. Again, sequential modules are used to examine each of the *DSM-IV* Axis II personality disorders. The SCID-II can also be used for detecting the *DSM* residual category (personality disorder not otherwise specified) and some unofficial diagnostic categories (depressive personality disorder). A SCID-I or SCID-II interview typically ranges from 45 to 90 minutes, depending on the complexity of patient report, including long-standing psychiatric history.

The SCID-I and SCID-II are available in research and clinician versions. The research versions closely

follow *DSM-IV* criteria including detailed questions to ascertain presence of *DSM-IV* subtype specifiers. The research versions can be highly useful when documenting multiple *DSM* subtype specifiers, as may be encountered when interviewing a person with a complicated history of depressive or manic episodes. Although the research versions are preferred when comprehensive diagnostic information is needed to meet research protocol criteria for participant inclusion and exclusion, these versions tend to be time consuming when one is interviewing patients with intricate psychiatric histories. Rest breaks may be offered if a patient appears to be fatigued by a lengthy interview. The test developers offer a one-sided master copy of the research version and will permit modifications if the full diagnostic interview is not needed for the intended research purposes. A one-time fee with photocopying privileges is available for research funded by nonprofit organizations. A per-use fee is required when research is funded by for-profit organizations (contact Biometrics Research, 212-543-5524). Clinician versions of the SCID are streamlined to cover major DSM disorders often seen in adult clinical populations and are available from American Psychiatric Press (appi.org). Computer-assisted versions and a variety of training resources are available from Multi-Health Systems (mhs.com). On-site training and a 20-hour video training series are available from Biometrics Research. The Structured Clinical Interview for DSM-IV Dissociative Disorders (SCID-D) Revised, developed separately by Marlene Steinberg, focuses specifically on dissociation, including modules for posttraumatic dissociative symptoms and acute stress disorder (see mhs.com).

Although the SCID-I and SCID-II have been used in more than 700 published studies, it is difficult to provide validity and reliability values as study populations have varied considerably. In general, moderate-to-high validity has been demonstrated when SCID-generated diagnoses are compared across expert clinicians. Reliability estimates tend to be higher for more severe psychiatric disorders, and summaries can be found on the biometrics Web site (www.scid4.org). The SCID-I and SCID-II are readily available in English. Although significant sections of the SCID have been translated into Spanish, French,

German, Danish, and six other languages, these translations have been made on an ad hoc basis outside the Biometrics Lab. Psychometric characteristics of non-English versions are not readily available.

SUNFLOWER PLOT

A sunflower plot is an extension of the scattergram for displaying the distribution of pairs of observations. In high-density regions of a scattergram, it often becomes impossible to assess the distribution of observations because the points lie on top of each other (known as *overstriking*). Sunflower plots overcome this problem by using sunflower-like symbols to represent the density.

The two-dimensional (x,y) plane is broken up into a regular lattice of square cells (cells may also be rectangular, depending on axis scale). The number of observations in each cell is counted. A point is placed in the center of every cell that contains one or more observations. Equiangular line segments (petals) are drawn radiating from the central point. The number of line segments is equal to the number of observations. No petal is drawn for a single observation.

A drawback of sunflower plots is that in low-density regions, the location of individual observations is lost. To overcome this issue, it is recommended that for cells containing a small number of observations, the points be positioned at their actual locations.

Figure 1 Sunflower Plot of Fisher's Iris Data on Petal Length and Petal Width in Centimeters

Note: The observation cells are 0.25 cm in width.

One issue with interpretation is that eyes can be drawn to meaningless artifacts as a result of the formation of neighboring sunflowers. This problem can be reduced by randomly rotating the sunflowers.

For cells of extremely high density, the petals may start to overlap and look like filled circles. In this case, it may be sensible to set the number of petals to be proportional to the number of observations (e.g., 1 petal per 10 observations).

Figure 1, created using R, is an example of a sunflower plot for Fisher's Iris data.

Many extensions of sunflower plots have been suggested. For example, the use of different symbols (e.g., circles, with size dependent on number of observations in cell) or cell shapes (e.g., hexagonal cells, which can be packed more tightly). The use of shading or colors can improve the legibility of sunflower plots and allow more information to be presented.

SUPPORT VECTOR MACHINES

Support vector machines (SVM) are a system of machine learning (or classification) algorithm that constructs a classifier to assign a group label to each case on the basis of its attributes. The algorithm requires that there be two variables for each case in the data. The first is the group variable to be classified and predicted (such as disease status or treatment), and the second is the variable of attributes, which is usually multidimensional numerical data (such as amount of daily cigarette consumption or abundance of particular enzymes in the blood). Normally a

classifier is learned from the method based on a set of training cases. The classifier is then applied to an independent test set to evaluate the classification accuracy.

SVM was first developed by Vladimir Vapnik in the 1990s. In the simplest situation, binary (e.g., “disease” vs. “normal”), separable, and linear classification is considered. The method seeks a *hyperplane* that separates the two groups of data with the maximum margin, where the margin is defined as the distance between the hyperplane and the closest example in the data. The idea came originally from the Vapnik Chervonenkis theory, which shows that the generalized classification error is minimized when the margin is maximized.

Why the name *support vector machines*? The answer is that the solution of the classification hyperplane for SVM depends only on the *support vectors* that are the closest cases to the hyperplane. All the remaining cases, farther away, do not contribute to the formulation of the classification hyperplane. The optimization problem is solved through quadratic programming techniques, and algorithms are available for fast implementation of SVM.

SVM is widely applied in virtually any classification application, including writing recognition, face recognition, disease detection, and other biological problems. Two important extensions in the development of SVM made it popular and feasible

in practical applications: *kernel methods* and *soft margin*. Kernel methods are used to extend the concept of linear SVM to construct a nonlinear classifier. The idea is to map the current space to a higher-dimensional space, with the nonlinear classifier in the current space transformed to a linear one in the new, high-dimensional space. The distance structure (dot product) is simply replaced by a kernel function, and the optimization is performed similarly. Common choices of kernel functions include polynomial, radial basis, and sigmoid. Soft margin is used when the two groups of cases are not separable by any possible hyperplane. Penalties are given to “misclassified” cases in the target function, and the penalized “soft margin” is similarly optimized.

Assumptions and Applications of SVM

SVM is a distribution-free method (in contrast to methods like linear discriminant analysis). It is thus more robust to skewed or ill-behaved distributed data. The major considerations when using SVM are the selection of a proper kernel function and the parameters of penalties for soft margins. Selections of kernels and parameters are usually determined by maximizing the total accuracy in cross-validation.

Using the Computer

Since SVM is a relatively modern statistical technique, it is not implemented in most major statistical software (e.g., SAS and S-PLUS). In the following, an extension package, *e1071*, of R software is used to implement SVM, and an example of classification of car fuel efficiency is demonstrated. The data are a sub-sample of 25 cars from the “auto-mpg” data set in the UCI Machine Learning Repository. Fuel efficiency, horsepower, and weight are shown in Table 1. The goal of the classification problem is to classify inefficient and economic cars based on their attributes of horsepower and weight. In Figure 1, inefficient cars are shown on the right, and economic cars are on the left. Linear SVM is applied, and the resulting

SUPPRESSOR VARIABLE

The suppressor phenomenon was first reported in the 1940s by P. Horst, who noted that variables that do not have a high zero order correlation with the dependent variable may contribute to an increased proportion of explained variance. He described how the selection of World War II pilots could be improved by including in the prediction equation not only a variable measuring their technical abilities but also a variable assessing their verbal ability, even though the latter variable is itself unrelated to the criterion (navigating skills). He found that the verbal ability regressor had a negative coefficient when entered into the prediction equation.

Subsequently, Quinn McNemar provided an intuitive explanation in terms of *common elements*. According to McNemar, a useful predictor has, of course, many elements in common with the dependent variable, but usually also irrelevant elements. A suppressor is a variable that has no elements in common with the dependent variable but does have irrelevant elements in common with the predictor. If the predictor and suppressor are positively correlated, then the suppressor has a negative regression weight after inclusion in the regression equation. This negative regression weight reflects the fact that the irrelevant

elements from the predictor are partialled out, which “purifies” the predictor and improves the prediction.

McNemar’s explanation proved relevant to more situations than Horst’s classical form. This is demonstrated by the examples displayed in Table 1, showing various patterns of bivariate correlations between a dependent variable *Y* and two independent variables X_1 and X_2 .

From Table 1, the following observations can be made:

1. The first example illustrates the *classical* suppressor condition.
2. In the second example, two independent variables have a positive zero order correlation with the dependent variable and correlate positively with each other. One of them receives a negative regression weight. This situation is referred to as *negative suppression*. Although the suppressor has relevant information in common with *Y*, they share fewer common elements than the common elements of irrelevant information shared by the suppressor and the other predictor.
3. The third situation involves two variables that can act as good predictors. They also share, however, information that is irrelevant to *Y*, but with an opposite orientation. When both variables are included in the regression equation, they suppress a part of each other’s irrelevant information. This case is called *reciprocal suppression*.
4. In all the situations, inclusion of a second predictor leads to an increase of the absolute value of the regression coefficient, as well as of the proportion of explained variance.

Table 1 Examples of Three Suppressor Situations

	1	2	3	4	5	8
<i>Situation</i>	r_{y1} (r^2_{y1})	r_{y2} (r^2_{y2})	r_{12}	$b_{y1.2}$	$b_{y2.1}$	$R^2_{y.12}$
Classical	.40 (.16)	.00 (.00)	.707	.800	-.566	.320
Negative	.50 (.25)	.10 (.01)	.710	.865	-.514	.381
Reciprocal	.50 (.25)	.30 (.09)	-.270	.627	.469	.454

On the latter characteristic, A. J. Conger based the following general definition: “A suppressor variable is defined to be a variable that increases the predictive validity of another variable (or set of variables) by its inclusion in a regression equation. This variable is a suppressor only for those variables whose regression weights are increased.” In a formula, variable X_2 is a suppressor for predictor X_1 (in relation to the dependent variable Y) if

$$\beta_1 r_{y1} > r_{y1}^2.$$

SURVEY WEIGHTS

Weights are numerical values that are used in surveys to multiply by response values in order to account for missing observations. The missing data may be absent as the result of a prearranged sample design or as the result of nonresponse. In the case of sample designs, weights are used to estimate totals or means for data of interest, such as acres of corn grown or household income, based on a selected subset of the entire population. The population could be, say, all farms or all households. The subset is known as a sample. In the case of nonresponse, the weights are inflated further to account for those missing observations. Another method for accounting for nonresponse is to replace those values with data derived from other information. That process is known as *imputation*. Whether compensation for nonresponse is done by imputation, by weighting the results of a census, or by adjusting the weights for a sample, one must consider whether the missing data are different in some way from the data actually observed. Here, however, we will examine the more straightforward use of weights in surveys: sampling weights.

Data collected on a given characteristic or characteristics for a population, such as acres of corn planted on farms in Minnesota, constitute a survey. Thus a characteristic for a data element could be number of acres of corn, and a population could be all farms in Minnesota. Often we want to estimate totals or means of data elements, such as total acres of corn in a population (here, Minnesota farms), by taking a sample of members of the population and from that data, inferring an estimate for the population. The sample is selected from the population according to varying rules, depending on the type of sample. Samples may be model based or design based. Often they are design based with model-assisted inference. If they are design based, then samples are collected on the basis of the randomization principle. This practice leads to the sample weights we discuss here.

For example, the simplest design-based sample is the simple random sample (SRS). If, for example, a sample of 20 were to be drawn at random from a population with 100 members, with an equal chance of selection for each member of the population, then that sample would be an SRS. Here the sample size is $n = 20$, and the population size is $N = 100$. The probability of selection for each member of the population to become a member of the sample is $\frac{20}{100} = \frac{1}{5}$. In general, the probability of selection for an SRS is $\frac{n}{N}$. Each value we collect for a characteristic, here acres of corn, for each member of the sample can be added together for a sample total. The sample weight that we need to multiply by this sample total to obtain an estimated population total would be the inverse of the probability of selection, or $w = \frac{N}{n}$, where w is the weight. In the above example, $w = 5$.

These weights are always the inverses of the corresponding probabilities of selection. The probability of selection depends on the structure of the design-based sample and can be complex. This process may involve various stages and adjustments, but the basic fact to remember is that a sample weight for any given observation is the inverse of its probability of selection.

SURVIVAL ANALYSIS

Survival analysis is a well-developed branch of statistics that concerns methods for the analysis of time-to-event data. Such data arise in a number of scientific fields, including medicine, biology, public health, epidemiology, engineering, economics, and demography, among others. Time-to-event data, sometimes also referred to as failure time data (in which case the event is regarded as a “failure”), have two unique features. First, the response of interest, time, is always nonnegative. Second, and more important, these data are often *censored* or *truncated* or both, making the survival analysis unique among most other statistical methods.

Survival analysis often models survival function and hazard function instead of the probability density function or cumulative distribution function. Throughout this discussion, we will assume that the time to event, denoted by T , is a nonnegative continuous random variable with a *probability density function* $f(t)$ and that $F(t) = P(T \leq t) = \int_0^t f(u) du$ is the corresponding *cumulative distribution function*. The *survival function* and the *hazard function* of T are then defined as $S(t) = P(T > t) = 1 - F(t)$ and $\lambda(t) = \lim_{\Delta t \rightarrow 0} P(t < T \leq t + \Delta t \mid T > t) / \Delta t$, respectively. It can be easily shown that $\lambda(t) = f(t) / S(t)$ and $S(t) = \exp\{-\Lambda(t)\}$ where $\Lambda(t) = \int_0^t \lambda(u) du$ is termed the *cumulative hazard function*. We see that the survival function gives the probability that an individual “survives” up to time t , while the hazard function represents the “instantaneous”

probability that the “failure” will occur in the next moment, given that the individual has survived up to time t . Both the survival function and the hazard function can be used to characterize the stochastic behavior of the random variable T .

Censoring and Truncation

Time-to-event data present themselves in unique ways that create special obstacles in analyzing such data. The most important one is known as *censoring*. Loosely speaking, censoring means that the data are incomplete. Although there exist many censoring mechanisms, we shall mainly focus on the two most frequently encountered types of censoring: *right censoring* and *interval censoring*.

Table 1 presents a typical right-censored data set resulting from a clinical trial. The purpose of this clinical trial was to evaluate the efficacy of maintenance chemotherapy for acute myelogenous leukemia (AML). In all, 23 patients were treated by chemotherapy, which led to remission, and then randomly assigned to two groups. The first group contained 11 patients and received maintenance chemotherapy. The second group contained 12 patients and did not receive maintenance chemotherapy. Time until relapse, the response variable denoted by T hereafter, was recorded in weeks. The objective of the survival analysis was to see if the maintenance chemotherapy prolonged time until relapse. In later sections, we will answer this question by applying appropriate survival analysis methods.

In Group 1, the first and the second patients had relapse times of precisely 9 weeks and 13 weeks, respectively. That is, $T_1 = 9$ and $T_2 = 13$. The third patient, however, was not able to provide an exact

Table 1 The Acute Myelogenous Leukemia Data

Groups	Time to relapse (in weeks)

relapse time, perhaps due to being dropped out of the study. All we know is that, at Week 13, this patient was still relapse free. Thus this patient’s relapse time should be greater than 13 weeks, which is denoted by 13+ in the table. One can see that for this patient, we have only “incomplete” information because instead of knowing the exact value of T_3 , we know only that $T_3 > 13$. Such censoring is called *right censoring*.

A more complicated censoring mechanism is interval censoring, which arises when the failure time of interest, T , is known only to be bracketed between two observation times, say, $L < T \leq R$. This can happen, for example, in a medical or health study that entails periodic follow-up. An individual who should be observed periodically for a clinically defined “failure” may miss one or more prescheduled visits and return after the failure occurred. In such cases, we know only that the true failure time is greater than the last observation time at which the failure had not occurred and less than or equal to the observation time at which the failure has been observed to occur.

Table 2 presents an interval-censored data set obtained from a cancer study. This study involved 94 early breast cancer patients with two treatments, radiotherapy (radiation therapy) alone and radiotherapy

with adjuvant chemotherapy. Among them, 46 patients were given radiotherapy alone, and 48 patients received radiotherapy with adjuvant chemotherapy. During the study, each patient was supposed to be checked every 4 or 6 months by physicians for the appearance of breast retraction, a response that has a negative impact on overall cosmetic appearance. However, actual observation times differ from patient to patient, and only interval-censored data are available for the appearance. For instance, the second patient in the radiotherapy group had not developed any symptom of breast retraction by Week 25. When she returned at Week 37, however, breast retraction had already appeared. Therefore, the failure time for this patient must be between 25 and 37 weeks. A main objective of the study was to compare the two treatments in terms of the time until the appearance of breast retraction, the survival time of interest.

Interval censoring can be regarded as a more general censoring mechanism than right censoring. If either $L = R - \epsilon$ for arbitrarily small ϵ or $R = \infty$, then we have an exact or a right-censored survival time.

Another important feature of many failure time data, sometimes confused with censoring, is *truncation*. Truncation of the failure time occurs when some individuals cannot be observed (and in fact may not even be known to exist) because their failure times do not lie in a certain observational window. This contrasts with censoring, in which case we at least have partial information of the censored observations. Therefore, truncated data must be analyzed under the restriction of conditional inference. In this article, we will focus on survival analysis of censored data and refer readers to some textbooks that discuss truncation in detail.

Kaplan-Meier Estimator and Related Methods

The *Kaplan-Meier (KM) estimation* is a nonparametric technique for estimating the survival function of a homogeneous

right-censored sample. If there is no censoring in the data, we can certainly use the empirical cumulative distribution function (and then subtract it from 1) as our estimator. However, existence of censoring requires more complex treatment.

Let $t_1 < t_2 < \dots < t_k$ represent the exactly observed (i.e., not censored) failure times in a sample of size n . We first estimate the hazard function at time t_i for $i = 1, \dots, k$. Obviously, an intuitive estimator of $\lambda(t_i) = f(t_i)/S(t_i)$ should be $\hat{\lambda}(t_i) = d_i/n_i$, where d_i is the number of failures at time t_i , and n_i is the number of participants at risk just prior to t_i . Given all the $\hat{\lambda}(t_i)$ estimated, the KM estimator for the unknown survival function $S(t)$ is simply $\hat{S}(t) = \prod_{i:t_i \leq t} [1 - \hat{\lambda}(t_i)]$. A heuristic argument of the validity of the KM estimator is outlined as follows. Note that we can rewrite $\lambda(x) = f(x)/S(x)$ as $S(t) = \exp[-\int_0^t \lambda(u) du]$. Therefore, a discrete approximation of $S(t)$, if we know only the values of $\hat{\lambda}(t)$ at $\{t_1, t_2, \dots, t_k\}$, is $\prod_{i:t_i \leq t} [1 - \hat{\lambda}(t_i)]$.

Confidence intervals of the survival function can be obtained by estimating the variance of $\hat{S}(t)$ via the so-called *Greenwood formula* and assuming asymptotic normality. This topic will not be explored further here.

We now illustrate the above procedure with the AML data in Table 1. For the maintained group, $n = 11$ and $k = 7$. For the other group, $n = 12$ and $k = 9$.

The intermediate quantities we need, together with the final estimate of $S(t)$, are shown in Table 3.

Notice that censored observations contribute to the change of n_i in the above calculation. In the next section, these two (estimated) survival functions will be plotted and contrasted to see whether maintenance prolongs time to relapse.

When interval-censored data are present, the KM estimator can no longer be used because we usually have not any exactly observed failure time (recall that now all failure times fall in some interval). In such cases, an extension of the KM estimator, the *Turnbull estimator*, should be employed. This estimation procedure, which is essentially an expectation maximization (EM)-type algorithm, requires iterative steps and is outlined as follows. Let the observed data be $\{(l_i, r_i]; i = 1, \dots, n\}$ and $0 = a_0 < a_1 < \dots < a_m = \infty$ such that each l_i and r_i is contained in the set. Define $\alpha_{ij} = 1$ if $(a_{j-1}, a_j]$ is a subset of $(l_i, r_i]$ and 0 otherwise for $i = 1, \dots, n$ and $j = 1, \dots, m$. Note that α_{ij} essentially indicates whether participant i contributes to the estimation of the survival function (of T) over the interval $(a_{j-1}, a_j]$, depending on whether it is likely that the (unobserved) failure time of the i th participant falls within this interval. The following Steps 1 to 3 are then iteratively repeated until convergence.

Table 4 Turnbull Estimates for the Breast Cosmetic Deterioration Data

t	0 – 4	5 – 6	7	8 – 11	12 – 24	25 – 33	34 – 38	40 – 48	≥ 48
$\hat{S}(t)$	1.000	0.954	0.920	0.832	0.761	0.668	0.586	0.467	0.000

Note: t = time to failure (i.e., time to breast cosmetic deterioration); $\hat{S}(t)$ = estimate of the survival function $S(t)$ at time t .

Step 0. Assign initial values to $S(a_j)$ for $j = 1, \dots, m - 1$ (recall that $S(a_0) = 1$ and $S(a_m) = 0$). A common choice is $S(a_j) = (m - j)/m$; that is, equal weight is given to each time point.

Step 1. Compute the probability p_j that an event occurs in interval $(a_{j-1}, a_j]$; that is, $p_j = S(a_{j-1}) - S(a_j), j = 1, \dots, m$.

Step 2. Update p_j by

$$p_j^{new} = \frac{1}{n} \sum_{i=1}^n \frac{\alpha_{ij} p_j}{\sum_{k=1}^m \alpha_{ik} p_k}$$

Note that the summand

$$\frac{\alpha_{ij} p_j}{\sum_{k=1}^m \alpha_{ik} p_k}$$

represents the probability that the i th failure time is in interval $(a_{j-1}, a_j]$ according to the (old) p_1, \dots, p_m .

Step 3. Compare p_j^{new} and p_j for all $j = 1, \dots, m$. If they are close enough, stop. If not, replace p_j by p_j^{new} in Step 1 and repeat Steps 2 to 3.

It can be shown that, under mild conditions, the above algorithm always converges although the convergence can be very slow when sample size is large. Table 4 gives the Turnbull estimate of the survival function for the radiotherapy group of the breast cosmetic deterioration data (see Table 2).

Some programming tips: In S-PLUS, the KM estimate is computed by the routine `Survfit`, and the Turnbull estimate can be obtained from `kaplanMeier`. SAS, however, has only `LIFETEST` for computing the KM estimate.

Log-Rank Tests

Sometimes it is of interest to test whether multiple survival functions are identical. For example, as

described above, a physician may want to know whether receiving maintenance chemotherapy really helps patients. In such a case, the null hypothesis is $H_0: S_1(t) = S_2(t)$ for all t , and the alternative hypothesis is $H_1: S_1(t) \geq S_2(t)$ for all t with at least one strict inequality. We first consider the right-censored AML data and plot the two estimated survival functions obtained earlier.

It seems that the null hypothesis should be rejected according to Figure 1. Nonetheless, we need to develop a test statistic to rigorously justify our conclusion. The *log-rank test*, which may be regarded as an extension of the Mann-Whitney test for uncensored data, is one of the most popular choices.

Let $t_1 < t_2 < \dots < t_m$ be the ordered observed distinct failure times (not censored observations) in the sample formed by combining the two groups, and let D_{1k} and Y_{1k} denote the number of observed failures and number at risk, respectively, for the first group at time $t_k, k = 1, \dots, m$. Also let D_k and Y_k be the corresponding values in the combined sample. Under the

Figure 1 AML Data: Kaplan-Meier Estimate of the Survival Functions

null hypothesis that the two groups share a common survival function (and thus hazard function), given Y_{1k} , D_k and Y_k , D_{1k} has a hypergeometric distribution with mean $E_{1k} = D_k Y_{1k} / Y_k$ and variance $V_{1k} = D_k Y_{1k} (Y_k - Y_{1k}) (Y_k - D_k) / Y_k^2 (Y_k - 1)$. Define the test statistic as

$$Z = \sum_{k=1}^m (D_{1k} - E_{1k}) / \sqrt{\sum_{k=1}^m V_{1k}} .$$

It can be shown that Z approximately follows a standard normal distribution when sample sizes are large. Note that the test statistic Z is essentially a quantity of standardized observed-minus-conditionally-expected number of events.

Applying the above test to the AML data, we obtain $Z = -1.843$, yielding a p value of 0.033 for the one-sided test specified above. Thus we may conclude that the maintenance chemotherapy prolonged time until relapse. If a two-sided test is preferred, that is, the alternative hypothesis is $S_1(t) \neq S_2(t)$ for some t , then the p value would be 0.065.

A few remarks are in order. First, the name *log-rank* arises from two facts. One is that, in computing the test statistic Z , we actually estimated two cumulative hazard functions (one for Group 1 and the other for the combined sample), which are the negative logarithm of the survival functions. The other fact is that what matters is really the ranks of the observed failure times. In other words, if one monotonically transforms the data, say by multiplying all the time points by 10 or taking square roots, the test statistic will remain unchanged.

Second, the log-rank test presented above has many modifications and extensions—so many that sometimes they become confused with each other. One major modification is that one can apply the above method to multiple (rather than only two) samples. Another is that one can specify various weight functions in calculating Z . Furthermore, the log-rank test we have discussed is not applicable if the data are interval censored. For such a case, we refer the readers to the book by J. Sun under “Further Reading” because the test procedures under interval censoring are usually complicated. Several excellent textbooks are also provided as further references.

Last, in S-PLUS, the routine `survdifff` can test the hypothesis laid out above. In SAS, the log-rank test is carried out by the `LIFETEST` procedure.

Semiparametric Regression Analysis

When covariates are present, especially when they are ordinal or continuous, regression analysis often needs to be performed. However, nonnegativity of the failure time and censoring complicate the problem. In addition, in medical studies, clinical trials, and many other fields, it is often not appropriate to make parametric assumptions. Consequently, semiparametric regression models are widely used in survival analysis.

The most commonly used semiparametric model, the *proportional hazards (PH) model*, is also termed as the *Cox model* in the literature. Denote the failure time by T as before, and a vector of covariates by \mathbf{Z} . The PH model assumes that $\lambda(t | \mathbf{Z} = \mathbf{z}) = \lambda_0(t) \exp\{\boldsymbol{\beta}'\mathbf{z}\}$, where $\boldsymbol{\beta}$ is a vector of unknown regression parameters, with $\boldsymbol{\beta}'\mathbf{z}$ denoting the inner product of two vectors $\boldsymbol{\beta}$ and \mathbf{z} , and $\lambda_0(t)$ is an unspecified nonnegative hazard function. Here $\lambda(t | \mathbf{Z} = \mathbf{z})$ should be interpreted as the hazard function of T given the covariate $\mathbf{Z} = \mathbf{z}$. Notice that when $\mathbf{Z} = \mathbf{0}$, the hazard function of T is nothing but $\lambda_0(t)$. Therefore, $\lambda_0(t)$ is termed the *baseline hazard function*. Because $\lambda_0(t)$, having an unknown form, is essentially a nonparametric component and $\exp\{\boldsymbol{\beta}'\mathbf{z}\}$ is obviously a parametric one, the PH model is therefore indeed a “semiparametric” model.

