carbamazepine (first choice)<sup>5</sup>: children and adults

or

sodium valproate (second choice) not <2 years or (others)

phenytoin, vigabatrin, gabapentin

### § Absence seizure

This type of generalised epilepsy typically affects children from 4 years up to puberty:<sup>2</sup> (see CHAPTER 84).

- child ceases activity and stares suddenly
- child is motionless (may blink or nod)
- no warning
- sometimes clonic (jerky) movement of eyelids, face, fingers
- may be lip-smacking or chewing (called complex absence)
- only lasts few seconds—usually 5–10 seconds
- child then carries on as though nothing happened
- usually several per day (not just one or two)
- may lead to generalised seizures in adulthood
- two types—childhood and juvenile

### Diagnosis

Best evoked in the consulting room by hyperventilation and 'windmill'.

EEG:

- classic 3 Hz wave and spike
- may be normal
- always include hyperventilation
- easier with sleep deprivation

### Medication

ethosuximide (first choice)<sup>5,10</sup>

or

sodium valproate (second choice)

or (others) e.g. clonazepam, gabapentin

childhood absence may not need pharmacotherapy

*Note:* Beware of hepatotoxicity with sodium valproate, especially in those under 2 years.

### § Narcolepsy

Narcolepsy is characterised by brief spells of irresistible sleep during daytime hours, usually in inappropriate circumstances, even during activity. Although patients are usually aware of their disorder, some may have no insight into the problem and present with the complaint of unusual turns. Narcolepsy can present as 'attacks' in which the patient may crumple and fall without losing consciousness. It can be part of a tetrad syndrome (daytime hypersomnolence, cataplexy, hypnagogic hallucinations, sleep paralysis).

Other features:

- onset in teens or 20s
- can have several attacks per day

Refer to CHAPTER 71.

## Diagnosis

- A clinical diagnosis  
If doubtful:
- EEG monitoring
- sleep laboratory studies (sleep latency test)—  
rapid eye movement is a hallmark

## Medication<sup>11</sup>

dexamphetamine (in slowly increasing doses to 60 mg daily)

or

methylphenidate (immediate release) up to 60 mg daily

or

modafinil 200–400 mg (o) daily

or

tricyclic antidepressants (e.g. clomipramine, fluoxetine), for associated cataplexy

## AMNESIC EPISODES

Amnesic episodes in which people cannot recall events or their own identity can be psychogenic (commonly), such as fugue states, conversion disorder, severe depression and factitious states. They may be related to an organic problem such as epilepsy, sleep apnoea, cerebrovascular disorder, post-trauma, Wernicke–Korsakoff syndromes and drugs (e.g. alcohol, cannabis and anaesthetic agents).

## § Transient global amnesia<sup>12,13</sup>

This is a benign, self-limited profound amnesic episode of unknown aetiology tending to occur in middle-aged or elderly people. Proposed causation includes transient ischaemia or dysfunction of the temporal lobes, similar to temporal lobe epilepsy or a migraine variant.

## Clinical features

- Typically last 4–8 hours (up to 24 hours)
- Identity and conscious state preserved
- Agitated, perplexed, anxious patient
- State of bewilderment (e.g. ‘where am I?’)
- Anterograde and retrograde amnesia
- Frequent repetition of questions
- Able to perform complex motor skills (e.g. driving)
- Usually single episode (20% recurrence)
- Complete resolution: good prognosis
- No abnormal neurological signs
- All investigations unhelpful

## Four diagnostic criteria (after Caplan)<sup>12</sup>

- Witnessed onset of attack (essential for diagnosis)
- Dysfunction during attack limited to amnesia and repetitive queries
- No other neurological features
- Memory loss should be transient lasting no longer than 24 hours

## Management

- Reassuring explanation/education
- Special investigations, including angiography, not needed if conform to above criteria
- No active treatment usually needed

## Cerebrovascular disorders

Cerebrovascular disease is one of the major causes of mortality and morbidity in developed countries and can cause recurrent attacks of ischaemia in the carotid and vertebrobasilar systems (particularly vertebrobasilar insufficiency), which may present as ‘funny turns’. In particular, brain-stem ischaemia causes ‘funny turns’ such as impaired consciousness, including transient global amnesia, drop attacks and the ‘locked-in’ syndrome.

## Orthostatic intolerance and syncope

There are three main syndromes of autonomic instability with orthostatic intolerance leading to syncope

- 1 *Reflex (vasovagal) syncope*. This affects 30% of the population, has a strong family history and an onset in the young. There is a hypotensive response. The multiple precipitants include coughing, micturition, fright, standing, heat and defecation (straining). Although consciousness quickly returns, recovery can be delayed (e.g. malaise for 12–24 hours). See CHAPTER 75.
- 2 *Postural orthostatic tachycardia syndrome (POTS)*.<sup>14</sup> This is orthostatic intolerance with dysautonomia upon changing from the supine to the upright position or head up tilt. Tachycardia with decreased ventricular filling is a feature with hypotension and possibly syncope. There are myriad symptoms including dizziness, fatigue, blurred vision, chest pain and cognitive impairment. Some consider it a variety of chronic fatigue syndrome. It has an adolescent onset and a familial history. Referral to a ‘syncope’ unit is recommended for this complex and

debilitating condition. One treatment option is fludrocortisone acetate.

- 3 **Autonomic failure.** This is age related and can be primary (e.g. multiple system atrophy) or secondary (e.g. diabetes, amyloid). It leads to hypoperfusion syncope. Precipitants include orthostasis, meals and alcohol. Recovery from syncope is rapid.

## Psychogenic or communication disorders

Psychogenic causes have to be considered. 'Hysterical fugue' is one such manifestation. The problem can be a communication disorder, such as an emotional person trying to communicate a problem in a language foreign to them.

Patients with psychiatric disorders such as schizophrenia or depression may experience feelings of depersonalisation or unreality, which can be interpreted as a 'turn' or even temporal lobe epilepsy.

Patients who complain of vague and bizarre symptoms, such as 'queer feelings in the head', 'swimming sensation', 'unreal feelings' and 'walking on air' are likely to have an anxiety state.

Severe anxiety or panic attacks typically cause lightheadedness that presents as a 'funny turn'. Other somatic symptoms include palpitations, sweating, inability to swallow, headache, breathlessness and manifestations of hyperventilation.

## Pitfalls in management<sup>2</sup>

- The main pitfall associated with seizure disorders and epilepsy is misdiagnosis (not all seizures are generalised tonic-clonic in nature).
- Failing to place appropriate emphasis on the history in making the diagnosis.
- Misdiagnosing syncope with some involuntary movements for epilepsy.
- Overlooking cardiac arrhythmias as a cause of funny turns, including recurrent dizziness.
- Failing to consider the possibility of aortic stenosis with syncopal attacks.
- Misdiagnosing vertigo and syncope for TIA.
- Mistaking visual or sensory migraine equivalents in young adults for TIA.
- Overlooking drugs (including self-administered drugs) as a cause of lightheadedness.

## When to refer

- Transient ischaemic attacks, especially if the diagnosis is in doubt

- Clinical suspicion of or proven cardiac arrhythmias
- Evidence of aortic stenosis
- Seizures
- General uncertainty of the diagnosis

## Practice tips

- A detailed clinical analysis is more important in the first instance than laboratory tests. The key to accurate diagnosis is a very careful history, taking the patient second by second through the attack and events preceding the turn.
- Talk to as many eyewitnesses as possible in unravelling the cause.
- For 'undiagnosed turns' ask the patient to keep a diary with an accurate record of the attack, including preceding events.
- Remember that migraine is a great mimic and can cause confusion in diagnosis.
- Remember that the EEG can be normal in the confirmed epileptic.
- The more bizarre the description of a 'funny turn', the more likely a functional problem is the cause.
- Transient hypoglycaemia can mimic a TIA.