Suppose individual i has a covariate vector \mathbf{Z}_i and another individual j has \mathbf{Z}_j . Then the two corresponding hazard functions suggest that

$$\begin{aligned} \frac{\lambda_i(t | \mathbf{Z}_i = \mathbf{z}_i)}{\lambda_j(t | \mathbf{Z}_j = \mathbf{z}_j)} &= \frac{\lambda_0(t) \exp\{\boldsymbol{\beta}'\mathbf{z}_i\}}{\lambda_0(t) \exp\{\boldsymbol{\beta}'\mathbf{z}_j\}} \\ &= \exp\{\boldsymbol{\beta}'(\mathbf{z}_i - \mathbf{z}_j)\} , \end{aligned}$$

which is a constant. In other words, the two hazard functions are proportional to each other. That is where the model obtains its name.

For the AML data, denote the unmaintained group by $Z = 0$ and the maintained group by $Z = 1$ (here Z is a scalar). The PH model says that time to relapse of those patients without maintained chemotherapy has a hazard

function $\lambda_0(t)$ while that of the patients receiving chemotherapy has $\lambda_0(t)e^\beta$. In other words, the difference caused by the maintained chemotherapy is reflected by e^β (or rather, β), which we will estimate next.

Often we are interested in estimating β , the regression parameter, because it determines how the covariates affect the failure time. An approach called *partial likelihood* enables us to fulfill the task without being troubled by the unknown $\lambda_0(t)$. Suppose there are no ties between the observed failure times (not censored observations). Let $t_1 < t_2 < \dots < t_m$ be the ordered observed failure times, $\mathbf{z}_{(j)}$ be the covariate associated with the individual whose failure time is t_j , and $R(t_j)$ the risk set at time t_j —, that is, the set of all individuals who are still under observation just prior to t_j , $j = 1, \dots, m$. The partial likelihood of the data, based on the PH model, is expressed by the following equation:

$$L(\beta) = \prod_{j=1}^m \frac{\exp\{\beta' \mathbf{z}_{(j)}\}}{\sum_{k \in R(t_j)} \exp\{\beta' \mathbf{z}_k\}}.$$

Maximizing the above partial likelihood or its logarithm, which requires numerical analysis tools, yields the estimator $\hat{\beta}$. Notice that the numerator utilizes the information contributed by the j th failure, whereas the denominator carries the information about all individuals who are still at risk, some of which may be censored later.

The partial likelihood specified above is not the usual full likelihood. It is not even a conditional likelihood, although under mild assumptions it coincides with the marginal likelihood. Nonetheless, it yields an efficient and asymptotic normal estimator of β and can be treated as an ordinary likelihood. In fact, the variance of $\hat{\beta}$ is estimated by calculating the inverted observed information matrix from the partial likelihood.

When ties are present, we need to modify the above partial likelihood to break the tie. Several methods exist in the literature for such a purpose. For example, the Breslow version of the modified partial likelihood is

$$L(\beta) = \prod_{j=1}^m \frac{\exp\{\beta' \mathbf{s}_{(j)}\}}{\left[\sum_{k \in R(t_j)} \exp\{\beta' \mathbf{z}_k\} \right]^{d_j}},$$

where d_j is the number of failures at time t_j and $\mathbf{s}_{(j)} = \sum_{i: t_i = t_j} \mathbf{z}_i$ is the sum of the covariates of individuals observed to fail at t_j .

Applying the PH model to the AML data by coding Z as mentioned earlier, we obtain $\hat{\beta} = -0.904$ with a standard error of 0.512. Thus the p value for testing $H_0: \beta = 0$ versus $H_1: \beta \neq 0$ is 0.078 (note that this result is consistent with the log-rank test result), indicating marginal significance. The value of $\hat{\beta}$ can also be interpreted via the hazard ratio—we may say that the hazard function corresponding to the maintained group is roughly 40% ($e^{-0.904} = 0.405$) of the hazard function corresponding to the unmaintained group. Put another way, if two patients, one in the maintained group and the other in the unmaintained group, both have survived up to time t , then the probability that the former will “fail” (in this case, relapse) in the next moment is only about 40% of the probability that the latter will.

It must be emphasized that one should ignore the baseline hazard function $\lambda_0(t)$ only when the interest of study lies solely in testing whether the covariate influences the failure time. If one also wants to predict the survival probability for a particular patient, then $\lambda_0(t)$ will need to be estimated too. The most commonly used estimator is the Aalen-Breslow estimator.

When interval censoring is present, things are much more complicated. The reason is that we will in general have to estimate the baseline hazard function $\lambda_0(t)$ simultaneously when we estimate β because the partial likelihood approach no longer applies. One remedy is to consider a more general type of semiparametric model, termed linear transformation models, which contain the PH model as a special case.

The SAS procedure PHREG contains many extensions of the PH model. The corresponding routine in S-PLUS is `coxph`.

SYSTEM OF MULTICULTURAL PLURALISTIC ASSESSMENT

The System of Multicultural Pluralistic Assessment, best known as SOMPA, was developed by S. Mercer and A. Lewis in 1978 to meet the educational and mental health needs of minority children. Published by the Psychological Corporation, the SOMPA was discontinued in 2003. The SOMPA was designed as a system for assessing the level at which children function in cognitive abilities, perceptual motor abilities, and adaptive behavior in a nondiscriminatory manner.

Intended to provide a comprehensive assessment of children ages 5 to 11, the SOMPA included a medical component, a social component, and a pluralistic component. The medical component determined the presence or absence of organic pathology. Six measures were used to assess the medical component: physical dexterity tasks (sensory motor coordination), the Bender Visual Motor Gestalt Test (perceptual and neurological factors), the Health History Inventories, weight by height norms (nutritional or developmental problems), vision (the Snellen Test), and auditory acuity (national norms).

The social component was concerned with a child's ability to adapt and function in social situations. Two measures were used to assess the social component: the Adaptive Behavior Inventory for Children and the Wechsler Intelligence Scale for Children-Revised (WISC-R).

Last, the pluralistic perspective yielded an index of a child's intelligence or Estimated Learning Potential through a "corrected" WISC-R score based on a comparison of how well the child performed on that test with the performance of other children who had had similar learning opportunities.

The procedures of the SOMPA provided an alternative testing method to increase the proportion of minority students in gifted education programs, particularly in states that used IQ cut-off scores for placement decisions. There was some evidence to suggest that IQ or Estimated Learning Potential, as measured by the SOMPA, was able to predict school achievement. In addition, the SOMPA had some utility as an aide to psychological assessment of Native American Navajo children. In spite of the general acceptance of the SOMPA as a tool for assessing children from culturally and linguistically diverse backgrounds, some criticism remained unresolved. One was the claim that the SOMPA was a better instrument than the WISC for predicting learning potential in a school environment. Also, concerns were raised regarding the national representativeness of the sample. Despite the criticism, the SOMPA represented the first attempt at reducing cultural biases and stigmatization in assessing culturally and linguistically diverse children.

***T* SCORES**

A *T* score is a type of standard (not standardized) score that has a mean of 50 and a standard deviation of 10. It is very similar in concept to a *z* score, which has a mean of 0 and a standard deviation of 1.

T scores are used when the researcher wants to convert raw scores to a metric that is comparable across distributions (different sets of scores) and where there is a desire to have all scores as positive values (which is the case unless a raw score is more than 3 standard deviations below the mean).

The formula for *T* score is

$$T = 50 + 10z,$$

where

T is the *T* scores,

50 is the mean of the set of *T* scores,

10 is the amount that one *T* score deviates from the mean, and

z is the corresponding *z* score for a particular raw score.

For example, here is a set of raw scores and their corresponding *z* scores and *T* scores:

T TEST FOR TWO POPULATION MEANS

The t test for independent means examines the difference between the means of two independent groups and requires that for each case in the sample, there be two variables. The first is the *group variable* (such as treatment or gender), and the second is the *test variable* (such as a score on a personality test or an achievement test). The second variable, sometimes known as the *grouping variable*, places each individual in one of two mutually exclusive categories, and the t test itself evaluates whether there is a significant difference between the two groups.

Why is it referred to as “Student’s t ?” The test was formulated by William Gossett (a student of Karl Pearson) in the early 1900s, when he was a chemist and a statistician at the Guinness Brewing Company. As is true today, many company secrets were proprietary, and his employer would not allow him to publish his own work under his own name (trade secrets and so forth). Instead, he was given permission to publish it under the pseudonym “Student.”

The Case Study and the Data

It is not difficult to find any school system that relies on testing for a variety of different purposes, such as adhering to different federal and state guidelines, for example, the No Child Left Behind Act of 2001. Another purpose might be to chart school progress or determine differences between classrooms at the same grade level. To examine whether such differences are significant, a t test for independent means can be applied. Table 1 shows the sample data set for 25 children, one set from Susan Graves’s classroom and one set from Jack Longer’s classroom.

The Assumptions Underlying the t Test

Three important assumptions underlie the use of the t test for independent means:

1. The test variable (which in this example is the math test score for each student) is normally distributed. If the sample is large enough (15 or more per group), this assumption is fairly resistant to being violated, but if the scores are not normal, then a larger sample size might be needed.
2. The variances for each of the test variables in both groups are equal to one another.
3. The cases in each of the samples are random in nature, and the scores on the test variable are independent of one another. If this assumption is violated, then the resulting t value should not be trusted.

The Research Hypothesis

The null hypothesis associated with this analysis is that there is a difference between the population

means of the two samples. This is a nondirectional test and can be stated as follows:

$$H_1 : \mu_1 = \mu_2,$$

where μ equals the population mean.

Computing the t Value

One formula for computing the t value is

$$t = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\left[\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2} \right] \left[\frac{n_1 + n_2}{n_1 n_2} \right]}}$$

where

\bar{X}_1 is the mean for Group 1, which in this example is 79.48;

\bar{X}_2 is the mean for Group 2, which in this example is 73.91;

n_1 is the number of participants in Group 1, which in this example is 25;

n_2 is the number of participants in Group 2, which in this example is 22;

s_1^2 is the variance for Group 1, which in this example is 11.17;

s_2^2 is the variance for Group 2, which in this example is 15.32.

Once the appropriate values are entered into the equation, it appears like this:

$$t = \frac{79.48 - 73.91}{\sqrt{\left[\frac{(25 - 1)11.17^2 + (22 - 1)15.32^2}{25 + 22 - 2} \right] \left[\frac{25 + 22}{25 \cdot 22} \right]}} = 1.436.$$

Using the Computer

For this example, SPSS was used to compute the t value for this test of independent means. The output shown in Figure 1 includes the mean standard deviation and standard error of the mean for the dependent variable (math score) for both the Graves and Longer classrooms. Also shown in the output is the computation of the t value (equal to 1.436), the degrees of freedom (45), and the associated and exact level of significance (.158). Other information in this output may be useful as well.

Applying Ideas in Statistics and Measurement

The following abstract is adapted from Heydenberk, R. A., & Heydenberk, W. R. (2005). Increasing metacognitive competence through conflict resolution. Applying ideas on statistics and measurement. *Education and Urban Society, 37*(4), 431–452.

The ***t* test** is one of the most popular of all inferential tests, since the comparison it does between two groups (be they independent or dependent) is such a common comparison found in almost any science. In this study, Heydenberk and Heydenberk, from Lehigh University, determined the effects of conflict resolution and related social skill development on students' metacognitive competencies. The study was conducted over a 5-year period in elementary schools in the Philadelphia School District and in a neighboring urban school district, and the participants were fourth and fifth graders. The performance of each student was assessed for significant pretest-to-posttest differences using a one-tailed ***t* test** with an alpha or significance level of .05. The results showed that students who received the treatment demonstrated significant improvement in metacognitive skills, and the research hypothesis was accepted—that the introduction of conflict resolution worked. Their conclusion? Integrating conflict resolution and social skills training into curricula is an effective way to affect students' metacognitive competences.

TEST-RETEST RELIABILITY

All observations and all measurements contain error. The focus of much work in measurement is on minimizing and estimating the amount of error in any given measurement. In classical test theory, X is an observed score that is composed of T , the true score, and E , the error score: $X = T + E$. The true score is never known, but it can be thought of as the long-range average of scores from a single instrument administered to an individual an infinite number of times (the expected value or expected score). The error score is random and may have many sources, including testing conditions, individual characteristics that fluctuate from administration to administration, differences in forms, and instability of an individual's ability or trait over time.

This random error score is quite different from systematic sources of error, like testwiseness, which may systematically increase an individual's score on each administration. Since testwiseness is systematic or

constant, it finds its way into the true score and creates problems regarding validity, since the trait being measured may be inadvertently influenced by testwiseness. Random error, since it varies randomly, influences the consistency of scores but not the expected value of a score (the true score) and thus influences reliability, not validity.

Theoretically, we can estimate the amount of error if we know how much of a given score is due to errors of measurement. If we were able to test a single person repeatedly without the effects of recall and fatigue, variation in that person's scores would be considered measurement error. If there were no measurement error, that person would get the same score on each administration. Since it is not possible to test individuals repeatedly without the interference of recall and fatigue, we employ groups to estimate measurement error variance. This allows us to estimate the *standard error of measurement*, the typical amount of measurement error in a set of scores.

If we take the classical test theory model of scores and consider groups of scores and their variances, we see that the variance of the observed scores equals the sum of the variance of true scores and the variance of error scores: $S_X^2 = S_T^2 + S_E^2$ (in sample notation).

This is the long way of introducing the need for reliability. *Reliability* is a tool used to estimate the standard error of measurement but also has some intrinsic benefits in and of itself. Theoretically, reliability is considered the correlation between scores on two parallel forms of a test. The idea is that if there is no measurement error at work, scores from two parallel forms administered to the same group of individuals should be perfectly correlated—each individual should obtain the same score. It can be shown that the correlation between two parallel forms of a test is equal to the ratio of true score variance to observed score variance—the proportion of variance in observed scores that is due to true individual differences: $r_{tt} = \frac{S_T^2}{S_X^2}$. This reliability coefficient can then be used in estimation of the standard error of measurement, because it tells us the proportion of observed variance that is *true variance*; the standard error of measurement is a function of the proportion of observed variance that is true variance.

Estimating Reliability

Based on the classical test theory conception of reliability, scores are reliable to the extent that individuals' scores remain constant on repeated measurements. One way to estimate the degree of consistency or stability of scores is to administer a test on multiple occasions. Each administration provides a separate observation or measurement, from which stability of scores can be observed directly.

This form of reliability is best estimated when the actual measurement procedure employs multiple administrations of a single form, because if scores vary between administrations for a single individual, we are likely to attribute this to differences in occasions or time sampling—errors result from conditions in the lapse of time. This is typically done by administering the test form to each individual twice, within a specified time period. The scores resulting from the two administrations are then correlated—this correlation is the *test-retest reliability coefficient*.

Formal Conditions for Parallel Forms Reliability

Test-retest reliability is estimated from the administration of one form on two occasions. This is appropriate when the measurement procedure includes a single form that may be administered on multiple occasions (pre-post tests or follow-up administrations) or the inference from scores is based on the ability to generalize in terms of the occasion or time frame of measurement. Knowledge of test-retest reliability allows one to generalize from one time of measurement to other time periods or occasions. For this to be a coefficient of reliability, the test should be administered in a specified time frame and occasion to the degree that is meaningful given the characteristics being measured. To be able to adequately interpret a test-retest reliability coefficient, one must know the length of time between administrations, the differences in specific occasions (time of day, day of week, etc.), and the existence of relevant intervening experiences that are likely to result in changes in scores.

At least three sources of score variability will lead to instability of scores over time. First, variation due to instability of the trait or ability being measured from time to time will lead to variation in scores. Variation in attention, motivation, and so on will lead to variation in scores. Finally, if the forms differ from one administration to another, content sampling will also introduce variation in scores (often referred to as a *stability-equivalence estimate* of reliability). To the extent that the trait is normally thought of as being unstable or easily malleable by intervening experiences, test-retest reliability would not be an appropriate method of estimating reliability. If we expected an intervention to alter scores and needed to estimate measurement error, an estimate of test-retest reliability would overestimate measurement error, since we produced a condition that created changes in scores (the intervention). Test-retest reliability is an appropriate estimate of reliability when the trait is generally expected to be stable over time and we are interested in estimating the stability of scores from an instrument intended to measure that trait.

Test-retest reliability coefficients are typically lower when the administrations occur over longer periods of time, when there are more opportunities for relevant intervening experiences that change the trait being measured, and when the content of the forms changes. At the same time, if a given form of a test is administered within a relatively short period of time, the effects of memory or recall are likely to influence scores in a way that is difficult to estimate. Recall will prevent the individual from responding in a truthful way and biasing results.

General Issues Regarding Reliability

Because the test-retest reliability estimate is based on a correlation, it is not simply a characteristic of the measurement instrument itself. Score variability directly influences correlations, such that all else being equal, the more score variance present, the higher the correlation and thus the higher the reliability. Correlational forms of reliability are sample specific and thus are not necessarily generalizable to other samples. They do, however, provide an estimate of score consistency for the scores at hand.

In any estimate of reliability, conditions present during the specific administration of the measurement instrument can impact performance and scores in random ways, leading to lower consistency of scores and lower reliability. Each type of reliability estimate (e.g., test-retest reliability) also captures a specific form of random error. The test-retest reliability primarily captures measurement error due to sampling time or occasions. If this source of error is important to estimate given the measurement procedure (because the test is administered multiple occasions over time), then it is an appropriate form of reliability. Technically speaking, an estimate of reliability should be obtained for each set of scores, since any one estimate is sample specific and the argument of generalizability across samples is difficult to make.

Finally, because sampling error is a function of sample size, all else being equal, longer forms will yield higher reliability coefficients. Better, larger samples of items from the domain will reduce the likelihood that two forms differ in their ability to cover the domain. A functional relation between form length and reliability is represented by the Spearman-Brown prophecy formula.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Weng, L.-J. (2004). Impact of the number of response categories and anchor labels on coefficient alpha and test-retest reliability. *Educational and Psychological Measurement*, 64(6), 956–972.

Of the several different types of reliability, test-retest is very often used to establish the consistency

of a measure. A total of 1,247 college students participated in this study on the effect of scale format on the reliability of Likert-type rating scales. The number of response categories ranged from 3 to 9. The results indicated that the scales with few response categories tended to result in lower reliability, especially lower **test-retest reliability**. The scales with all the response options clearly labeled were likely to yield higher test-retest reliability than those with only the end points labeled. Scale design that leads to consistent participant responses as indicated by test-retest reliability should be preferred.

TESTS OF MEDIATING EFFECTS

Mediator variables are common in disciplines such as psychology, sociology, management, education, political science, and public administration. A mediator variable (referred to hereafter as a *mediator*) transmits the effects of an independent variable to a dependent variable. This is illustrated in Figure 1a, which shows a causal chain involving an independent variable (Z_1), a mediator (Z_2), and a dependent variable (Z_3). In instances of actual (as opposed to assumed) mediation, two types of effects are possible. We illustrate these with reference to Figures 1a and 1b. In *complete mediation*, there is only an indirect effect of the independent variable on the dependent variable (see Figure 1a). However, in *partial mediation*, an independent variable has both a direct effect on the dependent variable and an indirect effect (see Figure 1b).

There are many examples of mediating effects. For instance, behavioral intentions are assumed to mediate the relation between attitudes and behavior, and stress is hypothesized to mediate the relation between stressors and strain.

Research Design Issues and Tests of Mediation

Tests of mediation may be based on data from studies using three major types of designs: randomized experiments, quasi-experiments, and nonexperiments. Inferences about mediation that stem from such tests

rest on a relatively firm foundation when they are based on data from randomized experiments. For example, in testing for the mediating effect of Z_2 on the relation between Z_1 and Z_3 , one randomized experiment can be used to show that Z_1 causes Z_2 , and another can be conducted to demonstrate that Z_2 causes Z_3 .

Unfortunately, when tests of mediation are based on data from quasi-experimental studies, inferences about mediation rest on a much weaker foundation. Moreover, when such tests rely on data from non-experimental research, inferences about mediating effects are almost never justified. One of the major

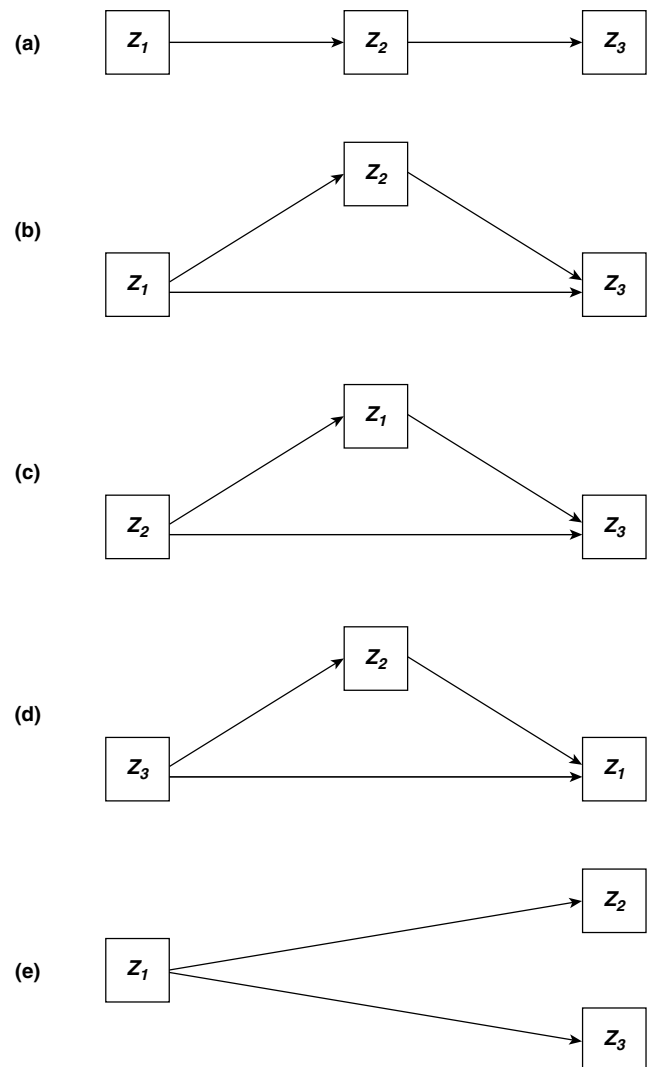

Figure 1 Some Possible Causal Relations Among Three Variables

Source: Stone-Romero & Rosopa (2004).

reasons for this is that when tests of mediation are based on data from nonexperimental research, all that a researcher can confidently conclude is that an observed pattern of relations (e.g., covariances, correlation coefficients) among the assumed independent, mediator, and dependent variables is consistent with a hypothesized model (e.g., that shown in Figure 1b). However, the same pattern of relations may also be consistent with a number of alternative models, including those shown in Figures 1c to 1e. Thus, the results of nonexperimental research almost always provide highly equivocal evidence about mediation. Moreover, as noted below, the validity of inferences about mediation is not at all improved by the use of various statistical procedures that purport to test causal models. One important reason for this is that in quasi-experimental or nonexperimental research, mediation models *assume* a specific set of causal connections between (among) variables (e.g., the model shown in Figure 1b), and statistical procedures are incapable of providing credible evidence of the correctness of the assumed pattern of relations.

Statistical Approaches for Testing Mediation Models

A number of statistical procedures have been used in tests of mediation that are based on data from nonexperimental or quasi-experimental research. Among these are *path analysis* (PA), *structural equation modeling* (SEM), and *hierarchical multiple regression* (HMR). Contrary to seemingly very popular beliefs, none of these provide valid tests of mediation. Reasons for this are detailed below.

Failure to Satisfy Requirements for Causal Inference

Three major conditions are vital to demonstrating a causal connection between a hypothesized cause and an assumed effect: (a) The hypothesized cause must precede the presumed effect in time; (b) the variables must be related to one another; and (c) the relation between the variables must not be a function of one or more alternative causes. These conditions are easy to satisfy in well-designed and well-conducted

experimental studies. However, in quasi-experimental research, only the first two conditions can be satisfied. And in nonexperimental research, only the second condition can be met. As a result, when techniques such as PA, SEM, and HMR are applied to data from quasi-experimental and nonexperimental research, there is no valid basis for inferences about causal connections among the hypothesized independent, mediator, and dependent variables. It is critical to recognize that just because variables are considered to be independent, mediator, and dependent in statistical analyses does not mean that they actually have this status. Regrettably, many researchers in psychology and other social sciences seem to have little understanding of or appreciation of this. As a result, they very frequently make unwarranted and inappropriate inferences about mediating effects using data from either quasi-experimental or nonexperimental studies.

It deserves adding that even individuals who advocate using statistical techniques to detect mediating effects recognize that inferences about mediation are problematic when they are based on data from nonexperimental research. For example, in 2002, MacKinnon et al. observed that the HMR procedure does not provide “the full set of necessary conditions for strong inference of a causal effect of the independent variable on the dependent variable through the intervening [mediator] variable.” However, they argued that it and similar procedures provide suggestive evidence on mediation. In addition, in 2002, Shrout and Bolger noted that “statistical analyses of association cannot establish causal links definitively.” Despite this, they stated that such analyses can “provide evidence that one mediation pattern is more plausible than another.” For the reasons noted above, Stone-Romero and Rosopa disagree strongly with this view.

Model Specification Issues

One of the major reasons that statistical tests of mediating effects are incapable of providing valid inferences about mediation is that *model misspecification* is always an issue in such tests. Several aspects of the misspecification problem are discussed below.

Alternative Causal Models

Tests of mediation models that are based on data from quasi-experimental or nonexperimental research assume a particular causal chain (e.g., Figure 1b). However, the actual causal sequence may be different from that which is specified by a researcher. For example, instead of the actual causal chain being the one illustrated in Figure 1b, it may be one of the other models shown in Figure 1 (e.g., the one in Figure 1c). This is an extremely important issue, because when HMR is applied to a set of covariances among three variables (e.g., Z_1 , Z_2 , and Z_3) that stem from quasi-experimental or nonexperimental research, the results of the analysis can often provide support for an incorrect causal model. The same is true of other statistical techniques (e.g., PA, SEM) that are frequently used to test assumed causal models. The fact that these techniques are used for the purpose of what is called *causal modeling* does not imply that the results of model testing provide a valid basis for inferring the validity of a hypothesized set of causal connections between (among) variables.

Model misspecification may manifest itself in several ways. We illustrate this with respect to the HMR technique (described below). In the interest of brevity, we comment on only four model misspecification problems here. First, variables in a model may be measured with error, and techniques such as HMR are incapable of addressing this issue. As a result, estimates of “effects” may be biased. Second, models tested by HMR assume that the causal flow is unidirectional. They have no capacity to model reciprocal causation. Third, HMR is typically used to test mediation models that involve a single mediator. However, there may be multiple mediators of relations between independent and dependent variables. Fourth, and finally, HMR-based tests of mediation do not control for the effects of confounding variables.

A Specific Strategy Used for Testing Mediation

One of the most commonly used techniques for testing hypothesized models involving mediation is the Baron and Kenny HMR procedure. It involves three

sequential multiple regression analyses, which are illustrated here, with reference to the model shown in Figure 1b.

Prior to describing the three analyses associated with HMR tests of mediation, it is important to note that the squared multiple correlation coefficients (R^2 's) for each must be nonzero. Unless they are, the results of the analyses cannot be used to infer the existence of relations between variables in models that are tested.

The Hierarchical Multiple Regression Analytic Strategy

In the first analysis, the hypothesized mediator (Z_2) is regressed on the assumed independent variable (Z_1). This analysis must show a statistically significant (i.e., nonzero) regression coefficient for Z_1 ($\beta_{2,1}$), supposedly implying that Z_1 causes Z_2 . In the second analysis, Z_3 is regressed on Z_1 . The analysis must produce a nonzero regression coefficient for Z_1 ($\beta_{3,1}$), ostensibly implying that Z_1 causes Z_3 . In the third analysis, Z_3 is regressed simultaneously on Z_1 and Z_2 , producing regression coefficients for both predictors. This analysis must show that the regression coefficient for Z_1 is lower than the coefficient for the same variable that resulted from the first analysis. Baron and Kenny argue that this provides a basis for inferring the existence of either partial or complete mediation. An inference of *partial mediation* results when the regression coefficient for Z_1 is nonzero in the third analysis, supposedly meaning that some of the effect of Z_1 on Z_3 is direct (nonmediated). The existence of complete mediation is inferred if the regression coefficient for Z_1 does not differ significantly from zero in the third analysis.

Problems With the Hierarchical Multiple Regression Technique

To illustrate the problems associated with the HMR technique, Stone-Romero and Rosopa conducted a simulation study in which four variables were manipulated: (a) The values of correlations among independent, mediator, and dependent variables in the model tested were set at values between .10 and .90; and (b) sample size (N) took on one of 13 values that ranged from 20 to 3,000. The manipulations resulted in over 8,400 unique combinations of correlation coefficients

and sample sizes. For each such combination, the HMR technique was used to test for mediation. The Type I error rate for these analyses was .05.

Note that two scenarios are possible for each test of mediation. One is that the model being tested (i.e., the one shown in Figure 1b) was properly specified; that is, it represented the true causal model underlying the set of correlation coefficients. The other scenario is that the model tested was misspecified; that is, the true causal model was the one shown in Figure 1e, but the model tested was the one depicted in Figure 1b.

Assuming that the model tested was *properly specified*, the HMR procedure provided evidence suggestive of (a) partial mediation in 3,647 cases (43.09% of all HMR analyses) and (b) complete mediation in only 630 cases (7.44% of all HMR analyses). Thus, even if one assumed that (a) the model being tested was properly specified and (b) data from nonexperimental research could serve as a legitimate basis for making causal inferences, the HMR procedure proved to be of relatively low value as a basis for inferring partial mediation. In addition, it provided support for inferences of complete mediation at a rate that was just slightly above the Type I error rate. It is critical to recognize, however, that if the model tested were misspecified, all inferences about mediation would be invalid. In view of the results of their simulation and issues associated with causal inference, Stone-Romero and Rosopa concluded that the HMR technique should not be used to test for mediation.

Other Research on the Power of the HMR Technique

Stone-Romero and Rosopa are not alone in demonstrating the low power of the HMR technique. For example, a 2002 simulation study by MacKinnon et al. showed that it had very low power when mediator effect sizes were small or when medium and sample size were under 100. Thus, they recommended that the difference in regression coefficients strategy be used to test for mediation, rather than the HMR technique. In addition, a 2002 simulation study by Shrout and Bolger showed that the usual HMR-based test of indirect effects had very low power. As a result, they

recommended that bootstrap procedures be used to develop a confidence interval around the estimate of the supposed indirect effect. Their simulation showed that this interval was superior to the interval based on ordinary least squares regression in terms of providing evidence of indirect effects.

Appropriate Strategies for Testing Causal Models Involving Mediation

Clearly, research shows that statistical procedures other than the HMR strategy have improved statistical power in supposed tests of mediation. Nevertheless, we believe that the most important objective in research aimed at showing mediating effects is demonstrating that the causal model hypothesized by a researcher (e.g., Figure 1a or 1b) is more plausible than alternative causal models (e.g., Figures 1c, 1d, and 1e). Statistical techniques have no potential whatsoever to accomplish this goal. Thus, it is recommended that the validity of causal models involving mediation be demonstrated through well-designed and well-executed experimental studies.

TEXT ANALYSIS

Text analysis constitutes a variety of social science research methods designed to ascertain meaning and bring structure to large amounts of unstructured information derived from different acts of communication embodied in written language. As such, text analysis differs from observation-based methods in that the acts in question have already taken place. Examples of texts include books, transcripts of political speeches, advertisements, interviews, newspaper editorials, and government documents. *Text analysis* can be generally defined as a research technique designed to make systematic and replicable inferences from texts. Text analysis is regularly utilized in a number of social science disciplines, including sociology, anthropology, psychology, and political science. With its focus on written language, text analysis is somewhat distinct from *content analysis*, which can focus on text but also encompasses other diverse symbolic behavior such as music, visual art, and body language.

Jack Sprat could eat no fat; his wife could
eat no lean.

And so betwixt them both, they licked the
platter clean.

The meanings inferred from written sources via text analysis may be either manifest or latent. *Manifest meaning* refers to the literal, surface meaning of the words in question. It is a recognition of the universal meaning of the words and phrases employed in the text, divorced from the intentions of the author and/or any reception from its intended audience. With this meaning in mind, one may infer from the age-old nursery rhyme above an equitable

division of a meal by a married couple. By contrast, it is the very situational context—the creator’s intent, the recipient’s response, the connection between the parties—that constitutes the latent meaning of a text. In this case, meaning can be inferred from factors such as the type of language employed (e.g., formal versus informal) or the identity and relative status of the author and of the addressees (e.g., government and citizens). That “Jack” and “his wife” refer to King Charles I and his queen and “the platter” refers to England’s treasury denotes a much more pointed outcome than the amicable repast the surface meaning implies.

Text analysis may be qualitative or quantitative in nature, depending on the orientation of the researcher and the research questions devised. Qualitative analyses tend to be more inductive and exploratory, whereby researchers examine data looking for patterns, while quantitative analyses are more deductive and used to confirm existing hypotheses. Often, both quantitative and qualitative methods are employed within a single research design.

A relatively recent innovation has been the introduction of computer software programs (e.g., ATLAS/ti, NUD*IST) designed to facilitate text analyses by cutting down or even eliminating many of the time-consuming elements, such as the coding of data by hand. In addition, the amount of readily available textual information produced and disseminated digitally by newspapers, academic journals, government publications, businesses, and so on continues to grow exponentially, furnishing a continuous and easily accessible supply of raw data for analysis.

THEMATIC APPERCEPTION TEST

The Thematic Apperception Test (TAT) (author Henry A. Murray; early coauthor Christiana Morgan) was published by Harvard University Press (<http://www.hup.harvard.edu>) in 1943 and is currently distributed by Harcourt Assessment, Inc. (<http://www.harcourtassessment.com>). It is a widely used performance-based personality assessment technique consisting of 31 achromatic cards. The cards contain scenes portraying either a solitary individual, individuals in diverse interpersonal situations, or landscapes. The pictures vary in their levels of ambiguity and detail. For example, one card features a young woman standing in the foreground of a rural scene with two individuals in various poses behind her, and another card is entirely blank. Examiners typically choose a subset of the cards to present, and the instructions may vary. Generally, however, the examinee is asked to create a story about each scene that includes a description of what is happening in the picture, what led up to this event, what the characters are thinking and feeling, and what the outcome is. The stories are often considered to contain projected material reflecting an individual's drives, motives, conflicts, needs, emotions, and other personality dynamics. The test generally takes about 1 to 2 hours to administer, depending on the number of cards that are chosen for presentation, and can be completed in one sitting or across time.

Because there are a number of ways the test is administered and scored, examiners may use a variety of methods for interpreting the stories produced by examinees. They may rely on clinical inference, standardized ratings systems, or both. A number of quantitative rating methods exist for use in clinical practice or in research, and although there is little adequate reliability and validity data available for the TAT itself, many of the scoring systems report their own psychometric properties. Examples of existing scoring systems include those that measure an individual's object relations, ego defense mechanisms, communication deviance, problem solving, and motives.

Although the TAT was designed for use with both children and adults, additional versions of the test

(i.e., the Children's Apperception Test and the Senior Apperception Test) have been created for more specific populations. Others have designed TAT cards for use with specific racial groups to address a concern about the TAT's cross-cultural applicability, though these versions do not appear to be widely used.

THREE-CARD METHOD

The three-card method is a technique for gathering information from people on questions that are sensitive or controversial in nature. Some topics of interest to researchers and policymakers concern illegal activities, unpopular opinions, and embarrassing personal details, such as alcohol and drug abuse, criminal activity, and sexual behavior. Respondents, if asked directly about sensitive topics, might refuse to answer or might provide false answers.

Instead of being asked a sensitive question directly, a respondent in the three-card method is shown one of three cards. Each card lists valid response categories organized into three distinct groups (A, B, or C). If a response category is sensitive, it is never the only category in a group on a card. That is, the sensitive response is matched with one or more nonsensitive responses on each card. Once shown a card, the respondent tells the interviewer the group to which he or she belongs. The

privacy of the respondent is protected, because the respondents never have to definitely identify themselves as belonging to the controversial group. For example, if foreign individuals in the United States are being asked about immigration status, one possible card would list both “green-card status” (a legal residency status) and “undocumented immigrant” (not a legal resident) in Group B. A second card could list “temporary work visa” (another legal residency status) with “undocumented immigrant” together as Group B. A respondent picking Group B on either card has not directly admitted to being in the United States illegally.

In the whole survey, three cards (Card 1, Card 2, and Card 3) with different alignments of categories are used. Each card is designed to protect respondent privacy. Each respondent is shown one card only. One third of the sample individuals are shown each card. Based on the pattern of responses to the three cards, it is possible to estimate the proportion of respondents in the sensitive category. For example, suppose there are at least four response categories; researchers are interested in the proportion of the population belonging to Categories 1 through 4; and Category 4 (e.g., illegal immigrant) is a sensitive category. Below are three cards that could be shown to the three thirds of the people chosen for the sample.

	Card 1	Card 2	Card 3
A	Category 1	Category 2	Category 3
B	Categories 2, 3, 4	Categories 1, 3, 4	Categories 1, 2, 4
C	Other categories	Other categories	Other categories

Suppose n people respond to each card. Let n_{A1} , n_{A2} , and n_{A3} be the number of respondents who choose Category A on the three cards, respectively. Let n_{B1} , n_{B2} , and n_{B3} be the number of respondents who choose Category B on the three cards, respectively. One estimate of the proportion of people belonging to category 4 is

$$(1/3)((n_{B1} + n_{B2} + n_{B3}) - 2(n_{A1} + n_{A2} + n_{A3}))/n.$$

A related set of methods for asking about sensitive questions are called *randomized-response* techniques.

In one version of randomized response, some respondents answer a sensitive question directly, but a randomly selected subset answers a different, noncontroversial question. Privacy is protected, because the interviewer does not know whether the subject is answering the sensitive or the nonsensitive question. Statistical methods are used to estimate the proportion of the population belonging to the sensitive category. Generally, the three-card method and randomized-response methods have the advantage of eliciting more truthful responses to questions. Their disadvantage is that they take more time than a direct question to explain to a participant in a survey. There is also some loss of precision over what would be attained with a direct question. Usually, though, the desire to receive truthful information outweighs either of the disadvantages.

The method is called the three-card method because its original formulation in the context of immigration studies used three cards, with three groups per card. Depending on the application, the method can be adapted to use different numbers of cards and different numbers of groups per card. Methods of statistical design can be used to design sets of cards for a particular question that yield efficient estimates of proportions. Statistical design can also be used to optimally divide the survey respondents among the available cards, instead of performing an even split of the subjects among the cards.

THURSTONE SCALES

Thurstone scales are a set of procedures used to construct attitude scales. These procedures were among the earliest systematic methods devised to measure attitudes. In the late 1920s, Louis L. Thurstone developed his *law of comparative judgment*. This provided a foundation for the idea that attitudes lie along a psychological continuum and can be measured despite lacking a physical dimension. This allowed for quantitative investigations of subjective psychological phenomena, such as attitudes. Thurstone developed three different attitude-scaling techniques: the method of equal-appearing intervals, the method of paired comparisons, and the method of successive intervals.

In his 1928 paper, "Attitudes Can Be Measured," Thurstone described his conceptualization of attitudes as complex and multifaceted. Specifically, he thought of an attitude as having a distribution of values on a continuum, rather than having a single value, and therefore it would not be adequately represented by a single number. He defined *opinion* as a verbal expression of a person's overall attitude. Therefore, he posited that opinions can be used to measure attitudes. Based on these assumptions, Thurstone developed his three methods to measure attitudes. However, the method of equal-appearing intervals has been the most widely used of the three methods and is the method generally referred to by the term *Thurstone scales*.

The Method of Equal-Appearing Intervals

In creating a scale using the *method of equal-appearing intervals*, the first step is in determining the

attitude object that will be evaluated. The next step is to construct a set of statements about the attitude of object that captures an entire range of opinions, from extremely unfavorable (e.g., "Abortion weakens the moral fiber of our society") to neutral (e.g., "Abortion brings happiness to some, unhappiness to others") to extremely favorable (e.g., "Abortion should be encouraged for unwanted pregnancies"). Thurstone used 130 statements to develop one of his original scales, although subsequent researchers have suggested that 40 to 50 statements are typically enough to fully capture the continuum of a particular attitude object.

Once the researcher develops a complete set of statements, judges rate favorability values for each statement using an 11-point scale, which may take various forms (see Figure 1). Typically, only the two extreme ends and the midpoint of the scale are labeled. These three forms are alternatives to Thurstone's original procedure of sorting the statements, presented one at a time on cards, into 11 physical piles. Thurstone used 300 judges to obtain favorability values, but other researchers have successfully constructed scales using as few as 10 to 15 judges.

When making these ratings for the pool of statements, judges are instructed to respond objectively on the favorableness or unfavorableness of the statements, not based on their personal agreement or disagreement with the statement. Judges are also asked to treat each interval as being equal. To ensure that judges' ratings are not careless and conform to the instructions, Thurstone recommended a screening procedure to eliminate the data set of judges who placed 30 or more statements (of the 130 total) into just 1 category out of the 11. This is equivalent to placing 23% or more statements into a single category, which may be problematic considering the care taken to develop the pool of statements to capture the entire range of opinions from favorable to unfavorable. After this screening procedure, a measure of central tendency for each statement and a measure of variability are calculated across the remaining judges. Thurstone used the median and interquartile range, but in recent years, means and standard deviations

1. For each statement, circle the number that indicates the degree of favorableness of the statement toward the attitude object.

Extremely unfavorable	Neutral	Extremely favorable	
1 2 3 4 5	6 7 8 9 10 11		a. Abortion weakens the moral fiber of our society.
1 2 3 4 5	6 7 8 9 10 11		b. Adoption is a good alternative to abortion.

2. For each statement, circle the letter that indicates the degree of favorableness of the statement toward the attitude object.

-----	-----		b. Adoption is a good alternative to abortion.

Figure 1 Three Possible Forms of the Scale Used by Judges to Rate Favorability of Attitude Statements

have more commonly been used. Low variability indicates relative consensus among the judges, whereas high variability indicates little agreement between the judges, signifying that the particular statement may be ambiguous.

At this point, the researcher now has mean favorability values and scores of variability between judges for each statement. For example, the statement “Abortion weakens the moral fiber of our society” may have a mean favorability score of 1.6, with a standard deviation of .3. From this original pool of statements, the researcher selects 20 to 25 statements using the mean and variability scores. Optimally, the selected statements should be equally spaced across the entire range. For developing a 20-item scale, items should be selected at intervals of .5. (There are 10 units from 1 to 11 on an 11-point scale; 10 units ÷ 20 items = .5.) Therefore, if the researcher were using the example statement with a mean value of 1.6, he or she would need to select 19 other statements with intervals of .5 between statements (i.e., a statement closest to each of the following values: 1.1, 1.6, 2.1, 2.6, 3.1, 3.6 . . . up to 10.6). These selected items should also have low variability ratings across judges.

Once the researcher selects 20 to 25 statements from the original set of statements using these criteria, these selected statements are presented, randomized, in a checklist form to create the final scale. In Figure 2, mean favorability values have been reported in

parentheses following each statement, to illustrate that the statements are presented in random order and show the value associated with the varying degrees of opinions. However, these values would not appear in an actual scale given to participants. Participants are instructed to place a check mark beside any of the statements with which they agree. The scale score for each respondent is calculated by finding the mean or median of the total scale values that they agree with. For example, a participant may agree with a total of three statements in Figure 2, Items 4, 10, and 17. The corresponding scale values are 6.0, 8.7, and 7.6. The participant’s overall scale score is obtained by taking the mean value, 7.4 in this case. A score of 7.4 indicates that this participant has a moderately favorable attitude toward abortion.

The Method of Paired Comparisons

In addition to the method of equal-appearing intervals, Thurstone also developed two other less commonly used methods. In the *method of paired comparisons*, each attitude statement is paired with every other attitude statement. For each pair, judges decide which statement of the pair is more favorable toward the attitude object. This information is used to position each statement on the attitude continuum. In this method, as in the other two methods, the final scale is constructed by eliminating ambiguous items, marked by high variability

Figure 2 Opinions About Abortion

between the judges, as well as eliminating irrelevant items that fail to discriminate people with differing attitudes from the pool of scaled attitude statements. A limitation of this method stems from the need to compare each statement with every other statement. For example, 10 statements require judging 45 pairings, and 20 statements require 190 pairings, making this technique cumbersome and unmanageable for scaling a large number of attitude statements.

The Method of Successive Intervals

Finally, the *method of successive intervals* is an extension of the method of equal-appearing intervals. As in the method of equal-appearing intervals, raters are asked to make one comparative judgment for each attitude statement, placing statements in categories

of varying degrees of favorability. However, in this method, equal intervals are determined statistically, rather than relying on raters' subjective judgments of equal intervals. Specifically, the interval widths are obtained based on the assumption that the distribution of the judgments follows the normal curve. Estimates of the widths of the intervals as well as the boundaries relative to a statement's scale value are obtained from the proportion of raters who place a statement in each favorability category. The final scale is constructed in the same way as the other two methods.

Evaluating Thurstone Scales

Reliability for the scale is high with Cronbach's alpha, typically reported in the .80s. The scale also has high test-retest reliability, in the range of .90 to .95. Compared with other scaling methods, it is considerably easier using the Thurstone method to create alternative forms of the same scale. This is because the researcher has a pool of statements that have been scaled by judges. To construct a second equivalent scale, the experimenter may simply choose statements from the pool that are comparable to, but not chosen for, the first complete scale. Thurstone scales also have the advantage of having a clear neutral point on the scale, unlike the Likert scale. This neutral point allows for absolute interpretation of scale scores.

One main disadvantage of Thurstone scales is that they are labor-intensive. They require generation of a comprehensive pool of sample statements, scaling the favorability of the statements using at least 10 to 15 judges, then selecting 20 to 25 of the statements to construct a final scale. Also, in the method of equal-appearing intervals, the researcher assumes that judges will follow the instruction of treating the intervals as being equal, but this assumption cannot be tested to verify whether it is warranted. Finally, there has been criticism regarding whether judges' personal attitudes affect the perceived favorability of the attitude statements. Although the evidence is mixed in this regard, this problem may affect the scaling of statements for the method of equal-appearing intervals, but the problem has shown to have little or no effect

for the method of successive intervals and the method of paired comparisons.

Although Thurstone scales were one of the first applications of formal scaling techniques to attitude measurement, they are still accepted as a theoretically sound and valid method of attitude measurement today. Thurstone scales are still in use. However, they are not the most commonly used form of attitude measurement, as some other less labor-intensive methods can produce attitude scales with adequate psychometric properties.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Marsella, A. J., Dubanoski, J., Hamada, W. C., & Morse, H. (2000). The measurement of personality across cultures: Historical, conceptual, and methodological issues and considerations. *American Behavioral Scientist*, 44(1), 41–62.

This article discusses historical, conceptual, and methodological issues (including familiarity with different types of measurement tools, such as Likert and **Thurstone Scales**) associated with the cross-cultural measurement of personality. It documents the extensive debate and discussion that have emerged from the juxtaposition of the trait-situation, universalism-relativism, quantitative-qualitative, and anthropology-psychology polarities

in the past decade. Following a discussion of these polarities, the article concludes that the contending (and contentious) positions should be replaced by collaborative disciplinary research efforts that are open to the possibility of both cultural variations and universals in human behavior. Fundamental similarities in behavior may exist across cultural boundaries because of bioevolutionary, natural language descriptors, and similar life activity and socialization contexts, and major differences may exist for the very same reasons.

TIME SERIES ANALYSIS

A time series is an ordered sequence of observations over time, and very often there is dependence between the past and the future values of these observations. Time series analysis is the branch of statistics that makes use of this serial dependence for the purpose of modeling.

An effective way to graphically represent a time series is by putting the observations on a Cartesian plane, with the times of occurrence as abscissas and the values of the observations as ordinates. Such a graphical representation is called a time plot. Figure 1, representing the quarterly time series of food retail sales in New Zealand (in millions of New Zealand dollars), provides an example.

Structural Models

Typically in a time series, four components can be distinguished: trend (*T*), cycle (*C*), seasonality (*S*), and irregular component (*I*). The *trend* is the longest-term behavior of the time series, and the *cycle* is a long-term cyclical component. Sometimes the time series is not long enough to distinguish between trend and cycle, and so a unique trend-cycle component can be considered. The *seasonality* is a short-term cyclical component often due to the seasons, and, finally, the *irregular component* is an erratic component obtained as residual once the other components are identified and removed. The nonsystematic behavior of the

Figure 1 Food Retail Sales in New Zealand

in this decomposition: trend-cycle, seasonality, and irregular component. The oscillations of the seasonal appear independent from the level of the series, suggesting an additive model.

It is a good strategy to remove the longer-term components first, and in this case, the trend-cycle ($T + C$) is exponential and can be estimated by the equation

$$X = c + \alpha t + \beta t^2 + \varepsilon ,$$

where t is a regular ascending sequence (0,1,2, . . .) representing a counter for the time and ε is the residual part. Consequently, the trend-cycle component is given by

$$T + C = c + \alpha t + \beta t^2 ,$$

irregular component is used to assess the goodness of the decomposition, and often it can be reasonably assumed that it follows a normal distribution.

There are two main basic ways in which the components mix together: the additive model

$$X = T + C + S + I, \tag{1}$$

where X is the original time series, and the multiplicative model

$$X = (T)(C)(S)(I).$$

If the oscillations of the cyclical components increase with a higher level of the time series, a multiplicative model is more appropriate; if the oscillations remain constant, an additive model is preferable.

A possible way to find the different components is based on regression, and the time series of food retail sales provides an example to illustrate it.

Food retail sales have a tendency to increase over time, and this could be explained by the presence of a trend or by an ascending part of a cycle, although given the nature of the series, affected by price inflation, it is more likely to be a trend. We then consider three components

where c , α , and β are the parameters to estimate. More specifically, the estimated equation by least squares is

$$T + C = 1729.54 + 4.88t + 0.43t^2.$$

The trend-cycle component estimated by the equation above is shown in Figure 2.

Figure 2 Trend-Cycle, Food Retail Sales, and Seasonal and Irregular Components

Figure 3 Irregular and Seasonal Components

The estimated component should then be removed from the original time series, and following Equation 1, we have

$$X - (T + C) = S + I. \tag{2}$$

The seasonal component can be identified by the equation

$$S + I = f_1 + f_2 + f_3 + f_4 + \varepsilon,$$

where the f_s are the seasonal factors, one for each quarter, as the series is quarterly. The seasonal component is estimated by the equation

$$S = f_1 + f_2 + f_3 + f_4$$

with a least squares estimate given by

$$S = -23.84f_1 - 61.80f_2 - 49.39f_3 + 137f_4,$$

where the sum of the weights is not far away from zero, the theoretical value. The irregular component is then found as a residual by the equation

$$I = (S + I) - S.$$

Eventually, the goodness of the decomposition can be assessed by an inspection of the distribution of the

irregular component. For the example of the food retail sales, the distribution of the irregular components is approximated by the histogram in Figure 4, which is close to a Normal.

ARIMA Models

A simple way to model the serial correlation in a time series is by expressing the current observation (x_t) as a function of the past observations ($x_{t-1}, x_{t-2}, \dots, x_{t-p}$) in a regression equation,

$$x_t = \alpha + \phi_1 x_{t-1} + \phi_2 x_{t-2} + \dots + \phi_p x_{t-p} + \varepsilon_t, \tag{3}$$

where

α is a constant that can be omitted if the time series is mean corrected,

$\phi_1, \phi_2, \dots, \phi_p$ are the parameters associated with the past observations, and

ε_t is the regression error, which should have zero mean and be uncorrelated with previous and future regression errors.

It is also often desirable for estimation and testing purposes that the regression error have a Normal distribution.

Equation 3 describes a regression of a variable on its own past, and for this reason is called *autoregression*;

Figure 4 Distribution of the Irregular Component

in particular, it is an autoregression of order p , indicated as $AR(p)$, because we consider observations up to x_{t-p} . A desirable feature for a time series model is stationarity with respect to the mean, where we would like a particular estimated time series model to provide an adequate estimation of the mean of x_t regardless of the specific time t considered. If a trend is present, the time series is not stationary, as its expected value depends on t ; nevertheless, the difference of successive values of the observations is an effective way to remove the trend.

Consider, as an example, a time series with an additive deterministic trend modeled by the equation

$$x_t = \alpha + \beta t + \varepsilon_t, \tag{4}$$

where

α is a constant,

β is the slope of the trend t , and

ε_t is a zero mean stationary component.

Its expected value,

$$E(x_t) = \alpha + \beta t,$$

depends on t . If we consider the first difference,

$$\begin{aligned} \Delta x_t &= x_t - x_{t-1} = \alpha + \beta t + z_t \\ &\quad - [\alpha + \beta(t-1) + z_{t-1}] \\ &= \beta + \varepsilon_t - \varepsilon_{t-1}, \end{aligned}$$

its expected value,

$$E(\Delta x_t) = \beta,$$

does not depend on t any more, the expected values of ε_t and ε_{t-1} being identical, given the stationarity in mean of ε_t .

Sometimes a higher order is needed to obtain stationarity in mean. As an example, consider the case of a time series with a second-order polynomial additive trend, modeled by the equation

$$x_t = \alpha + \beta_1 t + \beta_2 t^2 + \varepsilon_t. \tag{5}$$

Its first difference,

$$\begin{aligned} \Delta x_t &= x_t - x_{t-1} = \alpha + \beta_1 t + \beta_2 t^2 + \varepsilon_t \\ &\quad - [\alpha + \beta_1(t-1) + \beta_2(t-1)^2 + \varepsilon_{t-1}] \\ &= \beta_1 + 2\beta_2 t - \beta_2 + \varepsilon_t - \varepsilon_{t-1}, \end{aligned}$$

has expected value

$$E(\Delta x_t) = \beta_1 + 2\beta_2 t - \beta_2,$$

which still depends on t and hence is not stationary in mean; nevertheless, the second-order difference,

$$\begin{aligned} \Delta^2 x_t &= (x_t - x_{t-1}) - (x_{t-1} - x_{t-2}) \\ &= 2\beta_2 + \varepsilon_t - 2\varepsilon_{t-1} + \varepsilon_{t-2}, \end{aligned}$$

has expected value

$$E(\Delta^2 x_t) = 2\beta_2,$$

which is stationary in mean.