*The 'once smelt never forgotten' sickly smell of melaena can be diagnosed from a distance of 20 metres without trying.*

Acute severe upper GI haemorrhage is an important medical emergency. The dramatic symptom of haematemesis follows bleeding from the oesophagus, stomach and duodenum. More than half the patients are over 60 years of age.<sup>1</sup>

Haematemesis is the vomiting of blood appearing as fresh blood or 'coffee grounds'. Melaena is the passage of black tarry stools, with 50 mL or more of blood required to produce melaena stool (Greek *melas* = black). Melaena occurs in most patients with upper GI haemorrhage and haematemesis occurs in over 50%.<sup>1</sup>

Although the incidence is declining, the mortality rate of upper GI haemorrhage remains high at approximately 6–8%.<sup>2</sup>

### Key facts and checkpoints

- Chronic peptic ulceration accounts for most cases of upper GI haemorrhage.
- Haematemesis is almost always associated with some degree of blood in the stools, although melaena may not necessarily accompany it, especially if bleeding occurs from the oesophagus.
- Black stool caused by oral iron therapy or bismuth-containing antacid tablets can cause confusion.
- Always check for a history of drug intake, especially aspirin and NSAIDs.
- Corticosteroids in conventional therapeutic doses are thought to have no influence on GI haemorrhage.
- The volume of the bleeding is best assessed by its haemodynamic effects rather than relying on the patient's estimation, which tends to be excessive.
- Melaena is generally less life-threatening than haematemesis.
- Resuscitation of the patient is the first task.
- A sudden loss of 20% or more circulatory blood volume usually produces signs of shock such as tachycardia, hypotension, faintness and sweating. Younger patients can compensate better and tolerate a larger loss prior to the development of shock.<sup>1</sup> A useful guide is that shock in a previously well 70 kg man indicates an acute blood loss of at least 1000–1500 mL.

Emergency room supervisor, Brisbane 1985

### Causes of upper GI bleeding

The major cause of bleeding is chronic peptic ulceration of the duodenum and stomach, accounting for about half of all cases.<sup>3,4</sup> The other major cause is acute gastric ulcers and erosions, which account for at least 20% of cases. Aspirin and NSAIDs are responsible for many of these bleeds. Causes are summarised in TABLE 55.1 and illustrated in FIGURE 55.1.

**Table 55.1** Causes of upper gastrointestinal bleeding<sup>5,6</sup>

#### Common causes

- 1 Duodenal ulcer/duodenitis
- 2 Gastric erosion/gastritis
- 3 Gastric ulcer
- 4 Oesophagitis
- 5 Oesophageal varices
- 6 Mallory–Weiss (emetogenic) syndrome
- 7 Drugs e.g. NSAIDs, aspirin

#### Others

Gastric or oesophageal cancer  
 Stomal ulcer  
 Blood dyscrasias e.g. leukaemia, thrombocytopenia  
 Anticoagulant therapy  
 Vascular malformations/angiodysplasia  
 Hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome)  
 Swallowed blood e.g. epistaxis, haemoptysis  
 Scurvy  
 Spurious: deliberate swallowing and vomiting of blood  
 Haemobilia (blood in bile)  
 Meckel diverticulum

### Mallory–Weiss syndrome

In this condition a tear occurs at the lower end of the oesophageal mucosa (at the oesophagogastric junction) because of an episode of severe or protracted vomiting or coughing. Blood appears in the vomitus after a bout of heavy vomiting or dry retching. It is

**FIGURE 55.1** Important causes of haematemesis and melaena

usually seen in alcoholic patients. It is usually a self-limiting lesion. A definite diagnosis can only be made by oesophagoscopy.

### Gastro-oesophageal varices

Such varices are caused by portal hypertension, which in turn is usually due to cirrhosis of the liver. There is a raised incidence of peptic ulcer in those with liver cirrhosis, especially in biliary and alcohol-induced cirrhosis, so this should be kept in mind as a possible source of bleeding. Mortality is about 30%, despite advances, and 70% for untreated patients.<sup>6</sup>

Primary prevention of bleeding from varices is with the use of beta blockers such as propranolol if no contraindications.<sup>7</sup>

Management includes injection sclerotherapy, and then intravenous octreotide or terlipressin if it fails. Passage of a Sengstaken–Blakemore or Minnesota tube into the oesophagus and stomach to provide tamponade and the radiological procedure of using a transjugular intrahepatic portosystemic stent are possible options.

## The clinical approach

### History

It is important to establish the nature of the vomitus and the possibility of bleeding arising from the mouth, nose or pharynx. A coffee grounds vomitus indicates that the blood has been in contact with gastric acid. Oesophageal bleeding tends to lead to vomiting of fresh blood. Questions to help pinpoint the possible aetiology should be asked. Patients may confuse vomiting up and coughing up blood.

**Table 55.2** Drugs associated with gastrointestinal haemorrhage<sup>2</sup>

Aspirin
Clopidogrel
Other antiplatelet drugs
Heparin/new oral anticoagulants
NSAIDs/COX-2 inhibitors
Prednisolone
SSRI antidepressants
Warfarin

### Key questions

- What drugs have you been taking? (see **TABLE 55.2**)
- Have you been taking aspirin or tablets for arthritis or back pain?
- How much have you vomited?
- What did the vomit look like?
- Did you notice black dots like coffee grounds or any blood clots?
- Have you had any indigestion, heartburn or stomach pains recently?
- Have you opened your bowels and if so what was the colour?
- Have you noticed whether your bowel motions were black or unusual in any way?
- How much alcohol do you drink?
- Have you had any previous operations on your stomach for a peptic ulcer?
- Were you vomiting normal vomit before the blood appeared?

### Examination

The patient's general state, particularly the circulation, should be assessed immediately on presentation. It is critical to assess the patient's haemodynamic status with vital signs of heart rate, blood pressure and postural changes.<sup>2</sup> A careful abdominal examination should be performed including a digital rectal examination. As a rule abdominal findings are not remarkable except when a mass, hepatomegaly or splenomegaly, is found. Other evidence of liver disease should be sought.

### Investigations

Investigations to determine the source of the bleeding should be carried out in a specialist unit. Upper gastrointestinal endoscopy is the single most useful test and will detect the cause of the bleeding in at least 80% of cases.<sup>3</sup>

The haemoglobin level will not be an appropriate guide to blood loss or the need for transfusion during the early stages, because haemodilution occurs gradually over the 24 hours following a severe bleed. However, a level below 90 g/L during this period is usually regarded as an indication for transfusion.

Other tests to consider include FBE, *H. pylori*, LFTs, plain abdominal X-ray.

## Management

The immediate objectives are:

- 1 restore an effective blood volume (if necessary)
- 2 establish a diagnosis to allow definitive treatment

All patients with a significant bleed should be admitted to hospital and referred to a specialist unit. Urgent resuscitation is required where there has been a large bleed and there are clinical signs of shock. Such patients require insertion of intravenous lines and rapid infusion of isotonic saline followed by a plasma expander (e.g. Haemaccel) followed by transfusion with blood commenced as soon as possible.

Proton pump inhibitors should be commenced in most cases especially as 50% of bleeding is from peptic ulceration. Oral administration may be possible in most cases but intravenous PPI (e.g. omeprazole 80 mg over 15–30 minutes followed by infusion)<sup>7</sup> is appropriate for the seriously ill.<sup>4</sup> Eventually switch to oral PPIs.