The order, d , of the difference we need to consider to obtain stationarity is called *order of integration of the time series*, and it is indicated as $I(d)$; the time series arising from Equation 4 has order of integration one, $I(1)$, and the time series described by Equation 5 has order of integration two, $I(2)$.

In principle, we could consider any order of integration, but in practice, it is sensible to consider up to second order, as higher orders of integrations corresponding to polynomial trends of order higher than 2 may describe stationary cyclic time series.

An $AR(p)$ model can also be represented as a moving average of the errors ε_t . Consider the simple case of an $AR(1)$ model,

$$x_t = \phi x_{t-1} + \varepsilon_t.$$

By solving recursively,

$$\begin{aligned} x_t &= \phi(\phi x_{t-2} + \varepsilon_{t-1}) + \varepsilon_t \\ &= \dots = \phi^n x_{t-n} + \sum_{i=0}^{n-1} \phi^i \varepsilon_{t-1}, \end{aligned}$$

and for a large n and $|\phi| < 1$,

$$x_t \approx \sum_i \phi^i \varepsilon_{t-i}.$$

This suggests the possibility of modeling a time series by using a moving average of the errors ε_{t-i} , $i = 0, 1, \dots, q$; that is,

$$x_t = \varepsilon_t - \theta_1 \varepsilon_{t-1} - \dots - \theta_q \varepsilon_{t-q}, \quad (6)$$

where the parameters θ_i can be negative. Such a model is called a *moving average of order q* and is indicated as $MA(q)$. In many situations, the most parsimonious model in terms of parameters is obtained with a mixed model containing both *AR* and *MA* components. This leads to the general $ARIMA(p, d, q)$ model; that is, after having made a time series stationary by differencing it d times, we can show the model as follows:

$$\begin{aligned} x_t - \phi_1 x_{t-1} - \dots - \phi_p x_{t-p} &= \varepsilon_t \\ - \theta_1 \varepsilon_{t-1} - \dots - \theta_q \varepsilon_{t-q} &. \end{aligned} \quad (7)$$

Without any loss of generality, Equation 7 assumes the stationary time series x_t to have zero mean; this can easily be obtained by subtracting a nonzero mean from its original time series. Equation 7 encompasses as special cases the pure $AR(p)$ and $MA(q)$ models.

The orders p and q of *AR* and *MA* models can be identified by inspecting, respectively, the partial autocorrelation function and the autocorrelation function. An $AR(p)$ model is adequate if the autocorrelation function is not significantly different from zero after the lag p . Similarly, a $MA(q)$ model is adequate if the autocorrelation function is not significantly different from zero after the lag q . Both conditions ensure the adequacy of an $ARMA(p, q)$ model.

ARMA models are for single time series, but sometimes the consideration of more time series jointly is preferable so that their interdependence can also be modeled. If this is the case, *ARMA* models can be generalized to a multivariate situation. Such models are called *vector ARMA models* or, more simply, *VARMA models*.

TORRANCE, E. PAUL (1915–2003)

Ellis Paul Torrance is known throughout the world for his eponymous tests of creative thinking. Yet he considered the tests a means to an end rather than an end in themselves. His greatest interest and deepest sense of pride came from his work in developing creativity in all people.

Born on a farm in Milledgeville, Georgia, Paul was physically unable to plow a straight line or pick much cotton, but he showed precocious intellectual abilities. Thus, his father urged him to pursue an education. Lacking the funds to attend college during the Depression, Paul worked and saved to attend school when and where he could, including taking some classes by correspondence and enrolling one summer

as the only male at the Georgia State College for Women. Afterward, teaching at Georgia Military College, he became very interested in psychology and the students labeled as “troublemakers” who had a special “spark,” so he went on to earn an MA from the University of Minnesota. Lacking the funds to pursue the doctorate, he returned to a teaching and counseling career until he was drafted into the army to serve as a psychologist. There, he saw the same spark in the fighter pilots that he trained for survival and concluded that the spark was related to creativity. After completing his term of duty, he received the financial support needed to obtain his doctorate at the University of Michigan, in 1951.

In 1958, the launch of *Sputnik* and Guilford’s presidential speech to the American Psychological Association (APA) on creativity spurred the research push that provided Torrance the opportunity to study creativity. He was hired as the director of the Bureau of Educational Research at the University of Minnesota and commissioned to begin a 25-year study on giftedness. Torrance’s studies of creativity extended for more than 40 years.

As part of the research, Torrance developed many creativity measures, with the Torrance Tests of Creative Thinking (TTCT) and Thinking Creatively in Action and Movement (TCAM) being two of the best known. His studies with these measures helped dispel the idea that IQ tests alone gauged all intelligence. His 7-year, 12-year, 22-year, and 40-year longitudinal studies showed a strong relationship between test behavior in childhood and adult real-life creative behavior, thereby offering evidence of the predictive validity of the TTCT.

However, Torrance was most proud of the Future Problem Solving Program (FPSP) and the Incubation Model of Teaching, which he created to infuse creativity and relevancy into the school curriculum. Started in 1974, the FPSP is now an international program, with over 250,000 student participants and over 40 affiliate programs. The Incubation Model of Teaching, a three-dimensional curriculum model with the goal of encouraging children’s inherent curiosity, includes methods for guiding students to think about what they have learned, delve into the topic by asking

questions and experimenting, and, ultimately, use what they have learned. Upon Torrance’s retirement in 1984, The Torrance Center for Creative Studies was established to continue scholarly inquiry into the study of creativity.

TORRANCE TESTS OF CREATIVE THINKING

The Torrance Tests of Creative Thinking (TTCT, published by Scholastic Testing Service, <http://www.ststesting.com>) are a battery of figural and verbal tests designed to assess creative thinking in individuals from kindergarten through adulthood. Just as IQ tests are measures of some cognitive abilities related to intelligence, the TTCT are measures of intellectual abilities that are used in creative achievements. They are not purported to measure the entire global construct of creativity, as they don’t measure motivation, skill, or any other of the many components that may impact an individual’s ultimate creative productivity. Yet in the 40-plus years since they were created, the tests have been translated into more than 35 languages and have been used around the world. There are several studies affirming their predictive validity, most recently the results of the 40-year follow-up of elementary children who were given the tests in 1958 and were contacted in 1998 to assess their creative achievements in adulthood.

Torrance believed that everyone has creativity and that it can be nurtured. He designed the tests to measure creative thinking abilities so that they could be enhanced. The tests were seen as a means of assessing the effectiveness of creativity training, pointing

out abilities that might otherwise go unnoticed, understanding the human mind, and assisting with curriculum design and psychotherapy. He and his students and colleagues tested many stimuli to find ones that were motivating to children and adults, gender neutral, and not discriminatory to children from different racial or socioeconomic groups. The resultant tests are used for all ages, although the norms are age- or grade-based for conversion to standard scores.

The verbal tests consist of six activities and take about 1 hour to administer. The respondents are requested to ask questions, guess causes, predict consequences, improve a product, think of new uses for a common object, and reason in a hypothetical situation. The figural tests consist of three activities and take approximately 45 minutes to administer. The respondents are given 10 minutes each to add details to black-and-white shapes and abstract line drawings to make something out of them. The instructions for the activities are designed to motivate the respondents to give creative responses by instructing them to give many unusual, detailed ideas.

The TTCT are most often used as part of a multiple-criterion approach to identifying students for gifted programs. The recent and growing emphasis on identifying a broad array of talents in a diverse population of students has increased interest in assessments like the TTCT, especially the figural forms, which are not heavily dependent on language. Also, because Torrance was originally interested in creative students, “wild colts” who were often in trouble in schools, the TTCT may be particularly useful for discovering and redirecting such children’s energies and talents toward more positive pursuits.

TORRANCE THINKING CREATIVELY IN ACTION AND MOVEMENT

Thinking Creatively in Action and Movement (TCAM) was developed by E. Paul Torrance in 1981. Scholastic Testing Service, Inc. holds the copyright. The TCAM is designed to measure fluency, originality, and imagination in children age 3 to 8 through various movement and manipulation exercises.

The test consists of four activities:

Activity I, “How Many Ways?” is used to observe the child’s ability to move in alternate ways across the floor.

Activity II, “Can You Move Like?” asks the child to move like animals or a tree.

Activity III, “What Other Ways?” has the child place a paper cup in a wastebasket in alternate ways.

Activity IV, “What Might It Be?” involves the child coming up with a variety of uses for a paper cup.

The activities use paper cups, a wastebasket, pencils, and strips of red and yellow tape. The TCAM is administered individually, and it takes about 15 minutes. There is no time limit, but the administrator should keep a record of the time used. It is recommended that time be limited to a period that will not overly fatigue the child (generally 10–30 minutes). Only one child should be in the activity room, with enough space for movement. Warm-up and motivational procedures are suggested before administration so that children can relax and have fun with the activities.

The examiner records the variety of verbal and kinetic responses. A clear and easy-to-follow scoring guide is provided, with directions for scoring and administration procedures. Activities I, III, and IV are scored for fluency and originality. Activity II is scored for imagination. Fluency scores are the number of relevant responses; originality scores range from 0 to 3 points for each response and are based on an originality list derived from the statistical frequency of responses; and imagination scores are based on a 5-point Likert scale ranging from “no movement” to “excellent; like the thing.”

Norms for the TCAM are based on 1,896 children, age 3 to 8 years old, from 11 states and Guam, with equal representation among Whites and Blacks. Tables for converting raw scores to standard scores ($M = 100$; $SD = 20$) are reported only for 3- to 6-year-olds.

Interscorer reliability coefficients were reported as .90 to .99. Test-retest reliability coefficients were .84 for a sample of twenty 3- to 5-year-olds for a 2-week interval, and .71 to .89 for a sample of thirty 7- to 8-year-old boys with learning disabilities for 1- to 14-day intervals. In this study, the alpha coefficient for the test internal consistency was .79.

Validity studies showed significant positive correlations between TCAM and other characteristics of creativity, such as a modified Piaget measure of divergent thinking, a divergent problem-solving-based mathematics test, the production of humor, and the Multidimensional Stimulus Fluency Measure.

There are many advantages of using the TCAM. Studies found no evidence of bias for sex, socioeconomic status, or race. Another advantage is that the TCAM can be used with children with impairments, such as those who are emotionally disturbed or deaf and those who have behavior disorders or physical disabilities. Furthermore, the use of movement is an appropriate means of reaching young children’s creativity because it makes sense to children and can be administered in a playful, gamelike environment, rather than a sterile, testlike situation. Last, the TCAM is useful for teaching creative movement and brainstorming techniques, which can foster creativity in young children. One concern, however, is that the TCAM has not been renormed nor have the originality lists been updated since 1981. Because of this, the

credibility of the norms and originality scores can be questioned, because responses may have changed between 1981 and the present.

E. Paul Torrance is best known for developing the Torrance Tests of Creative Thinking (TTCT), which are the most widely used tests of creativity, for kindergarteners through adults.

TREE DIAGRAM

A tree diagram is used to summarize the probabilities associated with a sequence of random events. The set of branches emanating from any given start point represent all the possible events that could follow. Each branch is labeled according to the probability of the event occurring, given the events that have previously happened. Hence, the sum of probabilities from each set of branches must equal 1.

Each path from the start of the tree to the end defines an outcome in the sample space. The outcomes defined by the paths are mutually exclusive. All outcomes in the sample space are represented by a path. The probability of each outcome is obtained by multiplying the conditional probabilities along the path, which is often called the “Multiplication Rule.” Therefore, these probabilities sum to 1.

An interesting application of tree diagrams is provided by the following example, toward anonymizing a survey question. Consider the following:

- Toss a fair coin.
- If you get a “head,” answer the question:
 - Have you ever cheated in an exam? Yes or No.
- If you get a “tail,” answer the question:
 - Flip coin a second time. Did you get a head on the second flip? Yes or No.

It is not possible to tell whether a particular individual answered “Yes” because they cheated in an exam or got a head on the second flip. However, if we have a large sample of responses, we can estimate the proportion of people who have cheated in an exam.

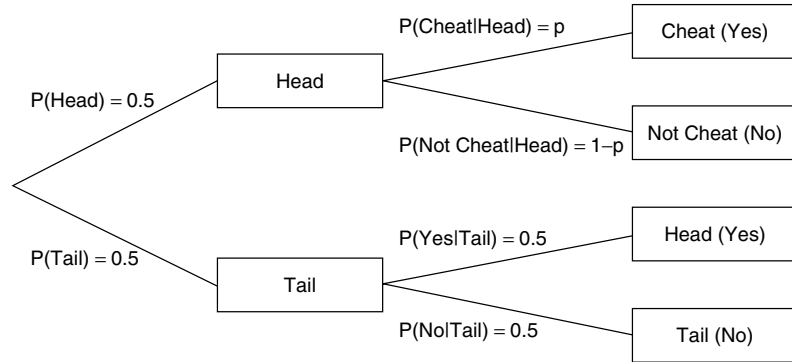

Figure 1 Tree Diagram for Anonymized Exam Cheating Question

Consider the tree diagram in Figure 1, created in PowerPoint.

The probability of answering “Yes” is given by

$$\begin{aligned} P(\text{Yes}) &= P(\text{Head} \cap \text{Cheat}) && \text{(addition across} \\ &+ P(\text{Tail} \cap \text{Head}) && \text{branches)} \\ &= 0.5 \times p + 0.5 \times 0.5 && \text{(multiplying} \\ & && \text{along path)} \\ &= 0.5p + 0.25 \end{aligned}$$

This calculation assumes a large sample with fair coins to minimize bias in the coin flip probabilities. If 35% of sample answered “Yes,” then

$$0.35 = 0.5p + 0.25,$$

which can be rearranged to give

$$p = P(\text{Cheat}|\text{Head}) = 2 \times (0.35 - 0.25) = 0.2.$$

The probability that someone cheated in an exam is independent of the first head, so $P(\text{Cheat}|\text{Head}) = P(\text{Cheat})$. Hence, from the survey, we estimate that around 20% of students have cheated in an exam.

TRUE/FALSE ITEMS

True/false items are used for achievement type tests when there is a clear distinction between the two alternatives, true and false. One of the best criteria for judging the value of a true/false item is whether the correct answer (be it true or false) is unequivocally the right one, the only one, and the correct one.

There are several things to keep in mind when writing true/false items:

1. True/false items are always stated as declarative sentences.
2. The alternative answers can be true-false, right-wrong, yes-no, like-dislike, and so on—as long as they are very clear choices.
3. A good true/false item focuses on one and only one idea, concept, or specific topic. With too many ideas, the test taker can become confused.
4. Double negatives should not be used in true/false questions.
5. Clues to the answer to a true/false item should not be included in the item.
6. A different type of item should be used for more complex types of inquiries that assess higher-order thinking.
7. It is preferable to have equal number of true and false items on the test. This minimizes the role that chance plays.

The Advantages and Disadvantages of True/False Questions

The advantages of multiple-choice items are considerable. First, they are convenient, such that several can be administered in a short amount of time. Second, they are very easy to score. If well written, the answers are either correct or incorrect.

But, as with all items, there are disadvantages as well. First, true/false items place a premium on memorization. It is tough to get beyond the most basic levels of knowledge with true/false items. Second, it is relatively easy to guess correctly; the probability of being right (or wrong) is 50%, and by chance alone, if the test taker selects T or F on a somewhat random

basis, the final score will be about 50%. Still, the odds of guessing correctly are much higher than in any other type of traditional item.

True/false test scores can be corrected for guessing (that is the chance outcome of getting 50% correct by guessing alone). This is a useful adjustment to make so that scores more truly reflect those who really do know more versus those who just guess.

Let's propose a scoring system where students get one point for being correct, one point for being incorrect, and nothing for leaving the item blank. So, the formula for correction (or CS, for corrected score) becomes

$$CS = R - W,$$

where

CS is the corrected score,

R is the number correct, and

W is the number incorrect.

For example, take the example of a 50-item test, where you would expect a score of 25 by chance alone ($.5 \times 50 = 25$). Bruce gets 35 correct on a 50-item test, and Bill gets 25 correct. How can we adjust these scores so that Bruce's performance (which is way above chance) is recognized?

Correcting the scores, it turns out that Bruce's new one is $35 - 15 = 20$, and Bill's is $25 - 25 = 0$. Bill is clearly "punished" for guessing.

Table 1 Corrected Scores on 50-Item Test

# Right	# Wrong	Corrected Score
50	0	50
45	5	40
40	10	30
35	15	20
30	20	10
25 (chance)	25 (chance)	0
20	30	-10
15	35	-20
10	40	-30
5	45	-40
0	50	-50

Table 1 shows the number correct on a 50-item test, the number wrong, and the corrected score.

TRUE SCORE

Classical true-score theory, most often traced to the work of Charles Spearman, has been profoundly influential in educational and psychological measurement since around the turn of the 20th century. True-score theory is essentially a model of relationships between measurement errors and observed test scores. The central notion is that any observed score can be decomposed into a "true" score component and a random-error term. Importantly, different sources of error that contribute to the observed score are not differentiated within the latter term.

Classical true-score theory is expressed symbolically in the well-known expression $X = T + E$, in which X represents an observed score for a test taker, T represents that test taker's true score, and E is the error score, or the error of measurement associated with that observed score. In this model, the "true" score component of any individual's observed test score is presumed to reflect the actual amount of the characteristic being measured by the test that is possessed by the individual—that is, the score that the person would have obtained in the absence of measurement errors. Measurement errors (i.e., discrepancies between the individual's observed and true scores) can result from any number of factors both

intrinsic and extrinsic to the test taker (e.g., the specific day on which the test is taken).

For any given test taker and test, T is assumed to be fixed, while E and X are assumed to vary for that same test taker across conditions. If a student is capable of attaining a score of 15 correct from 20 questions on a particular test but is ill on the day of testing and misses 5 questions at random, the true score T for that student would be 15; the observed score X would be 10; and the error score E would be -5 . If the same student takes the test again and this time not only performs at his or her ability level but also “gets lucky” in guessing two multiple-choice questions, that student’s X would be 17; E would be $+2$; but T would still be 15.

The utility and generality of any test model hinges on the assumptions it makes, because these dictate the conditions under which the model may be assumed to hold. Classical true-score theory is, accordingly, defined by a set of assumptions that dictate the circumstances under which the model may reasonably be applied. Most of these assumptions are associated with the definition of measurement error in the model as *random* (rather than *systematic*) discrepancies between true and observed test scores:

1. True scores and error scores combine *additively* to form observed scores. That is, there are no multiplicative or other relationships between true and error scores.

2. The population mean (expected value) of observed X scores is equal to the test taker’s true score, T , that is, $\epsilon(X) = T$. Stated alternatively, if the same test taker could complete a given test an infinite number of times, the mean of the scores obtained by that test taker on that test should be equal to his or her true score. This assumption, in fact, defines T —that is, T is the mean of the theoretical distribution of observed scores that a test taker would obtain across infinite independent attempts at the same test.

3. The error and true scores within a population of test takers are uncorrelated (i.e., $\rho_{ET} = 0$). This assumption stipulates that high or low scores on a given test should not be systematically associated

with more positive or negative error scores on that test. Consider, for example, a test in which one question is unsolvable. If all of the higher-achieving students waste large amounts of time on this question and thus do more poorly than they otherwise would on the rest of the test, this could create a situation in which there was a negative correlation between true and error scores.

4. The error scores on two different tests are uncorrelated (i.e., $\rho_{E1E2} = 0$, with $E1$ being the error score for Test 1 and $E2$ being the error score for Test 2). This means that if a particular individual had a positive error score on one test, he or she should not be more or less likely to obtain a positive error score on a second test. For example, if a group of test takers’ scores on different tests were greatly influenced by factors that were common across the tests (e.g., fatigue), this assumption would not be tenable.

5. The error scores on one test are uncorrelated with true scores on another test ($\rho_{E1T2} = 0$). This assumption stipulates that the factors that cause measurement errors on one test are not related systematically to some characteristic being measured on another test.

Other assumptions of the model are associated with parallel and t -equivalent tests. Specifically, while t -equivalent tests are those that yield the same true scores with the exception of an additive constant, two tests are deemed to be parallel only if both their true scores and their error variances are equal in the population.

The true-score model forms the basis for what has become known as *classical reliability theory*. As observed scores are assumed to comprise both true and random error scores, observed score variance is, accordingly, assumed to comprise both true and random-error score variance. In classical reliability theory, the reliability coefficient represents the ratio of true to observed score variability. Stated alternatively, reliability represents the extent to which variance in observed scores can be attributed to unobservable true-score variance.

Since the true-score model was initially posed, a vast array of techniques for estimating measurement errors (and thus test reliability) have emerged. These estimates consider measurement errors that are due to inconsistencies across different forms of tests (e.g., parallel-forms reliability), across raters or markers (e.g., interrater consistency), in domain representation/sampling within tests (e.g., internal consistency), and across test occasions (e.g., test-retest reliability).

One major limitation of the classical approach to reliability, however, lies in its failure to consider the impact of different error sources on observed scores *simultaneously*. In notions of reliability derived from the true-score model, there is an implicit assumption of overlap across different error sources—that is, an assumption that these are not cumulative and that they do not interact to create additional error variance.

Generalizability (G) theory, which subsumes classical true-score theory as a special case, provides a framework for estimating the magnitude of multiple error sources simultaneously. As such, this model allows an examination of cumulative and interactive effects among different error sources. Despite the relative advantages that this approach offers, financial and other practical constraints continue to make approaches based on classical true-score theory an attractive option for test developers.

TUKEY-KRAMER PROCEDURE

Tukey and Kramer proposed a procedure for pairwise testing of means in a one-way analysis of variance with unequal sample sizes. The procedure is routinely applied after a significant overall F test, although the F test is not required. In Tukey's honestly significant difference (HSD) procedure, a single critical difference, CD, is calculated for each pair of means. That critical difference uses critical values from the Studentized range statistic. In particular,

$$CD = q_{1-\alpha}(k, df_E) \sqrt{\frac{MS_E}{N}},$$

where

$q_{1-\alpha}(k, df_E)$ is the Studentized range statistic at Level α for k means and df_E ,

df_E is the error degrees of freedom,

MS_E is the error mean square, and

N is the common sample size.

In the Tukey-Kramer procedure, a different CD is required to evaluate the significance of the difference between each pair of means that are based on different sample sizes. The pairs are investigated independent of all other pairs. Critical differences are all based on the Studentized range distribution. The formula for the Tukey-Kramer CD testing means \bar{X}_i and \bar{X}_j is

$$CD = q_{1-\alpha}(k, df_E) \sqrt{\left[\frac{MS_E}{2} \left[\frac{1}{N_i} + \frac{1}{N_j} \right] \right]},$$

where

N_i is mean i ($i = 1, \dots, k$) and

N_j is mean j ($j = 1, \dots, k$), but $j \neq i$.

Anthony J. Hayter proved that the Tukey-Kramer is conservative, that is, the probability of one or more Type I error never exceeding α even if applied without a significant F test. However, if a significant F test is required, then the Tukey-Kramer CD becomes

$$CD = q_{1-\alpha}(k-1, df_E) \sqrt{\left[\frac{MS_E}{2} \left[\frac{1}{N_i} + \frac{1}{N_j} \right] \right]}$$

The CD has the value that would be used only with $k-1$ means. The resulting Hayter-Fisher version of the Tukey-Kramer procedure will be more powerful than the original Tukey-Kramer.

Illustrative Example

Consider the following data, in which four treatment groups are being compared to a control. Lower scores indicate better performance. The MS_{WG} for these data is 3.0326, with $df_{WG} = 179$.

	Control	Treat 1	Treat 2	Treat 3	Treat 4
Mean	4.05	3.52	3.18	3.15	2.24
N	42	24	38	40	40

The analysis of variance (ANOVA) for these data would give $F = 16.48 > 2.43 = F_{.95}(4, 160) > F_{.95}(4, 179) = CV$. Therefore, we reject the full null hypothesis at the .05 level and proceed to pairwise testing.

The CD for the Control ($N = 42$) and Treatment 1 ($N = 24$) group means is obtained from

$$CD = q_{1-\alpha}(k-1, df_E) \sqrt{\left[\frac{MS_E}{2} \left[\frac{1}{N_i} + \frac{1}{N_j} \right] \right]}$$

$$CD = 3.68 \sqrt{\left[\frac{3.0326}{2} \left[\frac{1}{42} + \frac{1}{24} \right] \right]}$$

$$= 3.68 \sqrt{1.5163[0.0238095 + 0.0416667]}$$

$$CD = 3.68 \sqrt{1.5163[0.065476]}$$

$$= 3.68 \sqrt{0.0992815} = 3.68(0.315089)$$

$$CD = 1.1595 = 1.16.$$

Applying the same calculations to the Control ($N = 42$) and Treatment 2 ($N = 38$) group means produces the CD

* $p < .05$

The largest difference is 1.81 between Treatment 4 and the Control. This exceeds the largest CD of 1.01 and is therefore significant. The individuals in Treatment 4 have significantly lower average scores than does the Control. The two second-largest differences are 1.28 and .90. The value of 1.28 also exceeds the CD of 1.17 and is significant. Those in Treatment 4 are significantly lower than are those in Treatment 1. However, .90 is less than the CD of 1.01 and is not significant. There is no significant difference between the mean for Treatment 3 and the Control. All other differences are less than their corresponding CD values and are therefore not significant.

Most computer packages continue to use the original and slightly less powerful version of the Tukey-Kramer. However, it is a rather simple matter to apply the more powerful Hayter-Fisher version described above. If a computer package is used to apply the Tukey-Kramer, then any nonsignificant pair can be tested by applying the more powerful Hayter-Fisher version.

TYPE I ERROR

Statistical significance is the degree of risk that a null hypothesis will be rejected when it is actually true. This level of risk is also known as a Type I error. Traditionally, the null (a statement of equality) says that there is no difference between the two groups. Perhaps, in reality, however, there is no difference, and if the null is rejected, an error is being made. This risk is known as a Type I error.

The level of significance has certain conventional values associated with it, such as .01 and .05. For example, if the level of significance is .01, it means that on any one test of the null hypothesis, there is a 1% chance the null hypothesis will be rejected when it is true—leading to the conclusion that there is a group difference when there really is no group difference. If the level of significance is .05, it means that on any one test of the null hypothesis, there is a 5% chance it will be rejected when the null is true—leading to the conclusion that there is a group difference when there really is no group difference. Notice that the level of significance is associated with an independent test of the null, and it is not appropriate to say that “on 100 tests of the null hypothesis, I will make errors on only 5.”

In a research report, statistical significance is usually represented as $p < .05$, read as the probability of observing that the outcome is less than .05, and often

TYPE II ERROR

The term *Type II error* describes a particular kind of inferential mistake one can make when using data to draw a conclusion about a null hypothesis within the strategy called *hypothesis testing*. Simply stated, a Type II error is committed when a false null hypothesis is not rejected.

To understand what a Type II error is and to gain insight into the various factors that operate to increase or decrease Type II error risk, one must first be aware of the logic and steps of hypothesis testing, a statistical strategy widely used by applied researchers in many disciplines.