In many patients bleeding is insufficient to decompensate the circulatory system and they settle spontaneously. Approximately 85% of patients stop bleeding within 48 hours.<sup>3</sup>

In some instances intervention via upper endoscopy to achieve haemostasis of bleeding point

with a heater probe (e.g. Gold Probe) or injection with adrenaline or both or application of clips will be employed. Occasionally surgery will be necessary to arrest bleeding but should be avoided if possible in patients with acute gastric erosion.

## Practice tips

- Ask the patient not to dispose of the evidence of vomitus, if possible.
- Patients with haematemesis should be assessed in the emergency department.
- Peptic ulcer disease remains the most common cause of upper gastrointestinal bleeding (UGIB).
- Upper endoscopy is the gold standard for diagnosis and therapy for acute UGIB.

*When the head aches, all the body is out of tune.*

Miguel de Cervantes (1547–1616)

Headache, one of the cardinal symptoms known to human beings, is a very common complaint in general practice. When a patient presents with 'headache' we need to have a sound diagnostic and management strategy as the problem can be confusing. The key to analysing the symptom of headache is to know and understand the cause, for 'one only sees what they know'.

The patient's manner of presentation can confuse us because many tend to influence us with preconceived ideas that they will verbalise—'I think I need my blood pressure checked' or 'My eyes need testing'—or they may not mention their anxiety about a cerebral tumour or an impending stroke.

Hypertension is such a rare cause of headache that one is tempted to stress the adage 'hypertension does not cause headache', but we do encounter the occasional patient whose headache appears to be caused by hypertension and it is mandatory to measure the blood pressure of patients presenting with headache. Patients expect this routine and reassurance is difficult without the appropriate physical examination. Where headaches and hypertension coexist, assume that the headaches are not due to hypertension.

The diagnosis of serious causes of headache depends on a careful history, a high index of suspicion of the 'different' presentations and the judicious use of CT scanning.

## Key facts and checkpoints

- Eighty-five per cent of the population will have experienced headache within 1 year and 38% of adults will have had a headache within 2 weeks.<sup>1</sup>
- Forty per cent of children will have experienced one or more headaches by the age of 7 and 75% by the age of 15.<sup>2</sup>
- Headache can be classified as primary or secondary e.g. intracranial pathology, TMJ, cervical spine.
- Migraine affects at least 10% of the adult population and one-quarter of these patients

require medical attention for their attacks at some stage.<sup>3</sup> It is under-recognised and poorly managed in the community.<sup>4</sup>

- Five per cent of children suffer from migraine by the age of 11 years.<sup>3</sup>
- Seventy per cent of sufferers have a positive family history of migraine.
- Many headaches previously considered to be tension are secondary to disorders of the neck, eyes, teeth, temporomandibular joints or other structures.<sup>3</sup>
- Drug-induced headaches are common and must be considered in the history.
- In children the triad of symptoms—dizziness, headache and vomiting—indicates medulloblastoma of the posterior fossa until proved otherwise.
- A typical triad of symptoms in an adult with a cerebral tumour (advanced) is headache, vomiting and convulsions.
- Eye strain is not a common cause.
- Secondary bronchogenic bronchial carcinoma is the commonest cause of intracerebral malignancy.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in **TABLE 56.1**.

## Probability diagnosis

The commonest cause of headache presenting in general practice is respiratory infection.<sup>1</sup> The most common causes of chronic recurrent headache are so-called transformed migraine, tension-type headache and combination headaches. Combination headaches, typified by relatively constant pain lasting for many days, have a mix of components such as tension, depression, cervical dysfunction, vascular headache and drug dependence. Neurologists may refer to these headaches as 'tension-vascular headache'. Tension headache is less common than previously promulgated.<sup>3</sup>

**Table 56.1** Headache: diagnostic strategy model

Q. Probability diagnosis
A. Acute: respiratory infection
Chronic:
• tension-type headache
• combination headache
• migraine
• transformed migraine
Q. Serious disorders not to be missed
A. Cardiovascular:
• subarachnoid haemorrhage
• intracranial haemorrhage
• carotid or vertebral artery dissection
• temporal arteritis
• cerebral venous thrombosis
Neoplasia:
• cerebral tumour
• pituitary tumour
Severe infections:
• meningitis, esp. fungal
• encephalitis
• intracranial abscess
Haematoma: extradural/subdural
Glaucoma
Benign intracranial hypertension
Q. Pitfalls (often missed)
A. Cervical spondylosis/dysfunction
Dental disorders
Refractive errors of eye
Sinusitis
Ophthalmic herpes zoster (pre-eruption)
Exertional headache
Hypoglycaemia
Post-traumatic headache
Post-spinal procedure (e.g. epidural, lumbar puncture)
Sleep apnoea
Rarities:
• Paget disease
• post-sexual intercourse
• Cushing syndrome
• Conn syndrome
• Addison disease
• dysautonomic cephalgia
Q. Seven masquerades checklist
A. Depression
Diabetes
Drugs
Anaemia
Thyroid/endocrine disorder
Spinal dysfunction (cervicogenic)
UTI
Q. Is the patient trying to tell me something?
A. Quite likely if there is an underlying psychogenic disorder.

## Transformed migraine<sup>5</sup>

This describes the progressive increase in frequency of migraine attacks until the headache recurs daily. The typical migraine features become modified so that the pattern resembles that of tension headache but with the unilateral situation of migraine. Analgesic abuse can transform episodic migraine into chronic daily headache.

## Serious disorders not to be missed

For the acute onset of headache it is vital not to miss subarachnoid haemorrhage (SAH) or meningitis. Intracranial haemorrhage, especially involving cerebellar, intraventricular and frontal lobe areas, needs to be considered.

## Acute 'thunderclap' headache<sup>5</sup>

This is a sudden severe headache that can be caused by the following:

- enlarging aneurysm—an enlarging aneurysm or vascular malformation can cause acute headache
- SAH—the pain is typically occipital, localised at first then generalised and may vary in intensity
- meningitis—must be considered if the headache is generalised, especially in the presence of malaise, fever and neck stiffness; the ache, which is constant and severe, may begin abruptly

For chronic headache, space-occupying lesions including subdural haematomas must be considered. Since headaches tend to decrease with age, headaches developing in the elderly should be viewed with suspicion and this includes considering temporal arteritis (TA). Benign intracranial hypertension should be considered, especially in young obese women. The dangerous cryptococcal meningitis can be difficult as the CT scan may be normal.

## Tips on sinister causes of headache<sup>4</sup>

- The most important indicator is time course: beware of acute or subacute tempo.
- Be suspicious of any focal symptoms or signs (except for typical migraine aura).
- Beware of fever, confusion, altered mental state or neck stiffness.

## Pitfalls

The list (see TABLE 56.1) contains some controversial causes of headache, although some should be obvious if a careful history is elucidated. These include post-traumatic headache, post-procedural headache (e.g. lumbar puncture and spinal anaesthesia) and exertional headache. Sinusitis can be overlooked in

the absence of respiratory signs. Refractive errors of the eye, although an uncommon cause of headache, do warrant consideration.

### General pitfalls

- Overinvestigating the patient with headache, especially as a substitute for a careful history and examination
- Failing to appreciate that a combination of factors and cervical dysfunction are common causes of headache
- Omitting to measure the blood pressure in the patient complaining of headache
- Rushing in with antibiotics for a patient (especially children) with fever and headache—bacterial meningitis may be masked
- Attributing the early headache of a space-occupying lesion to tension or hypertension

### Seven masquerades checklist

Of the masquerades, depression and drugs are important causes of headache. Cervical dysfunction is certainly an important cause and tends to be ignored by some doctors. Australian figures are misleading because many of these patients tend to gravitate to alternative health professionals.