Hypothesis Testing

In hypothesis testing, data are collected from one or more samples and then used to make an educated guess, or inference, as to the state of affairs within the relevant population(s). In any given study, this educated guess will be focused on a specific statistical characteristic of the population(s), such as the mean (μ), the variance (σ^2), or the correlation between two measured variables (ρ). After a researcher chooses his or her population(s), the variable(s) of interest, the statistical focus, and the planned method for analyzing the study's data, that researcher can use hypothesis testing as a strategy for making the desired statistical inference.

There are six steps involved in the most basic version of hypothesis testing. They involve the following:

1. Stating a null hypothesis (H_0)
2. Stating an alternative hypothesis (H_a)
3. Selecting a level of significance (α)
4. Collecting data from the study's sample(s)
5. Determining the probability, presuming H_0 to be true, of getting sample data like those actually collected or sample data that deviate even further from what would be expected (if H_0 were true)
6. Deciding either to reject H_0 or to fail to reject H_0

An example may help clarify the way these six steps permit a researcher to engage in hypothesis testing—and how hypothesis testing may lead to a Type II error. For this example, imagine that a researcher is hired to settle a dispute between two taxpayers from New York. One believes that if all high school seniors in the state of New York were given an intelligence test, the students' mean IQ would be higher than the national average of 100. The other believes just the opposite. Also imagine that the researcher, once hired, identifies a random sample of 25 students, that each student's intelligence is measured by a trained psychologist, and that the resulting IQ scores yield a mean of 104 with a standard deviation of 15. Finally, imagine that the researcher intended from the beginning to subject the data to a one-sample t test with a level of significance equal to .05. For this example, the six steps of the hypothesis testing procedure would be as follows:

1. $H_0: \mu = 100$.
2. $H_a \neq 100$.
3. $\alpha = .05$.
4. In the sample, $n = 25$, $M = 104$, and $SD = 15$.
5. $p = 0.1949$.
6. H_0 is not rejected.

As applied to this example, the logic of hypothesis testing is straightforward. If the null hypothesis were false, a random sample should most likely produce a mean that is dissimilar to the number specified in H_0 . However, the mean IQ of the 25 students, 104, is not very inconsistent with what would be expected if H_0 were true. (With the estimated standard error of the

mean being equal to 3.0, the t test's calculated value is equal to 1.33.) Because the probability associated with the sample ($p = .19$) is larger than the selected level of significance, the researcher decides that the evidence available is not sufficiently "at odds" with H_0 to cast doubt on the null statement that the mean IQ of high school students in New York is equal to 100. Consequently, the null hypothesis is not rejected.

In this example, it is possible that the researcher's conclusion—not to reject H_0 —may have been a mistake. Such would have been the case if the unknown population mean were equal to 115, 103, 98, or any number other than 100. The null hypothesis value of 100 was selected simply because it was the "line of demarcation" between the two taxpayers who held different opinions about the actual mean IQ of all high school students in New York. It is quite conceivable that the null hypothesis is wrong, and if that is the case, not rejecting H_0 would have been the wrong thing to do. Describing this possible mistake in statistical terms, a Type II error may have been made.

When Type II Errors Can and Cannot Occur

As indicated at the outset, a Type II error is committed when a false null hypothesis is not rejected. This kind of inferential error is always a possibility when any statistical test leads to a decision not to reject the null hypothesis being evaluated. In studies dealing with correlation, a Pearson r is often tested to see if it is significantly different from a null value of 0.00. In this kind of study, a Type II error is possible if a decision is reached not to reject $H_0: \rho = 0.00$. In studies in which k groups are compared in terms of their variances, a Type II error is possible if a fail-to-reject decision is reached when evaluating $H_0: \sigma_1^2 = \sigma_2^2 = \dots = \sigma_k^2$. In studies in which logistic regression is used to see which of several independent variables help predict status on a nominal dependent variable, a Type II error is possible if a particular variable's odds ratio is found not to differ significantly from the null value of 1.00. It is worth repeating that a Type II

error is always a possibility when any statistical test leads to a decision not to reject the test's null hypothesis.

There are two situations in which a Type II error cannot occur. On the one hand, a Type II Error cannot be committed if the null hypothesis is rejected. (In this case, a Type I error—rejecting a true H_0 —may or may not occur, but it is impossible to incorrectly fail to reject a false null hypothesis if that H_0 is rejected.) On the other hand, it is impossible to make a Type II error if the six-step hypothesis-testing procedure is turned into a four-step procedure by eliminating the third step (setting a level of significance) and final step (deciding to reject or not reject H_0). In this four-step approach to evaluating an H_0 , the size of the data-based p -value is interpreted as providing a “level of support” for the null hypothesis. The smaller the p , the lower the level of support. With no binary decision being made about H_0 , the notion of a Type II error (as well as the notion of a Type I error) does not apply.

Synonyms for Type II Error

There are different labels for this particular kind of inferential error. A Type II error is sometimes referred to as an *acceptance error*, a *false negative*, an *error of the second kind*, or a *beta error*. The first of these synonyms come into being because a decision not to reject H_0 makes it appear as if H_0 is being accepted. (Technically, it is wrong to “accept” H_0 in hypothesis testing.) The notion of a “false negative” comes from the medical field, in which diagnostic tests sometimes yield inaccurate results. An erroneous diagnosis can indicate that a patient has a disease when he or she doesn't (a false positive) or that the patient doesn't have a disease when he or she does (a false negative). The third synonym, error of the second kind, makes sense when one realizes that any inference in hypothesis testing, like a medical diagnosis, can potentially be wrong in either of two ways. (An error of the first kind, or Type I error, is committed whenever a true null hypothesis is rejected.) The final synonym, beta error, exists because a Type I error is sometimes referred to as an *alpha error*.

Type II Error as a Probability

After a study's data are collected but prior to the time a decision is reached about H_0 , there is a fixed probability that a Type II error will be made. This probability can be illustrated graphically, as shown in Figure 1.

Each of the two curves in Figure 1 represents the distribution of the test statistic (e.g., the computed z value if a z test is being conducted). The curve on the left is labeled H_0 because it represents the distribution of the test statistic that would occur if the null hypothesis happened to be true. The curve on the right is labeled H_a because it represents the distribution of the test statistic that would occur if the null hypothesis happened to be false by an amount equal to the horizontal distance between the two curves.

In Figure 1, there is a vertical line that simultaneously divides each curve into two parts. The position of that line was determined by considering only (a) the H_0 curve, (b) the directional or nondirectional nature of the alternative hypothesis, and (c) the level of significance. Because the illustration in Figure 1 has been set up to depict a one-tailed test conducted with α set equal to 0.05, the vertical line is positioned such that it creates, in the H_0 curve, a tail consisting of 5% of the full H_0 distribution. This portion of the baseline to the right of the vertical line is referred to as the *region of rejection*. Once computed, the data-based test statistic is simply compared to the numerical value on the baseline under the vertical line to see if the former exceeds the latter. If so, H_0 is rejected; if not, H_0 is not rejected.

The shaded part of the H_a curve represents the probability that a Type II error will occur. This portion of the right-hand curve shows the likelihood of

Figure 1 Type II Error Probability

not rejecting H_0 if the true state of affairs corresponds with H_a rather than H_0 . Because the shaded area of the right-hand curve constitutes 35% of the H_a curve, the probability of incorrectly failing to reject H_0 is 0.35.

Type II Error Probability and Power

In hypothesis testing, H_0 is either rejected or not rejected. If the null hypothesis is false, failing to reject it constitutes a mistake, a Type II error, while rejecting H_0 represents a correct decision. The probability that H_0 , if false, will be correctly rejected is called the statistical test's *power*.

Because the final decision in hypothesis testing is binary (either reject or do not reject H_0), one of the two events is guaranteed to occur. Therefore, the probability of not rejecting H_0 plus the probability of rejecting it is equal to 1.0. This is true regardless of whether H_0 is true or false. However, when H_0 is false, the first of these two probabilities is the probability of a Type II error, whereas the second one is the probability of a correct decision. Because the second probability is, by definition, the test's power, it follows that the probability of a Type II error + Power = 1. Rearranging terms, it also follows that Power = 1 – the probability of a Type II error. If the probability of a Type II error is represented by the word *beta* (because the terms *beta error* and *Type II error* are synonyms), it can be said that

$$\text{Power} = 1 - \text{beta.}$$

In Figure 1, the right-hand (H_a) curve is divided into two parts. The shaded part represents the probability of a Type II error (i.e., the likelihood of a beta error). The unshaded portion of the H_a curve represents the probability of correctly rejecting H_0 —the power of the statistical test. In Figure 1, power is equal to .65.

Factors That Affect the Probability of a Type II Error

When a single statistical test is run (and presuming all assumptions are met), the probability of a Type I error

is determined by one factor: the level of significance. In this same situation (one test with assumptions met), there are seven factors that jointly influence the probability of a Type II error: the numerical value in H_0 , α , the size of the sample(s), the variability in the population(s), the test used to analyze the data, the nature of H_a , and the true state of affairs in the population(s) of interest.

For any statistical test, the probability of a Type II error is lower to the extent that (a) there is a greater difference between the null hypothesis and the true state of affairs in the population(s), (b) the level of significance is lenient (i.e., high), (c) there is low variability in the population(s), and (d) large amounts of sample data are available. Also, certain statistical tests (e.g., a *t* test to compare two sample means) are less likely to produce a Type II error than are other tests (e.g., a median test). As long as they are “pointed” in the right direction, one-tailed tests are less prone to generate Type II errors than are two-tailed tests.

Because the likelihood of a Type II error is influenced jointly by many factors, any statement of Type II error risk in a given study is tied to the specific features of that particular study. Thus, the fact that Figure 1 has 35% of the H_a curve shaded is tied to a specific situation defined by the seven factors mentioned above. Make a change in any of those factors and the size of the shaded area in the H_a curve will either increase or decrease. For example, make the test two-tailed rather than one-tailed and the shaded area will increase.

Considering Type II Error Risk When Planning Studies

As indicated earlier, the most basic version of hypothesis testing involves six steps. Many researchers use that version of hypothesis testing. However, that method of research is considered by many authorities to be elementary, because no consideration is given to Type II error risk. More sophisticated studies have this kind of risk considered (and controlled) in the design phase of the investigation.

In any given study, it is possible to estimate the likelihood that a Type II error will be committed. This is done by means of a *power analysis*. In a power

analysis, a researcher indicates (or, in some cases, estimates) the seven factors mentioned in the previous section. A formula is then used to indicate the probability that a false H_0 will be rejected. That probability is the test's power. The complement of power is Type II error risk. Therefore, by doing a power analysis to see if sample sizes are large enough to produce a desired level of power, a researcher is simultaneously checking to see if the study's design is such that Type II error risk is at or below some predetermined level.

Common Misconceptions Concerning Type II Errors

There are three misconceptions that many people have about Type II errors. First, it is widely believed that Type II errors are not as “damaging” as Type I errors. (In some studies, it is far worse to draw a conclusion that is a false negative rather than a false positive.) Second, many people think that the probability of committing a Type I error is inversely related to the probability of a Type II error, with the thought being

that an increase in one brings about a decrease in the other. (Actually, it is possible to reduce both kinds of error possibilities.) Finally, it is generally thought that nonparametric tests are inherently less powerful—and thus less likely to generate Type II errors—than parametric tests. (In reality, certain nonparametric procedures, under specified conditions, have a lower Type II error risk than do their parametric counterparts.)

UNBIASED ESTIMATOR

Let the data be represented by X_1, X_2, \dots, X_n , a collection of random variables, whose behavior can be modeled by a probability distribution F_θ , where θ represents a parameter to be estimated from the data. Here, θ may be a k -dimensional vector. For example, F_θ may be the family of normal distributions with θ representing the mean of the X_i s, or θ may be a two-dimensional vector, $\theta = (\mu, \sigma^2)$, representing the mean and variance of the X_i s. Let $\delta(X_1, \dots, X_n)$ be a function of the data. That is, $\delta(X_1, \dots, X_n)$ is an estimator.

The estimator $\delta(X_1, \dots, X_n)$ is said to be *unbiased* for $g(\theta)$ if, for all θ ,

$$E_\theta(\delta(X_1, \dots, X_n)) = g(\theta). \quad (1)$$

When Condition 1 does not hold, the *bias* of δ is defined as $b(\theta) = E_\theta(\delta(X_1, \dots, X_n)) - g(\theta)$. Gauss introduced the concept of unbiasedness to denote lack of systematic error in the estimation process.

Example 1. Let X_1, \dots, X_n denote random variables with the same expectation θ . Because $E(\sum_{i=1}^n c_i X_i) = \theta$, whenever $\sum_{i=1}^n c_i = 1$, then $\sum_{i=1}^n c_i X_i$ is unbiased for θ .

Example 2 (Survey Sampling). Let a population consist of N individuals, each with annual income t_i , $i = 1, \dots, N$. To estimate the total income $T = \sum_{i=1}^N t_i$ take a random sample of size n and denote by $\{y_1, \dots, y_n\}$ the incomes of the n sampled individuals. Note that each of the $\{y_1, \dots, y_n\}$ has probability $\frac{1}{N}$ of being equal to each of the t_i , $i = 1, \dots, N$.

The following calculation shows that $\frac{N}{n} \sum_{i=1}^n Y_i$ is unbiased for T :

$$E \left\{ \frac{N}{n} \sum_{i=1}^n y_i \right\} = \frac{N}{n} \sum_{i=1}^n E(y_i) = \frac{N}{n} \sum_{i=1}^n \frac{1}{N} \sum_{j=1}^N t_j = T.$$

In most cases, the requirement of unbiasedness as defined by Condition 1 yields intuitive estimators with good properties. However, unbiased estimators may not exist, and when they do exist, sometimes they behave poorly.

Example 3. Let X be a *binomial* random variable with parameters n and $\theta =$ probability of success. It is known that there is no unbiased estimator for $g(\theta)$ unless $g(\theta)$ is a polynomial in θ of degree less than or equal to n . For example, there is no unbiased estimator for $\frac{1}{\theta}$ based on X . On the other hand, when a

geometric random variable Y with $\theta =$ probability of success is observed, Y is unbiased for $\frac{1}{\theta}$.

Example 4. Let X be a Poisson random variable with parameter θ . When estimating $(p\{X=0\})^2 = e^{-2\theta}$, the unique unbiased estimator is $\delta(X) = (-1)^X$, a silly estimator. Lehmann considers this issue and proposes that it is due to inadequate information. For example, if, instead of a single Poisson observation, there are n independent Poisson observations, setting $T = \sum_{i=1}^n X_i$ an unbiased estimator for $e^{-2\theta}$ is $\delta(T) = (1 - \frac{2}{n})^T$, which is a reasonable estimator for $n > 2$.

A general concept of unbiasedness was proposed by Lehmann. Let $(L(\delta(X), g(\theta)))$ represent the loss incurred in estimating $g(\theta)$ by $\delta(X)$. Then $\delta(X)$ is said to be L -unbiased with respect to the loss function L if, for all $\theta^* \neq \theta$,

$$E_{\theta}(L(\delta(X), g(\theta))) \leq E_{\theta}(L(\delta(X), g(\theta^*))). \quad (2)$$

When the loss function is squared-error loss, $L(\delta(X), g(\theta)) = (\delta(X) - g(\theta))^2$, Condition 2 is equivalent to Condition 1. When the loss function is absolute error, $L(\delta(X), g(\theta)) = |\delta(X) - g(\theta)|$, Condition 2 is equivalent to *median-unbiasedness*; that is, Condition 2 is equivalent to requiring that $\delta(X)$ satisfy the condition that for all θ ,

$$P_{\theta}\{\delta(X) > g(\theta)\} = P_{\theta}\{\delta(X) < g(\theta)\}.$$

Rojo and Klebanov studied the existence of L -unbiased estimators.

UNIVERSAL NONVERBAL INTELLIGENCE TEST

The Universal Nonverbal Intelligence Test (UNIT) is an individually administered test designed to measure the general intelligence and cognitive abilities of children and adolescents ages 5 through 17 years who may be disadvantaged by traditional language-loaded ability tests. The UNIT is intended to provide a fair assessment for children and adolescents who have speech, language, or hearing impairments; who have different cultural or language backgrounds (e.g., English as a Second Language); and who are verbally uncommunicative due to psychiatric (e.g., elective/selective mutism), developmental (e.g., autistic spectrum), or organic reasons (e.g., traumatic brain injury).

Although its administration and response formats are entirely nonverbal (i.e., no verbal directions, no verbal items, and no verbal responses), the UNIT employs eight standardized gestures to demonstrate the nature of each task and to guide test administration. The UNIT is a comprehensive measure of intelligence and assesses a broad range of complex memory and reasoning abilities, including those lending themselves to internal processes of verbal mediation (symbolic tasks) as well as those that are less conducive to such mediation (nonsymbolic tasks). UNIT memory subtests measure complex memory, with multiple salient characteristics to be recalled (e.g., color, object, location, and sequence). The UNIT reasoning subtests measure pattern processing, problem solving, understanding of analogic relationships, and planning abilities. Although the UNIT is a highly g -saturated measure of general intelligence, with five of six subtests having average g -loadings

above .70, exploratory and confirmatory factor analyses support the test’s 2 × 2 theoretical model (i.e., Memory/Reasoning; Symbolic/Nonsymbolic). Table 1 depicts the UNIT theoretical model in its entirety, including subtest representation and total sample alpha coefficients for the UNIT scale quotients and the full-scale IQ (FSIQ). As can be seen in Table 1, the UNIT is a highly reliable and comprehensive measure of general intelligence.

For additional versatility and practicality, the UNIT combines its three memory subtests and three reasoning subtests in a flexible manner that permits the use of three possible batteries. The 15-minute UNIT Abbreviated Battery includes only the first two subtests (i.e., Symbolic Memory and Cube Design); the 30-minute Standard Battery is a four-subtest configuration that adds Spatial Memory and Analogic Reasoning to the first two subtests. The 45-minute six-subtest Extended Battery adds Object Memory and Mazes to the first four subtests. Regardless of the desired length of administration, the UNIT’s theoretical model underpins each of the three batteries.

The UNIT is a standardized, norm-referenced measure. The normative data are based on a comprehensive national sample that closely matched the U.S. population on important demographic variables. The sample was composed of 2,100 children and adolescents, and included a proportional representation of students receiving services for identified exceptional needs as well as students receiving services for English as a Second Language (ESL) and bilingual education. The UNIT Examiner’s

Manual dedicates an entire chapter to the topic of fairness in testing, which highlights the authors’ efforts to render the instrument as fair as possible for all students. Comparative reliabilities and factor analyses by age, race/ethnicity, and gender are reported in the manual, as well as a large number of matched-sample mean score comparisons between various groups.

VALIDITY COEFFICIENT

The validity coefficient is a statistical index used to report evidence of validity for intended interpretations of test scores and defined as the magnitude of the correlation between test scores and a criterion variable (i.e., a measure representing a theoretical component of the intended meaning of the test). For example, the relationship between Scholastic Aptitude Test scores and college grade point average (GPA) as the criterion variable may demonstrate validity evidence for interpreting Scholastic Aptitude Test scores as an indication of academic success (intended meaning) in terms of achieving high grades (theoretical component).

According to the 1999 edition of the *Standards for Educational and Psychological Testing*, the term *validity* refers to the extent to which an intended interpretation of test scores is supported by evidence. Rather than discussing validity in terms of differing types (e.g., construct, content, and criterion-related validity), the 1999 standards view construct validity as the only type of validity that can be supported by evidence based on test content, response processes, internal structure, relations to other variables, and

consequences of testing. As empirically based forms of evidence, validity coefficients are determined by studies that examine relations to other variables (formerly referred to as criterion-related validity) and commonly include correlational studies.

Correlational studies of validity evidence often are discussed in terms of being concurrent or predictive in nature. Concurrent evidence is indicated by relations between test and criterion scores that are measured at approximately the same time, whereas predictive evidence reflects the relation between test scores gathered at one time and criterion scores measured at a later time. In other words, test scores that predict future behavior are said to have predictive validity, whereas test scores that reflect present behavior are said to have concurrent validity. For example, the relationship between Scholastic Aptitude Test scores of high school students at Time 1 and the same students' college GPAs at Time 2 would be an example of predictive validity evidence, whereas the relationship between the Scholastic Aptitude Test scores of high school students and the same students' high school GPAs would be an example of concurrent validity evidence. Table 1 presents hypothetical concurrent and predictive validity evidence for the Scholastic Aptitude Test.

Table 1 Hypothetical Concurrent and Predictive Validity Evidence for the SAT

<i>Test</i>	<i>Criterion</i>	<i>Type of Validity</i>	<i>Validity Coefficient</i>
SAT	GPA	Concurrent	.54
SAT	GPA	Predictive	.47
SAT	Class rank	Concurrent	.35
SAT	Class rank	Predictive	.32
SAT	ACT	Concurrent	.58

Less commonly used approaches for gathering evidence of the relation between test scores and criteria include the following:

studies of postdictive validity (the ability to relate to a criterion that had previously occurred)

studies of incremental validity (the ability to improve on the validity of an existing test)

studies of group comparison validity (the ability to measure expected differences for multiple groups)

studies of experimental validity (the ability to measure expected change in criteria)

Computation and Interpretation

Although there are a number of statistics for the computation of a correlation, such as the Spearman rank correlation (ρ) and Kendall's rank correlation coefficient (τ), the validity coefficient typically is computed with the Pearson product-moment correlation (r). The interpretation of validity coefficient values follows that of a correlation index. Thus, coefficient values may range from -1 to $+1$. The magnitude of the *relationship* is described in terms of strength, such that values near 0 indicate very weak relations between test and criterion scores, whereas values near $+1$ or -1 indicate very strong relations. Similarly, the magnitude of the *correlation* is discussed in terms of size (e.g., large or small). Positive values indicate direct relations (e.g., as test scores increase, so do criterion scores), whereas negative correlations indicate indirect relations (e.g., as test scores decrease, criterion scores increase).

The validity coefficient often is interpreted in terms of the square of its value (r^2). Referred to as the

coefficient of determination, the squared value represents the percentage of variance the test and criterion scores have in common. In other words, the square of the validity coefficient can be interpreted as the percentage of the variance in criterion scores that can be accounted for by test scores. For example, a validity coefficient value of $.50$ would indicate that 25% of the variance of the criterion (e.g., college GPA) could be accounted for by the test scores (e.g., Scholastic Aptitude Test).

In addition, the interpretation of coefficient values is often discussed with regard to statistical significance, which indicates that a true relationship between test scores and criterion scores is statistically probable. Statistical significance is a function of sample size (n), so significance can be achieved for relatively low coefficient values when such values are based on a large sample size. The statistical significance for a particular coefficient value can be determined by looking at a table of critical r values (i.e., values indicating the point when the null hypothesis should be rejected) or by computing the t statistic and looking at a table of critical t values.

The distinction between the terms *statistical significance*, *strength of the relationship*, and *meaningfulness* warrants additional discussion. Recall that a large coefficient value indicates a strong relation and that a significant value indicates that a true relationship is probable. However, a large correlation may not be significant, and a significant relationship may not be a strong one. In addition, because the validity coefficient is based on the correlation between test scores and criterion scores, a significant or strong relationship does not necessarily indicate what the test actually measures. In other words, a correlation index does not necessarily indicate a meaningful relation exists between test scores and criteria. For example, a correlation may be found between Scholastic Aptitude Test scores and shoe size, but clearly the Scholastic Aptitude Test is not a meaningful measure of shoe size. A meaningful criterion is one that is based on a sound theoretical rationale.

Last, when interpreting validity coefficient values, one should be aware that the formulas for computing correlations (e.g., Pearson's r) are based on the assumption that a linear relationship exists between

test and criterion scores. If in actuality a nonlinear (i.e., curvilinear) relationship exists, then coefficient values will be less accurate. Graphing data points in a scatter plot helps identify the linearity of a relationship.

Evaluating Validity With the Coefficient

Validity coefficient values may be evidence for the criterion validity of test score interpretation, but the evaluation of a single validity coefficient value cannot constitute an adequate validation process. Consequently, a gold standard or benchmark coefficient value that one could use to determine whether a particular interpretation of test scores is valid does not exist. Generally, however, coefficient values do not exceed .60, and values wide of .00 are commonly interpreted as indicating that test scores are superior to guesswork. To deem an interpretation to have adequate evidence of validity, one must consider other forms of information, such as the intended construct to be measured (e.g., academic achievement), the intended population of test takers (e.g., age), and the intended use of the test (e.g., college admissions). For example, the assertion that there is evidence for the validity of Scholastic Aptitude Test scores for the purpose of predicting the academic success of high school students would need to be based on an extensive examination of test scores in relation to the construct of academic success, the population of high school students, and the common use of test scores to determine college admittance.

A number of factors can influence the value of the validity coefficient. First, and perhaps most important, the meaningfulness of the criterion variable will tend to affect the coefficient value. When a criterion is not meaningful or relevant, the correlation between test scores and criterion scores likely will be weak. For instance, the validity coefficient of Scholastic Aptitude Test scores likely would be very low if the chosen criterion were a measure of shoe size. Again, meaningful criteria are based on sound theoretical rationales.

Second, the reliability of both the test scores and the criteria will influence coefficient values. This is because the validity of test scores is a function of their

reliability; that is, test scores cannot be valid if they are not reliable (although test scores may be reliable and not valid). Therefore, test scores or criteria with low levels of reliability will not be apt to achieve a high coefficient value.

Third, coefficient values also can be affected by the range of the test and criterion scores. For instance, as the range of a measure's scores increases, the corresponding coefficient values will tend to increase. The variability of criterion scores often is restricted or reduced in cases in which individuals with high test scores are selected for such things as admittance to highly competitive colleges or employment. For example, if Scholastic Aptitude Test scores of high-achieving students are collected and compared to the students' GPAs, the variability of test scores and GPAs would be relatively low (because nearly all the scores and GPAs will be very high), which would engender a low validity coefficient value. This type of situation is referred to as a *restriction of range*.

If restriction of range or a low level of reliability has occurred, correction formulas can be used to determine "corrected" validity coefficient values. An appropriate use of correction formulas would be to determine the degree that the validity coefficient would increase if the reliability for the test or criterion were to increase a given amount. This information would be helpful to test developers who may be considering a revision to an existing measure. An inappropriate use would be to evaluate the validity of test scores with corrected coefficient values. The following formula can be used to compute corrected coefficient values based on a change in the reliability of test scores or criteria:

$$r_c = r_o \left(\frac{\sqrt{\alpha_Y'} \sqrt{\alpha_X'}}{\sqrt{\alpha_Y} \sqrt{\alpha_X}} \right),$$

where

r_c is the corrected correlation value;

r_o is the observed correlation, .50;

α_Y' is the improved reliability coefficient for the criterion, .85;

α'_x is the improved reliability coefficient for the test, .89;

α_y is the measured reliability coefficient for the criterion, .75; and

α_x is the measured reliability coefficient for the test, .74.

After the values have been entered, the equation appears like this:

$$r_c = .5 \left(\frac{\sqrt{.85}\sqrt{.89}}{\sqrt{.75}\sqrt{.74}} \right) = .58.$$

Valid test scores may or may not be of value to test users; therefore, the validity coefficient alone also cannot indicate the overall value or goodness of a test. To make a judgment concerning the value of a particular test, one must examine the relevant types of validity and reliability; the relative value of a test also should be examined in terms of both the utility and cost of the test and the utilities and costs of preexisting tests. For instance, if a new measure were more costly than an existing measure but only slightly improved in terms of validity coefficient values, the new test would tend not to be of value to test users. However, if the measures were being used in high-stakes situations, the improved test might be of value.