A UK study placed headache from cervical spondylosis on almost equal terms with migraine.<sup>1</sup>

The explanation for referral of pain from disorders of the upper cervical spine to the head and eye is that some afferent fibres from the upper three cervical nerve roots converge on cells in the posterior horn of the spinal cord (which can also be excited by trigeminal afferent fibres), thus conveying to the

patient the impression of head pain through this shared pathway (see FIG. 56.1).

Question the possibility of the effect of any drug the patient is taking: important examples are alcohol, analgesics (rebound), antihypertensives (several), caffeine, COCP, corticosteroids, NSAIDs (especially indomethacin), vasodilators e.g. CCBs, nitrates, PDE inhibitors (e.g. sildenafil). Anaemia can cause headache, usually if the haemoglobin level falls below 100 g/L.<sup>5</sup> Hypo- and hyperthyroidism may also cause headache, and in diabetics hypoglycaemia is often responsible.

### Psychogenic considerations

Headache, like tiredness, is one of those symptoms that may reflect a 'hidden agenda'. Of course, the patient may be depressed (overt or masked) or may have a true anxiety state. The most characteristic feature of psychogenic headache is that the headache is present virtually every minute of the day for weeks or months on end. However, it is common for patients to deny that they are anxious, depressed or unduly stressed. For this reason a detailed history is important to identify lifestyle factors and historical events that can be associated with headache.

Some patients are fearful of their headache lest it represents a cerebral tumour, stroke or hypertension and need appropriate reassurance.

Conversion reactions and other aspects of compensation rewards, especially following an accident (e.g. rear-end collision), may make the symptom of headache difficult to manage. Headache, like backache, is one of the prime symptoms perpetuated or exaggerated for secondary gain.

Severe headaches, especially simulated migraine, are common 'tickets of entry' for drug addicts seeking narcotics from empathic practitioners. Such patients require very skilled management.

### Timelines for causes of headache/ facial pain

Acute severe headache e.g.:

- subarachnoid haemorrhage
- benign sex or exertional headache
- migraine/cluster headache

Subacute headache (recent onset, increasing):

- expanding intracranial lesion
- temporal arteritis

Recurrent episodes e.g.:

- migraine/cluster headache
- benign sex or exertional headache

FIGURE 56.1 Typical headache referral patterns for dysfunction of the upper cervical spinal segments

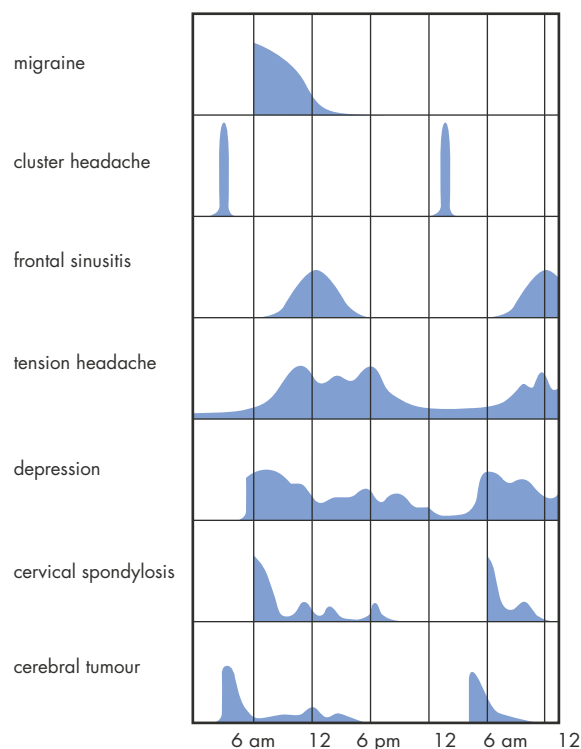

- neuralgias e.g. trigeminal

Chronic headache e.g.:

- tension-type headache
- transformed migraine/rebound headache
- cervicogenic/post-traumatic
- atypical facial pain

## Diurnal patterns of pain

Plotting the fluctuation of headache during the day provides vital clues to the diagnosis (see FIG. 56.2). The patient who wakes up with headache could have vascular headache (migraine), cervical spondylosis, depressive illness, hypertension or a space-occupying lesion. It is usual for migraine to last hours, not days, which is more characteristic of tension headache. The pain of frontal sinusitis follows a typical pattern, namely onset around 9 am, building to a maximum by about 1 pm, and then subsiding over the next few hours. In the absence of respiratory symptoms it is likely to be misdiagnosed as tension headache. The pain from combination headache tends to follow a most constant pattern throughout the day and does not usually interrupt sleep.

**FIGURE 56.2** Typical diurnal patterns of various causes of headache; the relative intensity of pain is plotted on the vertical axis

## The clinical approach

### History

A full description of the pain including a pain analysis should be obtained using one of the mnemonics (see CHAPTER 12) with an emphasis on relieving factors and associations.

It is useful to get the patient to plot on a prepared grid the relative intensity of the pain and the times of day (and night) that the pain is present. The history, especially of the tempo of the condition, should help diagnose headaches secondary to specific pathology.

### Key questions<sup>6</sup>

- Can you describe your headaches?
- How often do you get them?
- Can you point to exactly where in the head you get them?
- Do you have any pain in the back of your head or neck?
- What time of the day do you get the pain?
- Do you notice any other symptoms when you have the headache?
- Do you feel nauseated and do you vomit?
- Do you experience any unusual sensations in your eyes, such as flashing lights?
- Do you get dizzy, weak or have any strange sensations?
- Does light hurt your eyes?
- Do you get any blurred vision?
- Do you notice watering or redness of one or both of your eyes?
- Do you get pain or tenderness on combing your hair?
- Are you under a lot of stress or tension?
- Does your nose run when you get the headache?
- What tablets do you take?
- Do you get a high temperature, sweats or shivers?
- Have you had a heavy cold recently?
- Have you ever had trouble with your sinuses?
- Have you had a knock on your head recently?
- What do you think causes the headaches?

Differences between the clinical features of migraine and tension headache are presented in TABLE 56.2. 'Red flag' indicators of a serious cause of headache are outlined in the box.

### Examination

For the physical examination it is appropriate to use the basic tools of trade, namely the thermometer, sphygmomanometer, pen torch, and diagnostic set, including the ophthalmoscope and the stethoscope.

**Table 56.2** A comparison of typical clinical features of migraine and tension headache<sup>7</sup>

	Migraine	Tension headache
Family history	✓	
Onset before age 20	✓

### Red flag indicators for headache

- Sudden onset especially if no previous history
- Severe and debilitating pain
- Progressive
- Fever
- Vomiting
- Disturbed consciousness/confusion, drowsiness
- Personality change
- Worse with bending, coughing or sneezing
- Maximum in morning
- Wakes patient at night
- Neurological and visual symptoms/signs
- Seizure
- Young obese female: ? on medication
- 'New' in elderly, especially >50 years
- Post head injury

Inspect the head, temporal arteries and eyes. Areas to palpate include the temporal arteries, the facial and neck muscles, the cervical spine and sinuses, the teeth and temporomandibular joints. Search especially for signs of meningeal irritation and papilloedema.

A mental state examination is mandatory and includes looking for altered consciousness or cognition and assessment of mood, anxiety–tension–depression, and any mental changes. Neurological examination includes assessment of visual fields and acuity, reactions of the pupils and eye movements in addition to sensation and motor power in the face and limbs and reflexes, including the plantar response. 'Red flag' pointers from physical examination are given in the box.

### Red flag pointers: from physical examination

- Altered consciousness or cognition
- Meningism
- Abnormal vital signs: BP, temperature, respiration
- Focal neurological signs, including pupils, fundi, eye movement
- Tender, poorly pulsatile temporal arteries

### Special signs

- *Upper cervical pain sign.* Palpate over the C2 and C3 areas of the cervical spine, especially two finger breadths out from the spinous process of C2. If this is very tender and even provokes the headache it indicates headache of cervical origin.
- *Ewing sign for frontal sinusitis.* Press your finger gently upwards and inwards against the orbital roof medial to the supra-orbital nerve. Pain on pressure is a positive finding and indicates frontal sinusitis.
- *The invisible pillow sign.* The patient lies on the examination table with head on a pillow. The examiner then supports the head with his or her hands as the pillow is removed. The patient is instructed to relax the neck muscles and the examiner removes the supporting hands. A positive test indicating tension from contracting neck muscles is when the patient's head does not readily change position. This is uncommon.

### Investigations

Investigations can be selected from:

- haemoglobin ? anaemia
- WCC: leucocytosis with bacterial infection
- ESR/CRP: ? temporal arteritis
- radiography:
  - chest X-ray, if suspected intracerebral malignancy
  - cervical spine
  - skull X-ray, if suspected brain tumour, Paget disease, deposits in skull
  - sinus X-ray, if suspected sinusitis
  - CT scan: detection of brain tumour (most effective), cerebrovascular accidents (valuable), SAH
  - radioisotope scan (technetium-99m) to localise specific tumours and haematoma
  - MRI: very effective for intracerebral pathology but expensive; produces better

definition of intracerebral structures than CT scanning but not as sensitive for detecting bleeding; detects intracranial vasculitis in temporal arteries

- lumbar puncture: diagnosis of meningitis, suspected SAH (only if CT scan normal)

*Note:* Dangerous if raised intracranial pressure.

## Headache in children

Respiratory infections and febrile illnesses are common causes of headache in children but there are other causes that reflect the common causes in adults. Many childhood headaches are isolated but are chronic in a significant number. Migraine is relatively common before adolescence, while tension or muscle contraction headache is more common after adolescence.

Consider often overlooked causes such as hair traction, eye strain (measure and record vision) and hypoglycaemia. Children who have long periods without regular eating are prone to headache including exacerbations of migraine. They should not skip breakfast.<sup>8</sup>

Young children rarely experience sinus headache and this should not really be considered until the sinuses develop, around 5 years for the frontal sinuses.

From 1% of children aged 7 years to 5% or more of children aged 15 years suffer from migraine, with girls developing it at a higher rate<sup>2</sup> with increasing age. There is a strong family history. As a rule the prognosis is good as the majority will have no migraines in the long term. The type is mainly common migraine with symptoms such as malaise or nausea: classic migraine with the typical aura is not a feature of childhood migraine. The rather dramatic migraine, such as vertebrobasilar migraine, is frequent in adolescent girls and hemiplegia occurs in infants and children, especially with their first migraine attack.<sup>9</sup> Vomiting is not necessarily an associated symptom in children.

The possibility of cerebral space-occupying lesions requires due consideration, especially if the headaches are progressive. These are present typically in the morning and are associated with symptoms such as vomiting, dizziness, diplopia, ataxia, personality changes and deterioration of school performance. Symptoms that indicate a cerebral tumour or other serious problem are outlined in [TABLE 56.3](#).

Neonates and children aged 6–12 months are at the greatest risk from meningitis and it is important to keep this in mind.

**Table 56.3** Pointers to serious causes of headache in children

Headache features
Persistent or recurrent
Present first thing in morning
Wakes child at night
No past history
No family history
Associated poor health
Associated neurological symptoms
Unilateral localisation

*Source:* After Wright<sup>2</sup>

Management of the non-serious causes of headache includes reassurance (especially of parents), discouragement of excessive emphasis on the symptom and simple medications, such as paracetamol for the younger child and aspirin for the adolescent. Patients with undiagnosed and/or problematic headache should be referred.

## Pharmacological treatment in children<sup>9</sup>

Tension headache and migraine:

paracetamol 20 mg/kg (o) statim then 15 mg/kg 4–6 hourly up to 90 mg/kg/day (max. 4 g daily)

or

ibuprofen 5–10 mg/kg (o) statim up to 40 mg/kg/day (not for children <6 months)

## Headaches in the elderly

A recent onset of headache in the elderly has to be treated with caution because it could herald a serious problem, such as a space-occupying lesion (e.g. neoplasm, subdural haematoma), TA, trigeminal neuralgia or vertebrobasilar insufficiency. Cervical spondylosis is age-related and may be an important factor in the ageing patient. Age-related headaches are summarised in [TABLE 56.4](#).

Late-life migraine can be mistaken for cerebrovascular disease, especially in the presence of preceding neurological symptoms. It is the sequence of the visual and sensory symptoms with the spread from face to tongue to hand over some minutes, with clearing in one area as it appears that helps distinguish migraine from transient ischaemic attacks (TIAs). Although some patients experience headache with TIAs it is not a distinguishing feature. Vomiting is suggestive of migraine rather than cerebrovascular disease.<sup>10</sup>

**Table 56.4** Age-related causes of headache

Children	Intercurrent infections
	Psychogenic
	Migraine
	Meningitis
	Post-traumatic
Adults, including middle age	Migraine
	Cluster headache
	Tension
	Cervical dysfunction
	Subarachnoid haemorrhage
Elderly	Combination
	Cervical dysfunction
	Cerebral tumour
	Temporal arteritis
	Neuralgias
	Paget disease
	Glaucoma
	Cervical spondylosis
	Subdural haemorrhage

## § Tension-type headache

Tension or muscle contraction headaches are typically a symmetrical (bilateral) tightness. They tend to last for hours and recur each day. They are often associated with cervical dysfunction and stress or tension, although the patient usually does not realise the headaches are associated with tension until it is pointed out. Seventy-five per cent of patients are females.<sup>3</sup>

### IHS criteria for tension-type headache<sup>11</sup>

The International Headache Society (IHS3) criteria for episodic tension-type headaches involve the following:

- A The patient should have had at least 10 of these headaches.
- B The headaches last from 30 minutes to 7 days.
- C The headaches must have at least two of the following four:
  - 1 non-pulsating quality
  - 2 mild or moderate intensity
  - 3 bilateral location
  - 4 no aggravation with routine physical activity
- D The headaches must have both of the following:
  - 1 no nausea or vomiting
  - 2 photophobia and phonophobia are absent, or one but not the other is present
- E Not attributable to another disorder.

**FIGURE 56.3** Typical distribution of pain in tension-type headache

### Clinical features (tension headache)

Site:	frontal, over forehead and temples (see FIG. 56.3)
Radiation:	occiput
Quality:	dull ache, like a 'tight pressure feeling', 'heavy weight on top of head', 'tight band around head'; may be tightness or vice-like feeling rather than pain
Frequency:	almost daily
Duration:	hours (can last days)
Onset:	after rising, gets worse during day
Aggravating factors:	stress, overwork with skipping meals
Relieving factors:	alcohol
Associated features:	lightheadedness, fatigue, neck ache or stiffness (occiput to shoulders), perfectionist personality, anxiety/depression
Physical examination:	muscle tension (e.g. frowning), scalp often tender to touch, 'invisible pillow' sign may be positive

### Management<sup>9</sup>

- Careful patient education: explain that the scalp muscles get tight like the calf muscles when climbing up stairs.
- Counselling and relevant advice; CBT is as effective as any drug in all ages
  - Learn to relax your mind and body.
  - During an attack, relax by lying down in a hot bath and practise meditation.
  - Be less of a perfectionist: do not be a slave to the clock.
  - Don't bottle things up, stop feeling guilty, approve of yourself, express yourself and your anger.
- Advise stress reduction, relaxation therapy and yoga or meditation classes.