Last, it is the responsibility of publishers and test authors to provide adequate evidence of validity and reliability for test scores. Informed decisions with regard to appropriate test selection, usage, and interpretation of test scores require test users to be familiar with the psychometric data. In their validation processes, test users can find validity coefficient values and other validity and reliability evidence in test manuals and also in studies published in peer-reviewed journals. A comprehensive validation process considers the corpus of evidence supportive and contradictive of intended, as well as alternative, interpretations of test scores.

VALIDITY THEORY

The concept of *validity* is one of the most influential concepts in science because considerations about its nature and scope influence everything from the design to the implementation and application of scientific research. Validity is not an abstract property of any observable, unobservable, or conceptual phenomenon, such as a measurement instrument, a personality trait, or a study design. Rather, validity is a characteristic of the inferences that are drawn about phenomena by human agents and the actions that result from these inferences. Specifically, validity is always a matter of degree and not absolutes. This stems partly from the fact that validity is not an observable characteristic of inferences and actions but something that has to be inferred also.

The evaluation of the degree to which inferences are valid and resulting actions are justifiable is, therefore, necessarily embedded in a social discourse whose participants typically bring to the table diverse frameworks, assumptions, beliefs, and values about what constitutes credible evidence. Specifically, modern frameworks for validity typically list both rational and empirical pieces of evidence as necessary, but in each individual context, what these pieces should look like is open to debate. Put differently, a coherent statement about the validity of inferences and actions requires negotiation as well as consensus and places

multiple responsibilities on the stakeholders who develop such a statement.

Negotiating Validity

A metaphor may illustrate complications that can arise in a discourse about validity. If an educational assessment is viewed as the construction of a house, inferences are markers of the utility of the house. In this sense, an evaluation of the validity of inferences can be viewed as an evaluation of the degree to which the house provides structural support for the purposes that are envisioned for it. Obviously, the parties who are envisioning a certain use of the house are not necessarily the same as the designers or builders of the house, and so discrepancies can arise easily. Of course, other reasons for a mismatch are possible and could stem from a miscommunication between the designers of the house and the users of the house or from a faulty implementation of the design plans for the house. In a sense, the search for inferences that can be supported can be viewed as the search for how a house can be transformed into a home.

In general, the stakeholders in an assessment can be coarsely viewed as belonging to four complementary groups. First, there are the test developers, who create a research program, a framework, or an instrument under multiple considerations, such as theoretical adequacy and feasibility for practical implementation. Second are the examinees, whose needs in the process are typically more practical and may differ quite substantially from those of the other stakeholders involved. Third are the test users, or the decision makers who utilize the scores and diagnostic information from the assessment to make decisions about the examinees; only rarely are the examinees the only decision makers involved. Fourth are the larger scientific and nonscientific communities to which the results of an assessment program are to be communicated and whose needs are a *mélange* of those of the test developers, the test users, and the examinees. Therefore, determining the degree to which inferences and actions are justifiable is situated in the communicative space among these different stakeholders.

Not surprisingly, examples of problems in determining the validity of inferences abound. For example, the inferences that test users may want to draw from a certain assessment administered to a certain population may be more commensurate with an alternative assessment for a slightly different population. However, that is not a faulty characteristic of the assessment itself. Rather, it highlights the difference between the agents who make inferences and the agents who provide a foundation for a certain set of inferences, of which the desired inferences may not be a member.

Historical Developments of Validity Theories

Until well into the 1970s, validity theory presented itself as the coexistent, though largely unrelated, trinity of *criterion*-based, *content*-based, and *construct*-based conceptions of validity. According to the criterion-based approach, the validity of an assessment could be evaluated in terms of the accuracy with which a test score could predict or estimate the value of a defined criterion measure, usually an observable performance measure. The criterion-based model, notably introduced by Edward L. Thorndike at the beginning of the 20th century, owed much of its lingering popularity to an undisputable usefulness in many applied contexts that involve selection decisions or prognostic judgments, such as hiring and placement decisions in the workplace or medical and forensic prognoses. Depending on whether the criterion is assessed at the same time as the test or at a subsequent time, one can distinguish between *concurrent* and *predictive* validity, respectively. Though a number of sophisticated analytical and statistical techniques have been developed to evaluate the criterion validity of test scores, the standard methods applied were simple regression and correlation analyses. The resulting coefficient was labeled *validity coefficient*. Occasionally, these procedures were supplemented by the *known-groups method*. This approach bases validity statements on a comparison of mean test scores between groups with hypothesized extreme values (e.g., devout churchgoers and members of sex-chat

forums on the Internet on a newly developed sexual permissiveness scale).

The content-based model of validity comes into play when a well-defined and undisputed criterion measure is not readily available, especially when the prediction is targeted at a broader and multifaceted criterion (e.g., achievement in a content area like mathematics). An argument for content validity is usually established through a panel of experts, who evaluate the test content in terms of (a) relevance and (b) representativeness for the content area under scrutiny. Not surprisingly, the vagueness and subjectivity of the evaluation process has led many psychometricians to discount the content-based model as satisfying *face-validity* requirements at best. However, modern proponents of the content-based model have applied a wealth of sophisticated quantitative procedures to ensure and evaluate interrater agreement, thereby trying to lend credibility to otherwise qualitative and judgment-based validity evidence.

Shortcomings of the criterion-based and the content-based models of validity incited the American Psychological Association to set forth technical recommendations for justifying interpretations of psychological tests. As a result of this endeavor, the term *construct validity* was coined and later elaborated by Lee J. Cronbach and Paul Meehl. In the beginning, they tied their validity theory closely to a more general and abstract nomological network, which was described in 1952 by Carl G. Hempel in his classic essay *Fundamentals of Concept Formation in Empirical Science*. Metaphorically and graphically, the constructs are represented by knots, and the threads connecting these knots represent the definitions and hypotheses included in the theory. The whole system, figuratively speaking, “floats” above the plane of observation and is connected to it by “strings,” or rules of interpretation. The complex system of theoretical definitions can be used to formulate theoretical hypotheses, which can, in turn, be used to formulate empirical hypotheses about relationships among observable variables. In this framework, validity is not a characteristic of a construct or its observed counterpart but of the interpretation of defined logical relations of a causal nature that function

to semantically circumscribe a theoretical network of constructs and construct relations.

An obvious epistemological problem arises, however, when the observed relationships are inconsistent with theory, which is exacerbated by the dearth of developed formal theories in many psychological and social science domains. This lack of strong theory led Cronbach to coin the phrases “weak program” and “strong program” of construct validity. He cautions that, without solid theory (i.e., with only a weak program of construct validity), every correlation of the construct under development with any other observed attribute or variable could be accepted as validity evidence. Consequently, in the absence of any coordinated argument, validation research would then resemble more an empirical shotgun procedure than a scientific program.

Such problems notwithstanding, by the 1980s, the notion of construct validity became accepted as the basis for a new framework of validity assessment that is characterized by its unifying nature. The unifying aspect stems primarily from the acknowledgment that interpretive elements like assumptions and value judgments are pervasive when measuring psychological entities and, thus, are unavoidable in any discourse about any aspect of validity. As Samuel Messick, the most prominent proponent of a unified theory of validity, has framed it, “The validation process is scientific as well as rhetorical and requires both evidence and argument.”

The most controversial aspect of the unified concept of validity as developed by Messick pertains to the role of consequences in the validation process. In this view, a validity argument must specifically consider and evaluate the social consequences of test interpretation and test use, which are describable only on the basis of social values. Importantly, his notion of social consequences does not refer merely to test misuse but, specifically, to the unanticipated consequences of legitimate test score interpretation and use. A number of critics reject his idea that evidential and consequential aspects of construct validity cannot be separated, but despite this debate and recent clarifications on the meaning of the consequential aspects, the question of value justification within a unified validity approach persists.

Philosophical Challenges

The unification of validity theory under a constructivist paradigm has challenged the prevailing implicit and explicit philosophical realism that many applied social scientists had hitherto followed in their practical measurement endeavors. In philosophical realism, a test's task was to accurately measure an existing entity and not to question whether such an entity existed in the first place (an ontological question) or whether it could be assessed at all (an epistemological question). In the constructivist view, it is not a test that is validated but its interpretation (i.e., the inferences that are drawn from a test score). Therefore, it is insufficient to operationalize validity through a single validity coefficient. Rather, validation takes the form of an open-ended argument that evaluates the overall plausibility of the proposed test score interpretations from multiple facets. Currently, the strengthening of cognitive psychology principles in construct validation as described by Susan Embretson and Joanna Gorin, for example, appears to be one of the most promising avenues for developing validity theory toward a more substantive theory that can truly blend theoretical models with empirical observations. Models with genesis in cognitive psychology enable one to disentangle and understand the processes that respondents engage in when they react to test items and to highlight the test instrument as an intervention that can be used to search for causal explanations, an argument that was developed recently in detail by Borsboom, Mellenbergh, and van Heerden.

Perspectives for the Future

To comprehensively develop a unified theory of validity in the social sciences, a lot more must be accomplished besides a synthesis of the evidential and consequential bases of test interpretation and use. In particular, a truly unified theory of validity would be one that crosses methodological boundaries and builds on the foundations that exist in other disciplines and subdisciplines. Most prominently, consider the *threats-to-validity* approach for generalized causal inferences from experimental and

quasi-experimental designs, the closely related *validity generalization* approach by virtue of meta-analytical techniques, and the long tradition of validity concepts in qualitative research. In the end, it may be best to acknowledge that validity itself is a complex construct that also needs to be validated every once in a while.

VARIABLE

A variable represents a class of outcomes that can take on more than one value. For example, car make is a variable that can take on the values of Pontiac,

Volvo, or Chevrolet, among others. Other examples of variables are height (expressed as short or tall or 5 feet or 6 feet, etc.), income (expressed as more than \$60,000 or less than \$60,000, for example), age at menarche, number of badges earned, time in rank, speed for the 100-yard dash, and favorite type of food. All these characteristics can take on any one of several values.

Table 1 lists types of variables, definitions, and alternative terms for the variables.

The two most important variables are dependent and independent variables.

A dependent variable represents the measure that reflects the outcomes of a research study. For example, if the difference between two groups of adults on how well they can remember a set of 10 single digits after a 5-hour period is measured, the number of digits remembered is the dependent variable.

A dependent variable is the outcome measure that depends on the experimental treatment or on what the researcher changes or manipulates.

An independent variable represents the treatments or conditions that the researcher controls, either directly or indirectly, to test their effects on a particular outcome. An independent variable is also known as a treatment variable; it is in this context that the term *treatment* is most often used. An independent variable is manipulated in the course of an experiment to understand the effects of this manipulation on the dependent variable.

For example, the effectiveness of three different reading programs on children's reading skills may be tested. Method A includes tutoring, Method B includes tutoring and rewards, and Method C includes neither tutoring nor rewards (these kids just spend some time with the teacher). In this example, the method of reading instruction is manipulated, and it is the independent variable. The outcome, or dependent, variable could be reading scores. This experiment includes three levels of one independent variable (method of teaching) and one dependent variable (reading score).

The distinction between direct and indirect manipulation of the independent variable(s) has to do with whether the researcher actually creates the levels (such as Method A, Method B, and Method C above) or whether the levels occur naturally and cannot be manipulated directly but only tested. Examples of naturally occurring variables include differences such as gender (we cannot very well assign that trait to people) or age (we cannot make people younger or older).

The general rule to follow in experimental design is that when the researcher is manipulating anything or assigning participants to groups based on some characteristic, such as age or ethnicity or treatment, that variable is the independent variable. When researchers look at some outcome to determine whether the grouping had an effect, they are looking at the dependent variable.

Table 1 Types of Variables

<i>Type</i>	<i>Definition</i>	<i>Other Terms You Might See</i>
Dependent variable	A variable that is measured to see whether the treatment or manipulation of the independent variable had an effect	Outcome variable Results variable Criterion variable
Independent variable	A variable that is manipulated to examine its impact on a dependent variable	Treatment Factor Predictor variable
Control variable	A variable that is related to the dependent variable, the influence of which needs to be removed	Restricting variable
Extraneous variable	A variable that is related to the dependent variable or independent variable and that is not part of the experiment	Threatening variable
Moderator variable	A variable that is related to the dependent variable or independent variable and has an impact on the dependent variable	Interacting variable

Independent variables must take on at least two levels or values (because they are variables). For example, if a researcher were studying the effects of gender differences (the independent variable) on language development (the dependent variable), the independent variable would have two levels, male and female. Similarly, if a researcher were investigating differences in stress for people 30 to 39 years of age, 40 to 49 years, and 50 to 59 years, then the independent variable would be age, and it would have three levels.

The Relationship Between Independent and Dependent Variables

The best independent variable is one that is independent of any other variable that is being used in the same study. In this way, the independent variable can contribute the maximum amount of understanding beyond what other independent variables can offer. When variables compete to explain the effects, their potential influence is sometimes called confounding.

The best dependent variable is one that is sensitive to changes in the different levels of the independent variable.

VARIABLE DELETION

The law of parsimony (see “Ockham’s Razor”) states that the fewer variables used to explain a situation, the more probability that the explanation will be closer to

reality, which confers more replicability and more generalizability on the explanation. Reducing the number of variables lessens Type II error probability because degrees of freedom are also lessened. The goal is to estimate a given amount of variance with the smallest variable set possible; thus bigger is not better when one is using canonical correlation analysis (CCA), making variable deletion a necessity.

The following example uses CCA and variable deletion strategies (DSs) to illustrate how to arrive at the most parsimonious variable set for predicting how well students’ attitudes toward mathematics correlate with their geometric and spatial visualization abilities. Students were administered three tests: (a) a math attitude survey containing six subscales, usefulness (U), intrinsic value (I), worry (W), confidence (C), perceptions (P), and attitude (A) toward success, serving as the six predictor variables; (b) a spatial relationship test assessing spatial sense; and (c) a geometry content knowledge test ranging from Level 0 to Level 2. The two math tests and Level 0 of the geometry test served as the three criteria variables (space relationship test, or space rel; variable Level 0, or Lev 0; and geometry content knowledge score, or GCK sum). The command syntax for running the MANOVA analysis in SPSS was as follows:

```
MANOVA
spacerel lev0 gcksum with U I W C P A/
print=signif (multiv eigen dimenr)
discrim (stan estim cor) (alpha (.999))/design.
```

The results of the analysis are shown in Table 1.

To make the process of completing the table as clear as possible, the “func” (canonical function coefficient), the “ r_s ” (canonical structure coefficient), and the R_c^2 (squared canonical correlation coefficient) for each function were gotten directly from the SPSS printout. The r_s^2 (squared canonical structure coefficient) was figured by squaring the canonical structure coefficients for each variable and putting them in percentage format. The h^2 (communality coefficient) for each variable was obtained by summing all the r_s^2 s. The adequacy coefficient, an average of all the squared structure coefficients for the variables in one set with respect to one function, was calculated by

adding all the structure coefficients in the criterion set, dividing by the number of variables in the set, and placing the result in percentage format. The adequacy coefficient for the predictor set was determined by the same method. The redundancy coefficient (the measure of the proportion of the variance of the criterion variable set predictable from the predictor variable set) was calculated by multiplying the adequacy coefficient by the R_c^2 for each function.

After examining the full CCA, the law of parsimony needed to be invoked through variable deletion. In order to make this deletion process as understandable as possible, three different strategies will be examined.

During the deletion process, three coefficients will be looked at:

- r_s^2 : how much variance a variable linearly shares with a canonical variable
- h^2 : sum of all r_s^2 s; how much of the variance in a given observed variable is reproduced by the complete canonical solution
- R_c^2 : how much each function is contributing to the overall canonical solution

DS 1 looks at the h^2 s only and involves the following steps:

1. Look at all the h^2 s.
2. Find the lowest h^2 and delete it.
3. Check the change to the R_c^2 for each function.
4. If there is little change to R_c^2 , find the next lowest h^2 .
5. Delete that variable, and repeat the process until the R_c^2 change is too big.

Limitations of DS 1 are that contributions are not evaluated until after the variable is dropped, which results in retention of a large h^2 that happened only on the last canonical function and had a small R_c^2 effect size, as shown in Tables 2 and 3.

DS 2 looks at the contribution of each function to the total canonical solution. It includes the following steps:

1. Look at the R_c^2 for each function.
2. Omit the function with the smallest R_c^2 . See Table 4.
3. Compute the subset of h^2 s.

- Now find the variable that has the lowest h^2 ; drop it from the original solution.
- Repeat the preceding steps until the remaining variables are reasonably close in their subset h^2 values. This will be a matter of researcher judgment.

Limitations of DS 2 are that it ignores functions with small R_c^2 values and the variations as to where h^2 values come from. P, A, and U are deleted in Table 5.

DS 2 considers weighted h^2 s, looking at the variables' contribution to the complete canonical solution. It includes the following steps:

- Multiply R_c^2 times r_s^2 and add the products together for each row.
- Drop the lowest weighted h^2 .
- Look at the change in the R_c^2 ; if there is little change, drop the next-lowest h^2 .
- Repeat, taking out as many variables as possible without compromising the R_c^2 .

This is considered the best of the DSs because the h^2 s are weighted (see Table 6).

The goal of all DSs is a more parsimonious solution. Therefore, choosing the smaller variable set when the same amount of variance can be reproduced is the objective, because "bigger is not better!" in CCA.

VARIANCE

In addition to the standard deviation, a very common measure of variability is the variance. If you know the standard deviation of a set of scores, you can easily compute the variance of that same set of scores; the variance is simply the square of the standard deviation, as shown in the following formula:

$$s^2 = \frac{\sum(X - \bar{X})^2}{n - 1},$$

where

s^2 is the variance,

\sum is the summation of deviations from the mean squared,

X is the data point,

\bar{X} is the mean of the set of data points,

n is the sample size.

Consider the data set of 10 observations as follows:

5, 7, 5, 3, 4, 6, 5, 7, 9, 9,

which has a mean of 6. From the above formula, the value of the variance is 4.00.

Excel's VAR Function

While variance is a relatively easy descriptive statistic to compute by hand, it is much easier to use a software package such as Excel and the VAR function.

To compute the variance of a set of numbers by means of Excel, follow these steps:

1. Enter the individual scores into one column in a worksheet. The data in this example were entered into cells A1 through A10.
2. Select the cell into which you want to enter the VAR function. In this example, we are going to compute the variance in cell A11.

Figure 1 Using the VAR Function to Compute the Variance

3. Now click on cell A11 and type the Average function as follows,

$$=VAR (A1:A10),$$

and press the Enter key.

4. As you can see in Figure 1, the variance was computed and the value returned to cell A11. Notice that in the formula bar in Figure 1, you can see the VAR function fully expressed and the value computed.

VERBAL IQ

Verbal IQ is a measure of aspects of intelligence that relate to words and language and is associated with the Wechsler Intelligence Scale. When David Wechsler developed his IQ test in 1939, he divided it into two components—tasks that required mainly verbal abilities and tasks that required mainly perceptual-manipulative skills. The verbal IQ can be considered primarily a measure of acquired knowledge, verbal reasoning, and general verbal skills. It includes measures of vocabulary knowledge, verbal concept formation, arithmetic skill, auditory memory, general fund of information, and understanding of social rules and norms. Recent editions of the Wechsler scales have broken down verbal IQ into a verbal comprehension component and a working memory component. The verbal comprehension scale most closely represents what has traditionally been thought of as verbal IQ.

Another way of thinking about verbal IQ is that it is that aspect of intelligence that depends on

experience and learning, sometimes referred to as crystallized intelligence. Because of its dependence on experience, verbal IQ is highly culturally loaded. If an individual has not had life experiences similar to the typical United States citizen, her or his score may be artificially lowered. Although the research is far from definitive, there is some indication that skills measured by verbal IQ stay the same or increase with age and experience while those measured by performance IQ tend to decline. Attempts to tie verbal IQ to the left hemisphere of the brain and performance IQ to the right hemisphere have generally not been successful.

Applying Ideas on Statistics and Measurement

The following abstract is adapted from Gibson, C. L., Piquero, A. R., & Tibbetts, S. G. (2001). The contribution of family adversity and verbal IQ to criminal behavior. *International Journal of Offender Therapy and Comparative Criminology*, 45(5), 574–592.

Several studies have reported on the risk factor prevention paradigm, an effort to identify risk factors and protective factors that increase and decrease the odds of offending. For example, some have suggested that multiplicative interactions of such factors should be explored in an attempt to understand how they are linked to offending behaviors such as offending prevalence and early onset of offending. In this research, Chris Gibson and his colleagues examine Moffitt's interactional hypothesis, which states that two specific risk factors, **verbal IQ** and family adversity, interact to increase the probability of particular types of criminal behavior. Logistic regression analyses using data from the Philadelphia portion

of the Collaborative Perinatal Project of 987 African American youth indicate that the combined effect of verbal IQ and family adversity did not significantly increase the odds of becoming an offender, whereas the combined effect of low verbal IQ scores at age 7 and family adversity significantly increased the odds of early onset of offending.

VINELAND ADAPTIVE BEHAVIOR SCALES

The Vineland Adaptive Behavior Scales (VABS), published by American Guidance Service (<http://ags.pearsonassessments.com>), assess the personal and social sufficiency of individuals from birth to 90 years of age. They are used for diagnostic evaluations, program planning, and research investigations. The second edition of the Vineland Adaptive Behavior Scales (VABS-II) is currently in press and will be available by early 2006. The VABS are commonly used in conjunction with assessments of intellectual functioning to differentiate between individuals' intellectual ability and their everyday functioning. Intellectual ability scores that are within the intellectually handicapped range may not accurately describe individuals' abilities to fend for themselves in daily life. Therefore, an assessment of adaptive functioning is necessary to measure everyday living skills and design appropriate supportive interventions.

There are four versions of the VABS-II, all administered to a person who is familiar with the behavior of the individual of interest. The Survey Interview is a semistructured interview (requiring up to 60 minutes for administration) that provides a general assessment of adaptive functioning. The Expanded Interview (which takes up to 90 minutes to administer) offers a more comprehensive assessment and a systematic basis for preparing individual educational, habilitative, or treatment programs. The Parent/Caregiver Rating Form covers the same content as the Survey

Interview but uses a rating scale format and works well when time or access is limited. The Teacher Rating Form is independently completed by a classroom teacher, provides an assessment of behavior in the classroom, takes up to 20 minutes to complete, and applies to people from the age of 3 years to 22 years. Scoring can be done manually or by computer program and provides a profile of strengths and weaknesses across the domains measured.

Behaviors measured are divided into five domains: communication, daily living skills, socialization, motor skills, and maladaptive behaviors. The motor skills domain applies only to children under the age of 5 years, and the maladaptive behaviors domain applies only to children over the age of 5 years. The first four domains each have subdomains, and each subdomain has categories. For example, the daily living skills domain has a personal subdomain, which includes the categories of eating and drinking, toileting, dressing, bathing, grooming, and health care. Items are short sentences describing behaviors (for example, "Opens mouth when spoon with food is presented" or "Makes own bed when asked"), and the interviewer seeks behaviors that are regularly performed, not those that could be performed.

In the VABS-II, updating of content reflects tasks and daily living skills that are more attuned to current societal expectations than are those of the 1984 edition. Current norms match the latest census data in the United States, and current items encompass a wider range of functioning and a wider age range than did those of the first edition.

There are considerable data to support the reliability, validity, and cross-cultural stability of the VABS. They are the most highly rated scales of adaptive functioning in the United States and have been endorsed as a measure of adaptive behavior by the World Health Organization. A particular strength of the instrument is that, due to the interview structure, valuable qualitative information may be gleaned from the open-ended questions that are used to elicit specific information.

VINELAND SOCIAL MATURITY SCALE

The Vineland Social Maturity Scale (American Guidance Service, Inc., <http://ags.pearsonassessments.com>) is an assessment scale of personal and social skills pertaining to individuals from birth to 18 years, 11 months (including low-functioning adults). This evaluation measures four domains of adaptability, including communication, daily living, socialization, and motor skills, through semistructured interviews administered to the primary caregiver. This scale is one of the most common measures of adaptive behavior and is widely used to assess individuals with mental retardation or individuals who have difficulty performing in testing situations. The Vineland is used to identify not only individuals with mental retardation but also those with developmental delays, autism spectrum disorders, and other impairments, such as attention deficit/hyperactivity disorder, and also helps in the development of educational and treatment plans.

The Vineland Social Maturity Scale was originally developed and published in 1935 by Edgar A. Doll, who was one of the first people to define mental retardation as being characterized by a limitation in adaptive skills. The scale was revised in 1984 by Sara Sparrow, Domenic Cicchetti, and David Balla and renamed the Vineland Adaptive

Behavior Scales (VABS). The most current revision is the Vineland Adaptive Behavior Scales II (VABS-II). This latest revision includes a fifth domain that encompasses maladaptive behavior, covers an age range from birth to age 90, and has updated content regarding social expectations of tasks and living skills, as well as new norms based on current U.S. census data. The VABS is available in three formats: the expanded forms, which contain 577 items and take 60 to 90 minutes to administer; the survey form, which includes 297 items and takes 20 to 60 minutes to complete; and the classroom edition of 244 items, which is a questionnaire completed by an individual's teacher and takes approximately 20 minutes.

Items address the ability to perform tasks such as dressing or preparing meals, following rules, and building and maintaining relationships. Each of the domains contains two or three subdomains, which classify the behavior into specific categories. Communication comprises receptive, expressive, and written categories. Daily living skills include personal, domestic, and community categories. Socialization consists of interpersonal relationships, play, and leisure-time categories, and coping skills and motor skills are measured as fine and gross. The new maladaptive behavior index is an optional scale of internalizing, externalizing, and other behaviors that are assessed by questions that address inappropriate or dangerous behaviors. The individual receives a score in each of the domains and an Adaptive Behavior Composite with a mean of 100 and a standard deviation of 15. A score of 70 would suggest a diagnosis of mild mental retardation, and a score of 20 to 25 would be required for a diagnosis of profound mental retardation.

WECHSLER ADULT INTELLIGENCE SCALE

The Wechsler Adult Intelligence Scale (WAIS) is a set of tests that takes 90 to 120 minutes to administer and that assesses the intellectual functioning of adolescents and adults ages 16 to 89. It is the most widely used measure of adult intelligence, and its sister measures, the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI), are the most widely used for school-age children (6–16) and preschool children (ages 2–7), respectively.

The WAIS uses deviation IQ scores such that about 50% of people fall between 90 and 110, with 100 being the mean. Truly exceptional scores are 70 and below (possible mental retardation) and 130 and above (gifted). The test is divided into verbal subtests, which are designed to measure aspects of intelligence that rely on language (word meanings, general fund of knowledge, abstract verbal reasoning, etc.), and performance subtests, which measure reasoning that does not rely on language (visual pattern recognition, novel

problem solving, attention to visual detail, etc.). The Full Scale IQ (FSIQ) score is based on 11 subtests (6 verbal and 5 performance) and is generally considered the best measure of overall intelligence, unless there are large differences in performance among the subtests. Also generated are Verbal IQ and Performance IQ scores. Large differences between these scores (and between the subtests that make them up) can suggest strengths and weaknesses and in some cases neurological impairment.