- Advise and demonstrate massage of the affected area with a soothing analgesic rub.
- Medication—use mild analgesics such as ibuprofen or paracetamol. Discourage stronger analgesics. Avoid tranquillisers and antidepressants if possible, but consider these drugs if symptoms warrant medication (e.g. amitriptyline 10 mg(o) nocte increasing to 75 mg if necessary).

Special notes:

- The general aim is to direct patients to modify their lifestyle and avoid tranquillisers and analgesics.
- It is unusual to be awoken from sleep.
- Beware of depression.
- Consider muscle energy therapy and/or mobilisation of the neck followed by exercises if there is evidence of cervical dysfunction.
- Recommend a meditation program.

## § Migraine

Migraine, or the 'sick headache', is derived from the Greek word meaning 'pain involving half the head'. It affects at least 1 person in 10, is more common in females (18% of women, 6% men) and peaks between 20 and 50 years. There are various types of migraine (see TABLE 56.5), with classic migraine (headache, vomiting and aura) and common migraine (without the aura) being the best known. The most common trigger factor is stress.<sup>3</sup>

**Table 56.5** Types of vascular headache

Common migraine (aura is vague or absent)

Classic migraine

Complicated migraine

Unusual forms of migraine:

- hemiplegic
- basilar
- retinal
- migrainous (vestibular) vertigo
- migrainous stupor
- ophthalmoplegic
- migraine equivalents
- status migrainosus

Cluster headache

Chronic paroxysmal hemicrania

Menstrual migraine

Lower half headache

Benign exertional-sex headache (beware of SAH)

Miscellaneous (e.g. icepick pains, 'ice-cream' headache)

Source: After Day<sup>12</sup>

**DxT** headache + vomiting + visual aura → migraine with aura (classic)

### IHS3 criteria for common migraine<sup>11</sup>

The IHS3 criteria for migraine without aura involve the checklist following.

- A The patient should have had at least five attacks fulfilling criteria B and D.
- B The headaches last 4–72 hours.
- C The headache must have at least two of the following:
  - 1 unilateral location
  - 2 pulsing quality
  - 3 moderate or severe intensity, inhibiting or prohibiting daily activities
  - 4 headache worsened by routine physical activity
- D The headache must have at least two of the following:
  - 1 nausea and/or vomiting
  - 2 photophobia and phonophobia
- E Not attributable to another disorder.

### IHS3 criteria for migraine with typical aura (classic)<sup>11</sup>

- A At least two attacks fulfilling criteria B and C.
- B One or more of the following fully reversible aura symptoms: visual, sensory, speech and/or language, motor, brainstem, retinal.
- C At least two of:
  - 1 at least one aura symptom spreads gradually over at least 5 minutes
  - 2 each aura symptom lasts 5–60 minutes
  - 3 at least one symptom is unilateral
  - 4 headache follows aura within 60 minutes
- D Not attributable to another disorder including TIA.

## Management

Patient education: provide explanation and reassurance, especially if bizarre visual and neurological symptoms are present. Patients should be reassured about the benign nature of their migraine. For each migraine sufferer, an individual treatment plan including a migraine action plan should be devised.

## Counselling and advice

- Tailor the advice to the individual patient.
- Avoid known trigger factors, especially tension, fatigue, hunger and constant physical and mental stress.

- Advise keeping a diary of foodstuffs or drinks that can be identified as trigger factors. Consider a low amine diet: eliminate chocolate, cheese, red wine, walnuts, tuna, Vegemite, spinach and liver.
- Practise a healthy lifestyle, relaxation programs, meditation techniques and biofeedback training.
- Be open to non-drug therapies (e.g. trial of acupuncture, hypnotherapy).

### Clinical features (classic migraine)

Site:	temporofrontal region (unilateral) (see FIG. 56.4); can be bilateral
Radiation:	retro-orbital and occipital
Quality:	intense and throbbing
Frequency:	1 to 2 per month
Duration:	4 to 72 hours (average 6–8 hours)
Onset:	paroxysmal, often wakes with it
Offset:	spontaneous (often after sleep)
Precipitating factors:	tension and stress (commonest); others in TABLE 56.6
Aggravating factors:	tension, activity
Relieving factors:	sleep, vomiting
Associated factors:	nausea, vomiting (90%) irritability aura — visual 25% (scintillation, scotoma, hemianopia, fortification) — sensory (unilateral paraesthesia)
Other pointers:	abdominal pain in childhood; family history of migraine, asthma and eczema

### Treatment of the acute attack

- Commence treatment at earliest impending sign.
- Mild headaches may require no more than conventional treatment with 'two aspirin (or paracetamol), and a good lie down in a quiet dark room'.<sup>11</sup>
- Rest in a quiet, darkened, cool room.
- Place cold packs on the forehead or neck.
- Avoid drinking coffee, tea or orange juice.
- Avoid moving around too much.
- Do not read or watch television.
- For patients who find relief from simply 'sleeping off' an attack, consider prescribing temazepam 10 mg or diazepam 10 mg in addition to the following measures.<sup>3</sup>

FIGURE 56.4 Typical distribution of pain in migraine (right side)

- For moderate attacks use oral ergotamine or sumatriptan and for severe attacks use injection therapy.
- Avoid pethidine and other opioids.

Table 56.6 Migrainous trigger factors

#### Exogenous

Foodstuffs—chocolate, oranges, tomatoes, citrus fruits, cheeses, gluten sensitivity (possible)  
 Alcohol—especially red wine  
 Drugs—vasodilators, oestrogens, monosodium glutamate, nitrites ('hot dog' headache), indomethacin, OCP  
 Glare or bright light\* (32%)  
 Emotional stress\* (63%)  
 Head trauma (often minor) (e.g. jarring—'footballer's migraine')  
 Allergen  
 Climatic change  
 Excessive noise  
 Strong perfume

#### Endogenous

Tiredness, physical exhaustion, oversleeping  
 Lack of sleep  
 Stress, relaxation after stress—'weekend migraine'  
 Exercise/physical stress  
 Hormonal changes  
 — puberty  
 — menstruation\*  
 — climacteric  
 — pregnancy  
 Hunger  
 Familial tendency  
 ?Personality factors

\* Most common

### Medication (if necessary)<sup>9</sup>

First-line medication acute migraine:

- aspirin or paracetamol + anti-emetic: e.g. soluble aspirin (Disprin Direct) 600–900 mg (o) *and* metoclopramide 10 mg (o)
- paracetamol or ibuprofen (for children)
- consider NSAIDs (e.g. ibuprofen, naproxen, diclofenac rapid)

If nausea and vomiting is a feature:

- metoclopramide 10–20 mg IM or IV  
*or*
- prochlorperazine 12.5 mg IM or 12.5–25 mg rectally
- consider nasal sumatriptan

Alternatives:

Choose a triptan preparation.

#### Triptans

- sumatriptan (a serotonin receptor agonist)<sup>9</sup> 50–100 mg (o) at the time of prodrome, repeat in 2 hours if necessary to maximum dose 300 mg/24 hours  
*or*  
nasal spray 10–20 mg per nostril (up to 40 mg/24 hours)  
*or*  
6 mg, SC injection, repeat in 1 or more hours to maximum dose 12 mg/24 hours  
*or*
- zolmitriptan 2.5–5 mg (o), repeat in 2 hours if necessary (max. 10 mg/24 hours)  
*or*
- naratriptan 2.5 mg (o), repeat in 4 hours (max. 5 mg/24 hours)  
*or*
- rizatriptan 10 mg wafer, repeat in >2 hours (max. 30 mg/24 hours)  
*or*
- eletriptan 40–80 mg (o) up to 160 mg/24 hours

Avoid triptans in patients with coronary artery disease, Prinzmetal angina, uncontrolled hypertension or during pregnancy. Do not use with ergotamine simultaneously and cease if chest pain develops, albeit transient in a young patient. Use with caution in patients taking SSRIs, MAOIs and lithium.

### Treatment of the severe attack

(If other preparations ineffective.)

*Caution:* Consider the possibility of underlying cerebral vascular malformation, SAH or pethidine addiction.

- If at home:<sup>12</sup>  
sumatriptan 6 mg (SC)
- If in surgery or emergency room:  
metoclopramide 10 mg (IV) slowly over 2 minutes + oral analgesics  
*or*  
metoclopramide 10 mg (IV) + dihydroergotamine 0.5 mg IV slowly  
*or*  
sumatriptan 6 mg (SC)  
*or*  
chlorpromazine 0.1 mg/kg IV infusion over 30 mins

*Caution:* Do not use ergotamine preparations if sumatriptan used in previous 6 hours, and do not use sumatriptan if ergotamine preparations used in previous 24 hours.

### Practice tips for severe classic migraine:

- IV metoclopramide + 1 litre N saline IV in 30 minutes + oral aspirin or paracetamol
- Continue high fluid intake

*Status migrainosus* (persistent migraine): IV dihydroergotamine 0.25–1 mg—over 2 minutes (may have to be given 8 hourly over 3–7 days in hospital) or chlorpromazine 0.1 mg/kg IV, repeated every 15 minutes for up to 3 doses (if necessary). Consider corticosteroids (e.g. dexamethasone 10–20 mg IV statim and then taper).

### Prophylaxis

Non-drug self-management with avoidance of any known trigger factors is the key.

Consider prophylactic therapy for frequent attacks that cause disruption to the patient's lifestyle and well-being, a rule of thumb being two or more severe migraine attacks per month; certainly consider it for weekly attacks and a poor response to therapy for the acute attack. Do not give ergotamine.<sup>10</sup>

The most commonly used drugs include:

- beta blockers—propranolol 40 mg (o) bd or tds (max. 320 mg/day), metoprolol, atenolol\*

- tricyclic antidepressants—amitriptyline\*
- sodium valproate\*
- pizotifen 0.5–2.0 mg at night
- cyproheptadine (ideal for children)
- clonidine
- methysergide (reserve for unresponsive severe migraine) 1 mg tds after food—up to 4 months only
- calcium-channel blockers—nifedipine, verapamil
- NSAIDs—naproxen, indomethacin, ibuprofen
- MAOIs—phenelzine, moclobemide
- sumatriptan
- gabapentin
- topiramate
- botulinum toxin

\* first line

### Menstrual migraine

Naproxen 550 mg (o) bd, 48 hours before expected attack for 4–10 days or oestradiol gel 1.5 mg transdermally, once daily for 7 days.

### Guidelines<sup>9,13</sup>

Select the initial drug according to the patient's medical profile:

- if low or normal weight—pizotifen
- if hypertensive—a beta blocker
- if depressed or anxious—amitriptyline
- if tension—a beta blocker
- if cervical spondylosis—naproxen
- food-sensitive migraine—pizotifen
- menstrual migraine—naproxen or mefenamic acid or ibuprofen or oestradiol transdermal gel

Commonly prescribed first-line drugs are propranolol or pizotifen:<sup>10</sup>

propranolol 40 mg (o) bd or tds (at first) increasing to 320 mg daily (if necessary)  
pizotifen 0.5–1 mg (o) nocte (at first) increasing to 3 mg a day (if necessary)

Each drug should be tried for 2 months before it is judged to be ineffective. Amitriptyline 50 mg nocte can be added to propranolol, pizotifen (beware of weight gain) or methysergide and may convert a relatively poor response to very good control.<sup>3</sup>

### Cluster headache

Cluster headache is also known as migrainous neuralgia. It occurs in paroxysmal clusters of

unilateral headache that typically occur nightly, usually in the early hours of the morning, although patients may have headaches that occur at other times. A hallmark is the pronounced cyclical nature of the attacks and at least 5 attacks. It occurs typically in males (6:1 ratio) and is rare in childhood. There are no visual disturbances or vomiting.

**DxT** retro-orbital headache + rhinorrhoea + lacrimation → cluster headache

### Management

*Acute attack* (brief treatment seldom effective):

- consider 100% oxygen 10 L/min for 15 min (usually good response)
- sumatriptan 6 mg SC injection (or 20 mg intranasal)  
*or*
- metoclopramide 10 mg IV + dihydroergotamine 0.5 mg IV slowly or 1 mg IM
- consider local anaesthetic—greater occipital nerve block

Avoid alcohol during cluster.

*Prophylaxis* (once a cluster starts)

Consider the following:

- methysergide 1 mg (o) once daily up to 3 mg bd
- prednisolone 50 mg/day for 10 days then taper over 3 weeks (as a bridging treatment)
- lithium 250 mg (o) bd
- verapamil SR 160 mg (o) daily up to 320 mg
- pizotifen
- indomethacin (helps confirm diagnosis)
- sodium valproate

*Note:* Some of the above can be used long term for frequent clusters.

### Clinical features

Site:	over or about one eye (see FIG. 56.5); always same side
Radiation:	frontal and temporal regions
Quality:	severe
Frequency:	one every other day and 8 per day for more than half the time
Duration:	15 minutes to 180 minutes (average 30 minutes); the clusters last 4–6 weeks (can last months)

*continued*

continued

Onset:	suddenly during night (usually), same time about 2–3 hours after falling asleep; the 'alarm clock' headache (e.g. 2–4 am)
Offset:	spontaneous
Aggravating factors:	alcohol (during cluster)
Relieving factors:	drugs
Associated features:	family history; rhinorrhoea and/or congestion, ipsilateral nose; lacrimation; flushing and/or sweating of forehead and cheek; redness of ipsilateral eye; eyelid oedema; miosis and/or ptosis; sensation of fullness in ear; a sense of restlessness or agitation (see FIG. 56.6)

FIGURE 56.5 Typical distribution of pain in cluster headache

FIGURE 56.6 Features of an attack of cluster headache: ptosis, lacrimation and a discharge from the nostril on the side of pain

## § Cervical dysfunction/spondylosis

Headache from neck disorders, often referred to as occipital neuralgia or cervicogenic, is far more common than realised and is very rewarding to treat by physical therapy, including mobilisation and manipulation and exercises in particular. See CHAPTERS 24 and 62.

Headache can be caused by abnormalities in any structure innervated by the upper two cervical nerves C2, C3 (usually the C1–2, C2–3 facet joints). Pain from cervical structures can be referred retro-orbitally and over one-half of the head. The headache is often incorrectly diagnosed as migraine but clinical examination of the neck helps differentiation.<sup>14</sup> The neck may be responsible for so-called 'tension' headache but clinical differentiation can be more difficult.

### Clinical features

The pain is usually sited in the occipital region with possible radiation to the parietal region, vertex of skull and behind the eye (see FIG. 56.7). It is usually present on waking and settles during the day. There is usually a history of trauma including an MVA or blow to the head. Associated features include stiffness and grating of the neck. On examination there is usually tenderness to palpation over the C1, C2 and/or C3 levels of the cervical spine, especially on the side of the headache.

### Treatment

- Physiotherapy modalities: hydrotherapy, muscle energy therapy, mobilisation, manipulation (from experts) and neck exercises (very important)
- Supportive neck pillow
- NSAIDs for cervical spondylosis
- For intractable cases consider mobilisation under general anaesthesia, injections of corticosteroids around, or surgical section of, the greater occipital nerve<sup>14</sup>

FIGURE 56.7 Typical distribution of pain in cervical dysfunction (right side)

## § Combination headache

Combined (also known as mixed) headaches are common and often diagnosed as psychogenic headache or a typical migraine. They have a combination of various degrees of:

- tension and/or depression
- cervical dysfunction
- vasospasm (migraine)
- drugs: analgesics (rebound), alcohol, nicotine, caffeine, NSAIDs

The headache, which has many of the features of tension headache, is usually described as a heavy deep ache 'as though my head is ready to burst'. It tends to be constant, being present throughout every waking moment. It tends to last for days (average 3–7) but can last for weeks or months. It is often related to stress and adverse working conditions, and sometimes follows an accident.