The third edition (called WAIS-III and published in 1997) saw the addition of several supplemental scales that could be administered to generate index scores that were identified via factor analysis. These include the Verbal Comprehension Index (similar to Verbal IQ), Perceptual Organization Index (similar to Performance IQ), Working Memory Index (a measure of how much information someone can hold in awareness while solving problems), and Processing Speed Index (a measure of how quickly someone can perform routine visual tasks). Despite these changes, WAIS-III maintains the same basic structure as previous versions, allowing users to apply research with all versions as an aid in interpretation. The WAIS offers a

reliable and valid measure of intellectual functioning, with a large and representative standardization sample, and is used widely in research and clinical settings.

WECHSLER INDIVIDUAL ACHIEVEMENT TEST

The Wechsler Individual Achievement Test (WIAT; published by Harcourt Assessment, www.harcourtassessment.com) is a comprehensive measure of basic scholastic skills. The second edition (WIAT-II) is a general broadening and updating of the original WIAT. The WIAT-II is composed of nine subtests divided into four areas: reading, mathematics, written language, and oral language. The subtest scores yield composite scores for each area, as well as a total composite score. Each subtest is organized around grade levels, from pre-kindergarten to 16 (i.e., college students and adults); not all the tests are administered to pre-kindergarten and kindergarten children. The WIAT can be administered to individuals from ages 4 to 85 and requires between 45 minutes and 2 hours to complete. The test is suitable for individual administration only.

The reading composite score is made up of the word reading, reading comprehension, and pseudo-word decoding subtests. This area includes reading aloud from lists of words, decoding pseudowords, and answering questions on given comprehension passages. The mathematics composite score is derived

from the numerical operations and math reasoning subtests. This area includes straightforward calculations as well as word problems. The written language composite score is composed of the spelling and written expression subtests. This area includes simple spelling as well as sentence, paragraph, and essay composition. The oral language composite score contains the listening comprehension and oral expression subtests. This area tests understanding of orally presented material and the ability to generate words in a category for describing a complex pictorial scene and to give verbal directions for simple tasks. The total composite score gives a general overall assessment of achievement level. The raw scores from each subtest and the composite are converted to standard scores with a mean of 100 and standard deviation of 15. Average is defined as 90 (25th percentile) to 110 (75th percentile), and by increments of 10, three additional categories on each side are defined. Grade equivalents are also available.

The WIAT-II is useful for determining areas of strength or weakness, as well as ability-achievement discrepancies that may indicate a learning disability. To assist with discrepancy analysis, it has been linked through the normative sample to the Wechsler Adult Intelligence Scale-III, the Wechsler Intelligence Scale for Children-IV, and the Wechsler Preschool and Primary Scale of Intelligence-III. In the second edition, the listening comprehension subtest of the WIAT contains only receptive vocabulary, expressive vocabulary, and sentence comprehension. It does not test the comprehension of longer, more complex passages, as was done by the first edition, so it may overestimate listening comprehension for children with attentional or memory problems. Finally, given the increasing demands of modern curricula, caution must be used when achievement expectations as expressed by these test scores are transferred to the classroom, particularly when scores fall at the low end of the average range.

WECHSLER PRESCHOOL AND PRIMARY SCALE OF INTELLIGENCE

The third edition of the Wechsler Preschool and Primary Scale of Intelligence (WPPSI-III; published by the Psychological Corporation, www.harcourtassessment.com) is an individually administered, norm-referenced clinical instrument for assessing the intelligence of children between the ages of 2 years 6 months (2:6) and 7 years 3 months (7:3). The scale provides subtest and composite scores that represent intellectual functioning in verbal and performance cognitive domains, as well as a composite score that represents a child's general intellectual ability.

The scale consists of 14 subtests, grouped into three general categories: core, supplemental, and optional. The age range has been divided into two age bands to accommodate the substantial changes in children's cognitive development between the ages 2:6 and 7:3. For children age 2:6 through 3 years 11 months (3:11), the core verbal subtests are Receptive Vocabulary and Information. For the Receptive Vocabulary subtest, children look at pictures and are instructed to "Show me the cup" and "Show me raining." The core performance subtests are Block Design and Object Assembly. For Object Assembly, a child is presented with pieces of a puzzle and instructed to fit the pieces together in 90 seconds. Picture Naming is a supplemental verbal subtest. Four composite scores are possible for this age band: Verbal IQ, Performance IQ, Full Scale IQ, and General Language Composite.

For children age 4 years through 7:3, the core verbal subtests are Information, Vocabulary, and Word Reasoning. For the Information subtest, a

child responds to a question such as "Show me your nose" and "How many days make a week?" The core performance subtests are Block Design, Matrix Reasoning, and Picture Concepts. For the Matrix Reasoning subtest, the child looks at an incomplete matrix of pictures and chooses the missing portion from 4 or 5 choices. Coding is the core Processing Speed subtest. The supplemental verbal subtests are Comprehension and Similarities, and supplemental performance subtests are Picture Completion and Object Assembly. Symbol Search is the supplemental processing-speed subtest. Receptive Vocabulary and Picture Naming are optional verbal subtests but cannot be substituted for core Verbal subtests. Five composites are possible for this age band: Verbal IQ, Performance IQ, Processing Speed Quotient, Full Scale IQ, and General Language Composite.

For children age 2:6 to 3:11, administration of the core subtests takes 30 to 35 minutes; if the supplemental subtest is administered as well, 5 to 7 minutes should be added to the testing time. For children age 4 years to 7:3, administration of the core subtests takes 40 to 50 minutes; if all subtests are administered, an additional 30 to 35 minutes will be required.

The WPPSI-III can be used to obtain a comprehensive assessment of general intellectual functioning. The scale can also be used as part of an assessment to identify intellectual giftedness, cognitive developmental delays, and mental retardation. In addition, the results can serve as a guide for placement decisions in clinical or school-related programs.

Applying Ideas on Statistics and Measurement

The following is adapted from Farver, J. A. M., Kim, Y. K., & Lee-Shin, Y. (2000). Within cultural differences: Examining individual differences in Korean American and European American preschoolers' social pretend play. *Journal of Cross-Cultural Psychology, 31*(5), 583–602.

The assessment of intelligence has been the focus of thousands of papers and countless discussions in the area of measuring and understanding individual differences. This study by Jo Ann Farver and her colleagues examined such differences in 30 Korean American and 30 European American preschoolers' play behavior to better understand how intracultural variations in children's skills and behavioral characteristics are associated with social pretend play. Children's social behaviors and play complexity were observed and recorded, teachers rated children's social behavior, parents completed a child rearing questionnaire, and children were given the **Wechsler Preschool and Primary Scale of Intelligence** and the Multidimensional Stimulus Fluency Measure. The findings showed similar patterns predictive of pretend play for both groups. Overall, children's interactive style, positive social interaction with peers, and creativity scores significantly predicted pretend play.

WEST HAVEN-YALE MULTIDIMENSIONAL PAIN INVENTORY

The West Haven-Yale Multidimensional Pain Inventory (WHYMPI) is a 52-item, multidimensional measure of chronic pain that assesses status in the following domains: perceived pain intensity and impact of pain on various facets of a patient's life; perception of responses from significant others; participation in common activities; and activity level. Each domain is divided into 12 subscales. The first domain includes five subscales: perceived interference of pain in various aspects of functioning, support and concern of significant others, pain severity, self-control, and negative mood. The second domain includes three subscales: perceived frequency of punishing responses, perceived frequency of solicitous responses, and

perceived frequency of distracting responses from significant others. The third domain includes four subscales: participation in household chores, outdoor work, activities away from home, and social activities (these scores are added for a general activity score). Each item is answered on a 7-point scale that ranges from 0 (*never*) to 6 (*very frequently*). The WHYMPI is self-administered in approximately 10 to 20 minutes. Alternative versions offer a 61-item and a 48-item Multidimensional Pain Inventory. A substantial body of research literature is available to guide the WHYMPI's applications.

Validation of the original WHYMPI was conducted on a predominantly male population of veterans experiencing a broad array of chronic pain syndromes, with lower back pain afflicting 36% of the sample. Reliability and validity estimates have been reported for men and women and across various ages and pain conditions. The WHYMPI displays internal consistency reliability ranging from 0.70 to 0.90, with test-retest stability (generally with a 2-week interval) ranging from 0.62 to 0.91. Additional normative information for particular types and locations of pain is available at www.pain.pitt.edu/mpi/MPI_Norms.pdf. Research suggests the combination of the WHYMPI, the Beck Depression Inventory, the McGill Pain Questionnaire, and a clinical interview may provide the most useful description of a patient's pain experience with respect to the four-factor model of pain: affective distress, support from significant others, pain description, and functional capacity. The activities subscale of the WHYMPI may be compromised in predicting functional capacity because some items may be culturally related or gender related. Examiners may find it helpful to inquire whether an activity was prominent prior to the onset of pain. The WHYMPI has been validated in German, Swedish, Dutch, and English, its original format. A significant-other version of the WHYMPI has been developed to assess significant others' perception of the number of solicitous, distracting, and negative responses given by a chronic pain patient.

The instrument is available from Robert D. Kerns, one of its authors, and from the ProQolid Quality of

WILCOXON, FRANK (1892–1965)

Frank Wilcoxon was born in Glengarriffe Castle near Cork in Ireland on September 2, 1892 (his wealthy American parents had rented the castle for the occasion). However, Wilcoxon became something of a rebel, running away to sea as a teenager and spending periods as an oil-well worker and as a tree surgeon. It was not until after World War I that Wilcoxon finally went to university. He studied chemistry at Rutgers University, where he was a contemporary of the singer Paul Robeson. He obtained his MSc in 1921 and his PhD in 1924 (in physical chemistry, at Cornell University).

In 1925, Ronald Fisher had published the first edition of his classic work *Statistical Methods for Research Workers*. This was compulsory reading for Wilcoxon during his postdoctoral fellowship at the Boyce Thompson Institute for Plant Research in Yonkers, where he investigated the use of copper compounds as fungicides. Wilcoxon gained further

employment at the Institute before moving, in 1943, to become group leader of the insecticide and fungicide laboratory at American Cyanamid, where he contributed to the development of malathion.

Wilcoxon's first statistical papers appeared in 1945, and it was in the second of these that he introduced the rank-sum and signed-rank tests that nowadays bear his name. These tests, and their extensions, were collected in the 1947 pamphlet titled *Some Rapid Approximate Statistical Procedures*.

In 1960, following retirement from industry, Wilcoxon accepted a part-time appointment in the new department of statistics at Florida State University, in Tallahassee. Wilcoxon had been an enthusiastic cyclist in his younger days, and at Tallahassee his preferred method of transport was a motorcycle. He died there on November 18, 1965. His innovatory statistical work is now marked by the journal *Technometrics*, which gives an annual award in his name for the best practical applications paper.

WILCOXON MANN-WHITNEY TEST

See MANN-WHITNEY U TEST (WILCOXON RANK-SUM TEST)

WILCOXON SIGNED RANKS TEST

The Wilcoxon signed ranks test may be used as a one-sample test of location or as a test of difference in location between two dependent samples. The underlying assumptions are that the distribution is continuous and symmetric.

The Wilcoxon signed ranks procedure is primarily used as a test for location, such as the median. In the one-sample case, the one-sided test of the null hypothesis is $H_0: \varphi = \text{median}$, which is tested against the alternative $H_a: \varphi > \text{median}$ or $H_a: \varphi < \text{median}$. The alternative hypothesis for the two-sided test is $H_a: \varphi \neq \text{median}$. In the two-sample case, the Wilcoxon signed ranks test is applied to matched or paired data, such as an examination of pretest versus posttest scores. Although the Wilcoxon test may also be used as a test of symmetry, there are often more powerful procedures.

The Wilcoxon test is nonparametric. This means it preserves the Type I error rate (i.e., the false positive rate) to nominal alpha regardless of the population shape. This is a fundamental advantage over its parametric counterparts, the one-mean Student t test and the two-dependent-samples Student t test, which rely on the normality distribution assumption.

Theoretical power comparisons indicate that the asymptotic relative efficiency of the Wilcoxon signed ranks test with the Student t test is .955 for the normal distribution, but it can be as high as ∞ for nonnormal distributions. Monte Carlo simulations indicate that the spectacular power gains achieved by the independent-samples version of this test (i.e., the Wilcoxon rank-sum test; see the entry on Mann-Whitney U Test) over the Student t test are not realized although the Wilcoxon signed ranks test is often at least slightly more powerful than the t test for departures from population normality. The explanation is that in the paired-samples case, tests are conducted on the distribution of the difference scores. Subtracting a pretest score from the posttest score, for example, is a mildly normalizing procedure, producing a distribution that is less deviant than the parent population and more similar to the normal distribution.

To conduct the two-sample matched-pairs Wilcoxon signed ranks test, compute the difference (d) between each pair of scores, ignoring the signs. (This is achieved by taking the absolute value

$|d|$.) Next, denote the ranks of the positive differences with a + sign and the negative differences with a – sign. Finally, sum the ranks associated with the lesser-occurring sign.

Example

A claim is made by a test preparation corporation that its study program leads to a statistically significant increase in performance on a standardized college entrance exam. The pretest is the standardized score obtained by an examinee prior to the curriculum intervention, and the posttest score is the standardized score after participating in the study program. Suppose the test scores were those depicted in Table 1.

To test this claim, subtract the pretest score from the posttest score (d) and take the absolute value ($|d|$). Note that there are eight + ranks and two – ranks. For convenience, the test statistic T is based on the smaller number of signed ranks. Therefore, the sum of the ranks with negative signs is computed:

$$\begin{aligned} T &= 3 + 1 \\ &= 4. \end{aligned}$$

The critical values for a one-sided test with $n = 10$ for $\alpha = .05$ and $\alpha = .01$ are 10 and 5, respectively. The null hypothesis is rejected if T is less than or equal to the critical value. Thus, the null hypothesis is rejected

that the median score of the standardized test is 500. The claim can be tested by application of the Wilcoxon signed ranks test to the pretest scores, creating another column of 10 scores, each with the value of the median = 500. The sum of the lesser signed ranks is 26, and the associated p value is .878. Therefore, the claim is dismissed because there is no evidence that the group’s initial scores are statistically significantly different from the population median.

WOODCOCK JOHNSON PSYCHOEDUCATIONAL BATTERY

Originally published in 1977, the Woodcock Johnson (WJ) was the first comprehensive psychoeducational battery with conormed measures of cognitive abilities, academic achievement, and interests. It was revised in 1989 to become the Woodcock Johnson-Revised (WJ-R), dropping the interest measure and restructuring the cognitive measure to reflect the Cattell-Horn

Gf-Gc model of intelligence. The current version, the Woodcock Johnson-III (WJ-III), is comprised of two separate but conormed batteries: the Tests of Cognitive Abilities and the Tests of Achievement.

The WJ-III Tests of Cognitive Abilities was developed using an integration of the original Cattell-Horn Gf-Gc model of intelligence and Carroll's Three Stratum model, the Cattell-Horn-Carroll (CHC) theory. This second-iteration test development centering on essentially the same model has resulted in an instrument that is one of the most theoretically sound measures of intelligence on the market today. Consisting of 20 subtests organized into standard and extended batteries, the WJ-III Tests of Cognitive Abilities generates scores on seven broad CHC clusters as well as measures of general intellectual ability (brief, standard, and extended). Each subtest was chosen to represent a different narrow ability as defined by CHC theory (e.g., induction, associative memory) while the seven broad clusters represent broad CHC factors (e.g., fluid reasoning, long-term retrieval).

WOODCOCK READING MASTERY TESTS REVISED

The Woodcock Reading Mastery Tests Revised (WRMTR; published by American Guidance Service, <http://www.agsnet.com/>) are a set of scales that take

40–50 minutes to administer en toto and that assess reading achievement. The WRMTR contains tests of visual-auditory learning and letter identification, which comprise the Reading Readiness Cluster. The word identification and word attack tests combine to form the Basic Skills Cluster, and the word comprehension and passage comprehension tests make up the Reading Comprehension Cluster. The word comprehension test comprises three subtests: synonyms, antonyms, and analogies.

The WRMTR has two forms, only one of which (i.e., Form G) contains the Reading Readiness Cluster tests. The tests are intended for use with individuals from kindergarten through college-age students and with older adults (75 years and older). With the exception of the visual-auditory learning and word attack tests, starting point, basal, and ceiling rules are consistent throughout the battery. The two exceptions cause confusion for some examiners. Hand scoring can be time consuming and prone to error, but the available scoring software reduces scoring time by 70 to 80 percent. The WRMTR provides a full range of score types: age and grade equivalents, standard scores, percentile ranks, relative performance indices, and instructional ranges (i.e., easy, instructional level, and difficult). Standard errors of measurement allow the hand scorer to construct 68% confidence intervals to estimate the true score. Standard errors of differences, which would allow the user to estimate an examinee's strengths and weaknesses, are not available in the manual or the scoring software. Instead, the test author recommends profile analysis, which has inherent weaknesses and provides information that is prone to error.

New norms, which include only grades kindergarten through high school, were collected in 1995 to 1996 and were based on 1994 census data. Approximately 3,400 individuals were tested, though the exact number varies from one test or cluster to another. The sample was controlled for age, gender, race, region, socioeconomic status, community size, and special populations. Nevertheless, Native Americans, Asians, and Pacific Islanders are overrepresented, and the northeastern states are underrepresented in the WRMTR sample.

The author reports only split-half reliability coefficients. The median internal consistency reliability coefficient for the tests is .91 (range = .68 to .98). For the clusters, the median reliability coefficient is .95 (range = .87 to .98). For the full-scale score, the median reliability coefficient is .97 (range = .86 to .99). The lack of alternate-form and test-retest reliability estimates is a serious omission for this highly popular test battery.

Very little information on the validity of the WRMTR is presented in the manual; much of it is based on the original (1973) version of the battery. Presumably, independent research will clarify the validity of this set of instruments, but it remains incumbent on the author

of the assessment tool to provide evidence of the technical adequacy of his product.

Z SCORES

A score by itself does not tell much. If we are told that we have obtained a score of 85 on a beauty test, this could be very good news if most people have a score of 50 but less so if most people have a score of 100. In other words, a score is meaningful only relative to the means of the sample or the population. Another problem occurs when we want to compare scores measured with different units or on different populations. How to compare, for example a score of 85 on the beauty test with a score of 100 on an IQ test?

Scores from different distributions, such as the ones in our example, can be standardized in order to provide a way of comparing them that includes consideration of their respective distributions. This is done by transforming the scores into z scores, which are expressed as standardized deviations from their means. These z scores have a mean of 0 and a standard deviation equal to 1. Z scores computed from different samples with different units can be directly compared because these numbers do not express the original unit of measurement.

Definition of z Scores

In order to compute a z score, we start with an original score (called Y) obtained from a sample (or a population) with a mean of M_Y and a standard deviation of S_Y . We eliminate the mean by subtracting it from the score, which transforms the original score into a deviation from its mean. We eliminate the original unit of measurement by dividing the score deviation by the standard deviation. Specifically, the formula for calculating a z score is

$$Z = \frac{Y - M_Y}{S_Y}.$$

We say that subtracting the mean *centers* the distribution and that dividing by the standard deviation *normalizes* the distribution. The interesting properties of the z scores are that they have a zero mean (effect of centering) and a variance and standard deviation of 1 (effect of normalizing). It is because all distributions expressed in z scores have the same mean (0) and the same variance (1) that we can use z scores to compare observations coming from different distributions.

An Example

Applying the formula for a z score to a score of $Y = 85$ coming from a sample of mean $M_Y = 75$ and standard deviation $S_Y = 17$ gives

$$Z = \frac{Y - M_Y}{S_Y} = \frac{85 - 75}{17} = \frac{10}{17} = .59.$$

Effect of z Scores

When a distribution of numbers is transformed into z scores, the shape of the distribution is unchanged, but this shape is translated in order to be centered on the value 0, and it is scaled such that its area is now equal to 1.

As a practical guide, when a distribution is normal, more than 99% of the z scores lie between the values -3 and $+3$. Also, because of the central limit theorem, a z score with a magnitude larger than 6 is extremely unlikely to occur regardless of the shape of the original distribution.

Demonstrating That z Scores Have a Mean of 0 and a Variance of 1

In order to show that the mean of the z scores is equal to 0, it suffices to show that the sum of the z scores is equal to 0. This is shown by developing the formula for the sum of the z scores:

$$\begin{aligned} \sum Z &= \sum \frac{Y - M_Y}{S_Y} \\ &= \frac{1}{S_Y} \sum (Y - M_Y) \\ &= \frac{1}{S_Y} (\sum Y - NM_Y) \\ &= \frac{1}{S_Y} (NM_Y - NM_Y) \\ &= 0. \end{aligned}$$

In order to show that the variance of the z scores is equal to 1, it suffices to show that the sum of the squared z scores is equal to $(N - 1)$ (where N is the number of scores). This is shown by developing the formula for the sum of the squared z scores:

$$\begin{aligned} \sum Z^2 &= \sum \left(\frac{Y - M_Y}{S_Y} \right)^2 \\ &= \frac{1}{S_Y^2} \sum (Y - M_Y)^2. \end{aligned}$$

But $(N - 1)S_Y^2 = \sum (Y - M_Y)^2$, hence:

$$\begin{aligned} \sum Z^2 &= \frac{1}{S_Y^2} \times (N - 1)S_Y^2 \\ &= (N - 1). \end{aligned}$$

Ten Commandments of Data Collection

The following text is taken from Neil J. Salkind's best-selling introduction to statistics text, *Statistics for People Who (Think They) Hate Statistics*, 2nd edition (2004).

Now that you know how to analyze data, you would be well served to hear something about collecting them. The data collection process can be a long and rigorous one, even if it involves only a simple, one-page questionnaire given to a group of students, parents, patients, or voters. The data collection process may very well be the most time-consuming part of your project. But as many researchers do, this period of time is also used to think about the upcoming analysis and what it will entail.

Here they are: the ten commandments for making sure your data get collected in a way that they are usable. Unlike the original Ten Commandments, these should not be carved in stone (because they can certainly change), but if you follow them, you can avoid lots of aggravation.

Commandment 1. As you begin thinking about a research question, also begin thinking about the type of data you will have to collect to answer that question. Interview? Questionnaire? Paper and pencil? Find out how other people have done it in the past by reading the relevant journals in your area of interest and consider doing what they did.

Commandment 2. As you think about the type of data you will be collecting, think about where you will be getting the data. If you are using the library for historical data or accessing files of data that have

already been collected, such as census data (available through the U.S. Census Bureau and some online), you will have few logistical problems. But what if you want to assess the interaction between newborns and their parents? The attitude of teachers toward unionizing? The age at which people over 50 think they are old? All of these questions involve needing people to provide the answers, and finding people can be tough. Start now.

Commandment 3. Make sure that the data collection forms you use are clear and easy to use. Practice on a set of pilot data so you can make sure it is easy to go from the original scoring sheets to the data collection form.

Commandment 4. Always make a duplicate copy of the data file, and keep it in a separate location. Keep in mind that there are two types of people: those who have lost their data and those who will. Keep a copy of data collection sheets in a separate location. If you are recording your data as a computer file, such as a spreadsheet, be sure to make a backup!

Commandment 5. Do not rely on other people to collect or transfer your data unless you have personally trained them and are confident that they understand the data collection process as well as you do. It is great to have people help you, and it helps keep the morale up during those long data collection sessions.

But unless your helpers are competent beyond question, you could easily sabotage all your hard work and planning.

Commandment 6. Plan a detailed schedule of when and where you will be collecting your data. If you need to visit three schools and each of 50 children needs to be tested for a total of 10 minutes at each school, that is 25 hours of testing. That does not mean you can allot 25 hours from your schedule for this activity. What about travel from one school to another? What about the child who is in the bathroom when it is his turn, and you have to wait 10 minutes until he comes back to the classroom? What about the day you show up and Cowboy Bob is the featured guest . . . and on and on. Be prepared for anything, and allocate 25% to 50% more time in your schedule for unforeseen happenings.

Commandment 7. As soon as possible, cultivate possible sources for your subject pool. Because you already have some knowledge in your own discipline, you probably also know of people who work with the type of population you want or who might be able to help you gain access to these samples. If you are in a

university community, it is likely that there are hundreds of other people competing for the same subject sample that you need. Instead of competing, why not try a more out-of-the-way (maybe 30 minutes away) school district or social group or civic organization or hospital, where you might be able to obtain a sample with less competition?

Commandment 8. Try to follow up on subjects who missed their testing session or interview. Call them back and try to reschedule. Once you get in the habit of skipping possible participants, it becomes too easy to cut the sample down to too small a size. And you can never tell—the people who drop out might be dropping out for reasons related to what you are studying. This can mean that your final sample of people is qualitatively different from the sample you started with.

Commandment 9. Never discard the original data, such as the test booklets, interview notes, and so forth. Other researchers might want to use the same database, or you may have to return to the original materials for further information.

And Number 10? Follow the previous 9. No kidding!

Table 2 *t* Values Needed for Rejection of the Null Hypothesis

How to use this table:

1. Compute the *t* value test statistic.
2. Compare the obtained *t* value to the critical value listed in this table. Be sure you have calculated the number of degrees of freedom correctly and you have selected an appropriate level of significance.
3. If the obtained value is greater than the critical or tabled value, the null hypothesis (that the means are equal) is not the most attractive explanation for any observed differences.
4. If the obtained value is less than the critical or table value, the null hypothesis is the most attractive explanation for any observed differences.

Table 3 Critical Values for Analysis of Variance or *F* Test

How to use this table:

1. Compute the *F* value.
2. Determine the number of degrees of freedom for the numerator ($k - 1$) and the number of degrees of freedom for the denominator ($n - k$).
3. Locate the critical value by reading across to locate the degrees of freedom in the numerator and down to locate the degrees of freedom in the denominator. The critical value is at the intersection of this column and row.
4. If the obtained value is greater than the critical or tabled value, the null hypothesis (that the means are equal to one another) is not the most attractive explanation for any observed differences.
5. If the obtained value is less than the critical or tabled value, the null hypothesis is the most attractive explanation for any observed differences.

Table 4 Values of the Correlation Coefficient Needed for Rejection of the Null Hypothesis

How to use this table:

1. Compute the value of the correlation coefficient.
2. Compare the value of the correlation coefficient with the critical value listed in this table.
3. If the obtained value is greater than the critical or tabled value, the null hypothesis (that the correlation coefficient is equal to 0) is not the most attractive explanation for any observed differences.
4. If the obtained value is less than the critical or tabled value, the null hypothesis is the most attractive explanation for any observed differences.

Table 5 Critical Values for the Chi-Square Test

How to use this table:

1. Compute the χ^2 value.
2. Determine the number of degrees of freedom for the rows ($R - 1$) and the number of degrees of freedom for the columns ($C - 1$). If it's a one-dimensional table, then you have only columns.
3. Locate the critical value by locating the degrees of freedom in the titled (df) column, and under the appropriate column for level of significance, read across.
4. If the obtained value is greater than the critical or tabled value, the null hypothesis (that the frequencies are equal to one another) is not the most attractive explanation for any observed differences.
5. If the obtained value is less than the critical or tabled value, the null hypothesis is the most attractive explanation for any observed differences.

Appendix B

Internet Sites About Statistics

What follows is a listing of Internet sites and a brief description of each that focus on the general areas of statistics and measurement. Also included are sites where data (on many different topics) have been collected and can be accessed.

As you use these, keep in mind the following:

- Internet addresses (known as URLs) often change, as does the content. If one of these Internet addresses does not work, search for the name of the site using any search engine.
- Any Internet site is only as good as its content. For example, N or $N - 1$ might be given as the correct denominator for a formula, and although that might be true, you should double check any information with another Internet resource or a book on the subject.
- If you find something that is inaccurate on a site, contact the Webmaster or the author of the site and let him or her know that a correction needs to be made.

Name: statistics.com

Where to find it: <http://www.statistics.com/>

If there is a queen of statistics sites, then statistics.com is it. It offers not only links to hundreds of other sites and an online introductory statistics course, but also online professional development courses. You can try statistics software, look at the free stuff available on the Web, get help if you're a teacher with quizzes and other teaching materials, and

even participate in online discussions. This is *the* place to start your travels.

Name: U.S. Department of Labor, Bureau of Labor Statistics

Where to find it: <http://www.bls.gov/>

Local, state, and federal government agencies are data warehouses, full of information about everything from employment to demographics to consumer spending. This particular site (which is relatively old at 10 years on the Web) is for the Bureau of Labor Statistics, the principal fact-finding agency for the federal government in the areas of labor economics and statistics. It is full of numbers and ideas. Some of the data can be downloaded as HTML or Excel files, and you can also get historical data going back 10 years in some instances.

Name: Probability and Quintile Applets

Where to find it: <http://www.stat.stanford.edu/~naras/jsm/FindProbability.html>

Applets are small programs that can visually represent an idea or a process very effectively. These two, by Balasubramanian Narasimhan from Stanford University, do such things as compute the probability of a score under the normal curve (see Figure 1 on the following page) and calculate the quintiles (fifths) of a distribution. They are easy to use, fun to play with, and very instructional. You can find another similar applet by Gary McClelland at <http://psych.colorado.edu/~mcclella/java/normal/handleNormal.html>

Probability Applet

The first applet below calculates areas under the standard normal density curves. You are presented with two fields and three buttons on top of a normal density curve. The buttons allow you to calculate areas to the left or to the right or between.

- For areas to the left, use the left data entry field.
- For areas to the right, use the right data entry field.
- For areas between two points, use both fields.

The interface is quite forgiving. If you mess up, it takes you right to the field where you have to type.

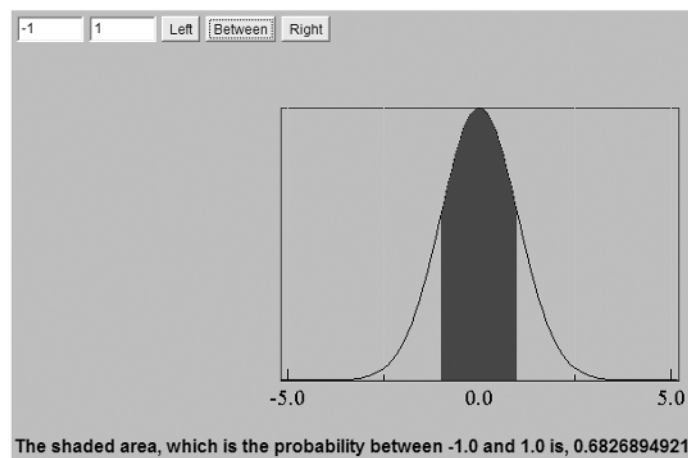

Figure 1 Probability Applet

Name: FedStats

Where to find it: <http://www.fedstats.gov/>

Here's another huge storehouse of data that is the entry point for many different federal agencies. You can easily access data from individual states or from agencies by subjects (such as health), access published collections of statistics, and even get the kids involved in child-oriented agency Web sites both entertaining and educational.

Name: Random Birthday Applet

Where to find it: <http://www-stat.stanford.edu/~susan/surprise/Birthday.html>

This is an incredible illustration of how probability works. You enter the number of birthdays you want generated at random, and the laws of probability should operate so that in a group of 30 such random selections, the odds are very high that there will be at least two matches for the same birthday. Try it—it works.

Name: The Statistics Homepage

Where to find it: <http://www.statsoftinc.com/textbook/stathome.html>

Here you'll find a self-contained course in basic statistics, brought to you by the people who developed and sell StatSoft, one of many statistical programs. On this site, you will find tutorials that take you from the elementary concepts of statistics through the more advanced topics, such as factor and discriminant analysis.

Name: National Center for Health Statistics

Where to find it: <http://www.cdc.gov/nchs/>

The National Center for Health Statistics compiles information that helps guide actions and policies to improve health in the United States. Among other things, these data are used to help identify health problems, evaluate the effectiveness of programs, and provide data for policymakers.

Name: The World Wide Web Virtual Library: Statistics

Where to find it: <http://www.stat.ufl.edu/vlib/statistics.html>

The good people at the University of Florida's Department of Statistics bring you this page, which contains links to statistics departments all over the world. It provides a great deal of information about graduate study in these areas as well as other resources.

Name: Social Statistics Briefing Room

Where to find it: <http://www.whitehouse.gov/fsbr/ssbr.html>

This service, which calls the White House home, provides access to current federal social statistics and links to information from a wide range of federal agencies. This is a very good, and broad, starting point to access data made available through different agencies.

Name: Statistics on the Web

Where to find it: <http://my.execpc.com/~helberg/statistics.html>

More groupings of URLs and Internet addresses from Clay Helberg. A bit like statistics.com, but full of listings of professional organizations, publications, and software packages (many of which you can download for a trial).

Name: Food and Agriculture Organization for the United Nations

Where to find it: <http://faostat.fao.org/>

If you want to go international, this is a site containing online information (in multilingual formats) and databases for more than 3 million time series records covering international statistics in areas such as production, population, and exports.

Name: Web Pages That Perform Statistical Calculations!

Where to find it: <http://members.aol.com/johnp71/javastat.html>

At the time of this writing, this site contains more than 600 links to books, tutorials, free software, and interactive tools, such as a guide to what statistical test to use to answer what questions, all assembled by John Pezzullo.

Name: Free Statistical Software

Where to find it: <http://freestatistics.altervista.org/stat.php>

An extensive collection of statistical analysis software packages that range from simple programs for students to advanced programs that do everything from statistical visualization to time series analysis. Many of these programs are freeware, and many are open source, available to be modified by users.

Name: Java Applets

Where to find it: <http://www.stat.duke.edu/sites/java.html>

The Institute of Statistics and Decision Sciences at Duke University and NWP Associates put together a collection of Java applets (Java is the language in which these small programs are written, and applets

are small applications) that allows the user to demonstrate interactively various statistical techniques and tools, such as constructing histograms and illustrating how the central limit theorem works.

Name: HyperStat Online Textbook

Where to find it: <http://davidmlane.com/hyperstat/>

This site contains an entire online course in basic statistics from David Lane that covers every topic from simple descriptive statistics to effect size. The “Hyper” nature of the site allows the user to easily move from one topic to another through the extensive use of live links. And, as a bonus, each new screen has additional links to sites that focus on learning statistics.

Name: Rice Virtual Lab in Statistics

Where to find it: <http://www.ruf.rice.edu/~lane/rvls.html>

This is where the HyperStat Online Textbook has its home and is the main page (also done by David Lane) of Rice University’s statistics program. In addition to the HyperStat link, it has links to simulations, case studies, and a terrific set of applets that are very useful for teaching and demonstration purposes.

Name: Reliability, Validity, and Fairness of Classroom Assessments

Where to find it: <http://www.ncrel.org/sdrs/areas/issues/methods/assment/as5relia.htm>

A discussion of the reliability, validity, and fairness of classroom testing from the North Central Educational Laboratory.

Name: The Multitrait Multimethod Matrix

Where to find it: <http://www.socialresearchmethods.net/kb/mtmmmat.htm>

A very good site for a discussion of validity issues in measurement in general and specific discussion about the multitrait multimethod brought to you by William M. K. Trochim.

Name: Content Validity, Face Validity, and Quantitative Face Validity

Where to find it: <http://www.burns.com/wcbcontval.htm>

Although a bit dated (around 1996), this Web site offers a detailed discussion by William C. Burns on content, face, quantitative, and other types of validity.

Name: The National Education Association

Where to find it: http://www.nea.org/parents/testing_guide.html.also

This national organization of teaching professionals provides assistance to parents, teachers, and others in understanding test scores.

Name: The Learning Center

Where to find it: <http://webster.comnet.edu/faculty/~simonds/tests.htm>

It's a reality that other than through studying, test scores can be improved if test takers understand the different demands of different types of tests. This item contains information on using different strategies to increase test scores.

Name: The Advanced Placement

Where to find it: <http://apbio.biosci.uga.edu/exam/Essays/>

This is an old site, but people at the University of Georgia have posted items from a variety of different topic areas covered in the Advanced Placement (AP) exams that high school students can take in a step to qualify for college credit.

Name: Essay Question

Where to find it: http://www.salon.com/tech/feature/1999/05/25/computer_grading/

Salon.com offers a discussion of automated grading in general and specially, as well as essay question grading using computers.

Name: Matching Questions on Minerals and Rocks

Where to find it: <http://www.usd.edu/esci/exams/matching.html>

A good example of how easy it is to adapt matching questions to an interactive electronic format.

An increasingly large part of doing research, as well as other intensive, more qualitative projects, involves specially designed software. At <http://www.scolari.com/>, you can find a listing of several different types and explore which might be right for you if you intend to pursue this method (interviewing) and this methodology (qualitative).

FairTest—The National Center for Fair and Open Testing at <http://www.fairtest.org/index.htm> has as its mission to “end the misuses and flaws of standardized testing and to ensure that evaluation of students, teachers and schools is fair, open, valid and educationally beneficial.” A really interesting site to visit.

Preparing Students to Take Standardized Achievement Tests (at <http://pareonline.net/getvn.asp?v=1&n=11>) was written by William A. Mehrens (and first appeared in *Practical Assessment, Research & Evaluation*) for school administrators and teachers and discusses what test scores mean and how they can be most useful in understanding children's performance.

The Clifton StrengthsFinder™ at <http://education.gallup.com/content/default.asp?ci=886> is a Web-based assessment tool published by the Gallup Organization (yep, the poll people) to help people better understand their talents and strengths by measuring the presence of 34 themes of talent. You might want to take it and explore these themes.

Find out just about everything you ever wanted to know (and more) about human intelligence at Human Intelligence: Historical Influences, Current Controversies and Teaching Resources at <http://www.indiana.edu/~intell/>

The following text is taken from Neil J. Salkind's best-selling introduction to statistics text, *Statistics for People Who (Think They) Hate Statistics*, 2nd edition (2004).

Pages and pages of every type of statistical resource you can want has been creatively assembled by Professor David W. Stockburger at <http://www.psychstat.smsu.edu/scripts/dws148f/statisticsresourcesmain.asp>. This site receives the gold medal of statistics sites. Don't miss it.

For example, take a look at Berrie's page (at <http://www.huizen.dds.n~berrie/>) and see some QuickTime (short movies) of the effects of changing certain data points on the value of the mean and standard deviation. Or, look at the different home pages that have been created by instructors for courses offered around the country. Or, look at all of the different software packages that can do statistical analysis.

Want to draw a histogram? How about a table of random numbers? A sample-size calculator? The Statistical Calculators page at <http://www.stat.ucla.edu/calculators/> has just about every type (more than 15) of calculator and table you could need. Enough to carry you through any statistics course that you might take and even more.

For example, you can click on the Random Permutations link and complete the two boxes (as you see in Figure 2 for 2 random permutations of 100 integers), and you get the number of permutations you want. This is very handy when you need a table of

random numbers for a specific number of participants so you can assign them to groups.

The History of Statistics page located at <http://www.Anselm.edu/homepage/jpitocch/biostatshist.html> contains portraits and bibliographies of famous statisticians and a time line of important contributions to the field of statistics. So, do names like Bernoulli, Galton, Fisher, and Spearman pique your curiosity? How about the development of the first test between two averages during the early 20th century? It might seem a bit boring until you have a chance to read about the people who make up this field and their ideas—in sum, pretty cool ideas and pretty cool people.

SurfStat Australia (at <http://www.anu.edu.au/nceph/surfstat/surfstat-home/surfstat.html>) is the online component of a basic stat course taught at the University of Newcastle, Australia, but has grown far beyond just the notes originally written by Annette Dobson in 1987, and updated over several years' use by Anne Young, Bob Gibberd, and others. Among other things, SurfStat contains a complete interactive statistics text. Besides the text, there are exercises, a list of other statistics sites on the Internet, and a collection of Java applets (cool little programs you can use to work with different statistical procedures).

This online tutorial with 18 lessons, at <http://www.davidmlane.com/hyperstat/index.html>, offers nicely designed and user-friendly coverage of the important basic topics. What we really liked about the site was the glossary, which uses hypertext to connect different concepts to one another. For example, in Figure 3, you can see the definition of descriptive statistics also linked to

Figure 2 Generating a Set of Random Numbers

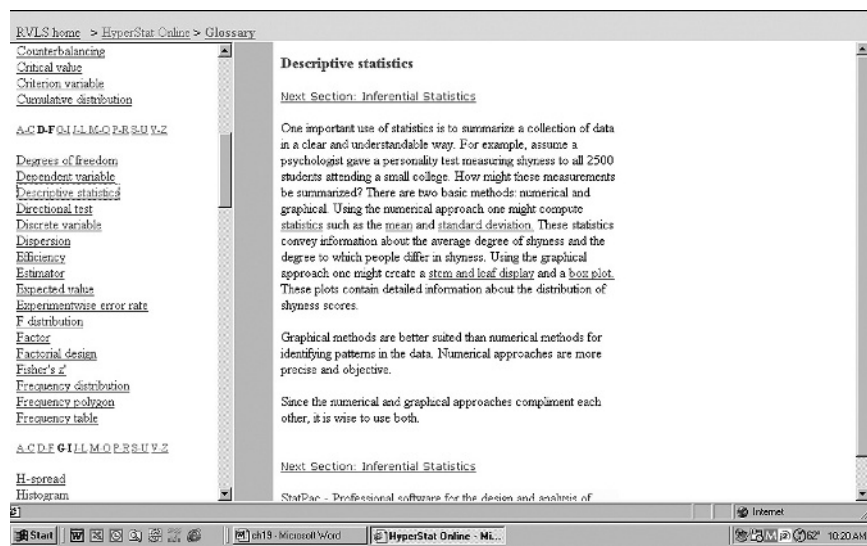

Figure 3 Sample HyperStat Screen

other glossary terms, such as mean, standard deviation, and box plot. Click on any of those and zap! you're there.

There are data all over the place, ripe for the picking. Here are just a few. What to do with these? Download them to be used as examples in your work or as examples of analysis that you might want to do, and you can use these as a model.

- Statistical Reference Datasets at <http://www.itl.nist.gov/div898/strd/>
- United States Census Bureau (a huge collection and a gold mine of data) at http://factfinder.census.gov/servlet/DatasetMainPage-Servlet?_lang=en
- The Data and Story Library (<http://lib.stat.cmu.edu/DASL/>) with great annotations about the data (look for the stories link)
- Tons of economic data sets at Growth Data Sets (at <http://www.bris.ac.uk/Depts/Economics/Growth/datasets.htm>)

Then there are all the data sets that are available through the federal government (besides the census). Your tax money supports it, so why not use it? For example, there's FEDSTATS (at <http://www.fedstats.gov/>), where more than 70 agencies in the U.S. federal government produce statistics of interest to the public. The Federal Interagency Council on Statistical Policy

maintains this site to provide easy access to the full range of statistics and information produced by these agencies for public use. Here you can find country profiles contributed by the (boo!) CIA; public school student, staff, and faculty data (from the National Center for Education Statistics); and the Atlas of the United States Mortality (from the National Center for Health Statistics). What a ton of data!

The University of Michigan's Statistical Resources on the Web (at <http://www.lib.umich.edu/govdocs/stats.html>) has hundreds and hundreds of resource links,

including those to banking, book publishing, the elderly, and, for those of you with allergies, pollen count. Browse, search for what exactly it is that you need—no matter, you are guaranteed to find something interesting.

At <http://mathforum.org/workshops/sum96/data.collections/datalibrary/data.set6.html>, you can find a data set including the 1994 National League Baseball Salaries or the data on TV, Physicians, and Life Expectancy. Nothing earth-shaking, just fun to download and play with.

The World Wide Web Virtual Library: Statistics is the name of the page, but the one-word title is misleading because the site (from the good people at the University of Florida at <http://www.stat.ufl.edu/vlib/statistics.html>) includes information on just about every facet of the topic, including data sources, job announcements, departments, divisions and schools of statistics (a huge description of programs all over the world), statistical research groups, institutes and associations, statistical services, statistical archives and resources, statistical software vendors and software, statistical journals, mailing list archives, and related fields. Tons of great information is available here. Make it a stop along the way.

Statistics on the Web at <http://www.maths.uq.edu.au/~gks/webguide/datasets.html> is another location that's

just full of information and references that you can easily access. Here, you'll find information on professional organizations, institutes and consulting groups, educational resources, Web courses, online textbooks, publications and publishers, statistics book lists, software-oriented pages, mailing lists and discussion groups, and even information on statisticians and other statistical people.

If you do ever have to teach statistics, or even tutor fellow students, this is one place you'll want to visit: <http://noppa5.pc.helsinki.fi/links.html>. It contains hundreds of resources on every topic that was covered in *Statistics for People Who (Think They) Hate Statistics* and more. You name it and it's here: regression, demos, history, Sila (a demonstration of inference), an interactive online tutorial, statistical graphics, handouts to courses, teaching materials, journal articles, and even quizzes! Whew, what a deal. There tends to be a lot of material that may not be suited to what you are doing in this class, but this wide net has certainly captured some goodies.

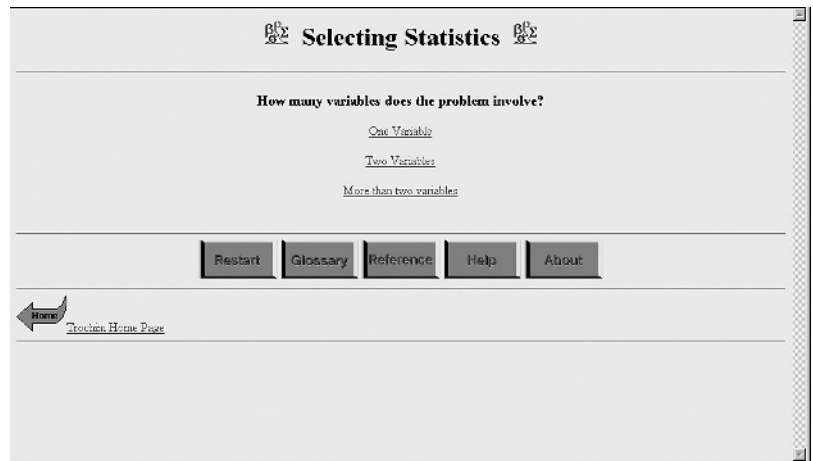

Figure 4 Selecting the Correct Stat Technique to Use—Just a Few Clicks Away

Statistics.com (www.statistics.com) has it all—a wealth of information on courses, software, statistical methods, jobs, books, and even a homework helper. For example, if you want to know about free Web-based stat packages, click on that link on the left-hand side of the page. Here's one (see Figure 4) from Dr. Bill Trochim. . . . You just click your way through answering questions to get the answer to what type of analysis should be used.

Appendix C

Glossary

The following text is taken from Neil J. Salkind's best-selling introduction to statistics text, *Statistics for People Who (Think They) Hate Statistics*, 2nd edition (2004).

Analysis of variance

A test for the difference between two or more means. A simple analysis of variance (or ANOVA) has only one independent variable, whereas a factorial analysis of variance tests the means of more than one independent variable. One-way analysis of variance looks for differences between the means of more than two groups.

Arithmetic mean

A measure of central tendency that sums all the scores in the data sets and divides by the number of scores.

Asymptotic

The quality of the normal curve such that the tails never touch.

Average

The most representative score in a set of scores.

Bell-shaped curve

A distribution of scores that is symmetrical about the mean, median, and mode and has asymptotic tails.

Class interval

The upper and lower boundaries of a set of scores used in the creation of a frequency distribution.

Coefficient of alienation

The amount of variance unaccounted for in the relationship between two variables.

Coefficient of determination

The amount of variance accounted for in the relationship between two variables.

Coefficient of nondetermination

See coefficient of alienation

Concurrent validity

A type of validity that examines how well a test outcome is consistent with a criterion that occurs in the present.

Construct validity

A type of validity that examines how well a test reflects an underlying construct.

Content validity

A type of validity that examines how well a test samples a universe of items.

Correlation coefficient

A numerical index that reflects the relationship between two variables.

Correlation matrix

A set of correlation coefficients.

Criterion

Another term for the outcome variable.

Criterion validity

A type of validity that examines how well a test reflects some criterion that occurs either in the present (concurrent) or in the future (predictive).

Critical value

The value necessary for rejection (or nonacceptance) of the null hypothesis.

Cumulative frequency distribution

A frequency distribution that shows frequencies for class intervals along with the cumulative frequency for each.

Data

A record of an observation or an event such as a test score, a grade in math class, or a response time.

Data point

An observation.

Data set

A set of data points.

Degrees of freedom

A value that is different for different statistical tests and approximates the sample size of number of individual cells in an experimental design.

Dependent variable

The outcome variable or the predicted variable in a regression equation.

Descriptive statistics

Values that describe the characteristics of a sample or population.

Direct correlation

A positive correlation where the values of both variables change in the same direction.

Directional research hypothesis

A research hypothesis that includes a statement of inequality.

Effect size

A measure of the magnitude of a particular outcome.

Error in prediction

The difference between the actual score (Y) and the predicted score (\bar{Y}).

Error of estimate

See error in prediction

Error score

The part of a test score that is random and contributes to the unreliability of a test.

Factorial analysis of variance

An analysis of variance with more than one factor or independent variable.

Factorial design

A research design where there is more than one treatment variable.

Frequency distribution

A method for illustrating the distribution of scores within class intervals.

Frequency polygon

A graphical representation of a frequency distribution.

Histogram

A graphical representation of a frequency distribution.

Hypothesis

An if-then statement of conjecture that relates variables to one another.

Independent variable

The treatment variable that is manipulated or the predictor variable in a regression equation.

Indirect correlation

A negative correlation where the values of variables move in opposite directions.

Inferential statistics

Tools that are used to infer the results based on a sample to a population.

Interaction effect

The outcome where the effect of one factor is differentiated across another factor.

Internal consistency reliability

A type of reliability that examines the one-dimensional nature of an assessment tool.

Interrater reliability

A type of reliability that examines the consistency of raters.

Interval level of measurement

A scale of measurement that is characterized by equal distances between points on some underlying continuum.

Kurtosis

The quality of a distribution such that it is flat or peaked.

Leptokurtic

The quality of a normal curve that defines its peakedness.

Line of best fit

The regression line that best fits the actual scores and minimizes the error in prediction.

Linear correlation

A correlation that is best expressed as a straight line.

Main effect

In analysis of variance, when a factor or an independent variable has a significant effect upon the outcome variable.

Mean

A type of average where scores are summed and divided by the number of observations.

Mean deviation

The average deviation for all scores from the mean of a distribution.

Measures of central tendency

The mean, median, and mode.

Median

The point at which 50% of the cases in a distribution fall below and 50% fall above.

Midpoint

The central point in a class interval.

Mode

The most frequently occurring score in a distribution.

Multiple regression

A statistical technique where several variables are used to predict one.

Nominal level of measurement

A scale of measurement that is characterized by categories with no order or difference in magnitude.

Nondirectional research hypothesis

A hypothesis that posits no direction, but a difference.

Nonparametric statistics

Distribution-free statistics.

Normal curve

See bell-shaped curve

Null hypothesis

A statement of equality between a set of variables.

Observed score

The score that is recorded or observed.

Obtained value

The value that results from the application of a statistical test.

Ogive

A visual representation of a cumulative frequency distribution.

One-tailed test

A directional test.

One-way analysis of variance

See analysis of variance

Ordinal level of measurement

A scale of measurement that is characterized by an underlying continuum that is ordered.

Outliers

Those scores in a distribution that are noticeably much more extreme than the majority of scores. Exactly what score is an outlier is usually an arbitrary decision made by the researcher.

Parallel forms reliability

A type of reliability that examines the consistency across different forms of the same test.

Parametric statistics

Statistics used for the inference from a sample to a population.

Pearson product-moment correlation

See correlation coefficient

Percentile point

The point at or below where a score appears.

Platykurtic

The quality of a normal curve that defines its flatness.

Population

All the possible subjects or cases of interest.

Post hoc

After the fact, referring to tests done to determine the true source of a difference between three or more groups.

Predictive validity

A type of validity that examines how well a test outcome is consistent with a criterion that occurs in the future.

Predictor

The variable that predicts an outcome.

Range

The highest minus the lowest score, and a gross measure of variability. *Exclusive* range is the highest score minus the lowest score. *Inclusive* range is the highest score minus the lowest score plus 1.

Ratio level of measurement

A scale of measurement that is characterized by an absolute zero.

Regression equation

The equation that defines the points and the line that are closest to the actual scores.

Regression line

The line drawn based on the values in the regression equation.

Reliability

The quality of a test such that it is consistent.

Research hypothesis

A statement of inequality between two variables.

Sample

A subset of a population.

Sampling error

The difference between sample and population values.

Scales of measurement

Different ways of categorizing measurement outcomes.

Scattergram, or scatterplot

A plot of paired data points.

Significance level

The risk set by the researcher for rejecting a null hypothesis when it is true.

Simple analysis of variance

See analysis of variance

Skew, or skewness

The quality of a distribution that defines the disproportionate frequency of certain scores. A longer right tail than left corresponds to a smaller number of occurrences at the high end of the distribution; this is a *positively* skewed distribution. A shorter right tail than left corresponds to a larger number of occurrences at the high end of the distribution; this is a *negatively* skewed distribution.

Source table

A listing of sources of variance in an analysis of variance summary table.

Standard deviation

The average deviation from the mean.

Standard error of estimate

A measure of accuracy in prediction.

Standard score

See z score

Statistical significance

See significance level

Statistics

A set of tools and techniques used to organize and interpret information.

Test-retest reliability

A type of reliability that examines consistency over time.

Test statistic value

See obtained value

True score

The unobservable part of an observed score that reflects the actual ability or behavior.

Two-tailed test

A test of a nondirectional hypothesis where the direction of the difference is of little importance.

Type I error

The probability of rejecting a null hypothesis when it is true.

Type II error

The probability of accepting a null hypothesis when it is false.

Unbiased estimate

A conservative estimate of a population parameter.

Validity

The quality of a test such that it measures what it says it does.

Variability

The amount of spread or dispersion in a set of scores.

Variance

The square of the standard deviation, and another measure of a distribution's spread or dispersion.

 Y' or Y prime

The predicted Y value.

z score

A raw score that is adjusted for the mean and standard deviation of the distribution from which the raw score comes.