## Management

An important strategy is to evaluate each possible component of the headache as a stepwise trial by an elimination process:

- drug evaluation and modification
- cervical dysfunction—physical therapy if present
- depression
- tension and stress
- other psychogenic factors (e.g. conversion reaction)
- vasospasm

Treatment includes cognitive therapy, reassurance that the patient does not have a cerebral tumour, and lifestyle modification. The most effective medication is amitriptyline or other antidepressant. Propranolol and the antiepileptics can be considered.

## § Temporal arteritis

TA is also known as giant cell arteritis or cranial arteritis. There is usually a persistent unilateral throbbing headache in the temporal region and scalp sensitivity with localised thickening, with or without loss of pulsation of the temporal artery. It is related to polymyalgia rheumatica—20% of sufferers will develop TA. See CHAPTER 32.

TA is a type of collagen disease causing inflammation of extracranial vessels, especially the superficial temporal artery. It usually presents as a unilateral intermittent headache in a person over 50 years.

## Clinical features

Age:	over 50 years (mean age 70 years)
Site:	forehead and temporal region (unilateral) (see FIG. 56.8)
Radiation:	down side of head towards occiput
Quality:	severe burning pain
Frequency:	daily, a constant ache
Duration:	usually constant (getting worse)
Onset:	non-specific, tends to be worse in morning
Offset:	nil
Aggravating factors:	stress and anxiety
Relieving factors:	nil
Associated features:	malaise, vague aches and pains in muscles (especially of neck), weight loss
Other pointers:	intermittent blurred vision tenderness on brushing hair jaw claudication on eating polymyalgia rheumatica hypertension abnormal emotional behaviour

TA may also involve the intracranial vessels, especially the ophthalmic artery or posterior ciliary arteries, causing optic atrophy and blindness. Vision is impaired in about one-half of patients at some stage. Once the patient goes blind it is usually irreversible.

## Diagnosis

Diagnosis is by biopsy and histological examination of the superficial temporal artery. The ESR is usually markedly elevated but may be normal. The biopsy may be normal as TA has a focal nature. MRI has a high sensitivity and specificity.

*Note:* Consider it with any 'new' headache.

FIGURE 56.8 Typical distribution of pain in temporal arteritis (right side)

## Treatment

TA is very responsive to corticosteroids; start treatment immediately to prevent permanent blindness. Initial medication is prednisolone 40–60 mg orally daily in two divided doses initially for 2–4 weeks. Dose reduction and progress is monitored by the clinical state and ESR and CRP levels.<sup>10</sup> Concomitant use of H<sub>2</sub>-receptor antagonists may be appropriate initially. Temporal arteritis may take 1–2 years to resolve.

## § Frontal sinusitis

The headache of frontal sinusitis can be a diagnostic problem especially in the absence of, or a lapse in time since, an obvious upper respiratory infection or vasomotor rhinitis. Some patients do not have a history of a preceding respiratory infection, nor any signs of nasal obstruction or fever. Contrary to popular belief, sinusitis is a relatively uncommon source of headache.

## Clinical features

It presents typically as a frontal or retro-orbital headache (see FIG. 56.9). A characteristic is its diurnal variation, developing in the morning around 9 am, being most intense in the middle of the day, then subsiding to offset around 6 pm.

## Examination

There is tenderness over the frontal sinus and pain on percussion over the sinus. Ewing sign may be elicited. Fever and oedema of the upper eyelid may be present.

## Management

### Principles of treatment

- Drain the sinus conservatively using steam inhalations
- Antibiotics: amoxycillin or amoxycillin/clavulanate or cefaclor or doxycycline
- Analgesics

FIGURE 56.9 Typical distribution of pain of frontal sinusitis (right side)

## Referral

If resolution cannot be accomplished by conservative means then referral to an ENT specialist is advisable. Acute purulent sinusitis can be treacherous if it persists and spreads, causing collections of pus in the extradural or subdural space, cerebral abscess or blood-borne spread of infection.

## Complications

- Orbital cellulitis
- Subdural abscess
- Osteomyelitis
- Cavernous sinus thrombosis

Symptoms indicating spread of infection:

- increase in fever and chills
- vomiting
- oedema of the eyelids and forehead
- visual disturbances
- dulling of the sensorium
- convulsions

## § Raised intracranial pressure

Important causes of a space-occupying lesion include a cerebral tumour and subdural haematoma. Sometimes it is not possible to differentiate between a subdural and an extradural haematoma, although the latter classically follows an acute injury (see CHAPTER 75). Typical features are generalised headache, usually worse in the morning, aggravated by abrupt changes in intra-cranial pressure and later associated with vomiting and drowsiness. Headache is an uncommon presenting symptom of a cerebral tumour.

**DxT** drowsiness + vomiting + seizure →  
raised intracranial pressure

## Clinical features

Site:	generalised, often occipital
Radiation:	retro-orbital
Quality:	dull, deep steady ache
Frequency:	daily
Duration:	may be hours in morning
Onset:	worse in mornings, usually intermittent, can awaken from sleep
Offset:	later in day (if at all)

Aggravating factors:	coughing, sneezing, straining at toilet
Relieving factors:	analgesics (e.g. aspirin), sitting, standing
Associated features:	vomiting (without preceding nausea); vertigo/dizziness; drowsiness; seizures; confusion (later); neurological signs (depending on side)

### Examination

- Focal CNS signs
- Papilloedema (see FIG. 56.10) (but may be absent)

FIGURE 56.10 Papilloedema with swollen optic disc of the ocular fundus due to raised intracranial pressure

### § Intracerebral tumours

- Incidence is 5–10 per 100 000 population
- Two peaks of incidence: children <10 years<sup>3</sup> and 35–60 years
- Main types of tumour:
  - children: medulloblastoma, astrocytoma (posterior fossa), ependymoma, glioma (brain stem)
  - adults: cerebral glioma, meningioma, pituitary adenoma, cerebral metastases (e.g. lung)

### Investigations

- CT scan and MRI

### § Subarachnoid haemorrhage

SAH is a life-threatening event that should not be overlooked at the primary care level. The incidence is 12 per 100 000 population per annum. About 40% of patients die before treatment, while about one-third have a good response to treatment.

Approximately 75% will present with an acute severe headache and the remainder with loss of consciousness.

### Clinical features

- Sudden severe ‘thunderclap’ headache
- Occipital location
- Localised at first, then generalised
- Pain and stiffness of the neck follows
- Vomiting and loss of consciousness often follow
- Confusion or a lowered consciousness level
- $\pm$  seizures
- Kernig sign positive (see CHAPTER 30)
- Neurological deficit may include: hemiplegia (if intracerebral bleed), third nerve palsy (partial or complete) (see FIG. 56.11)

About one-third of patients experience a ‘sentinel’ headache.

**DxT** occipital headache + vomiting + neck stiffness → SAH

### Diagnosis

CT scanning is the investigation of choice and should be performed in the first few hours (blood has dispersed by 6 hours). Lumbar puncture is not necessary if the diagnosis can be made by CT, but is used if the CT scan is negative (usually 10–20% of cases). It may be falsely negative after 7 days. Even blood staining of CSF and xanthochromia is a positive feature on lumbar puncture.

### Special notes

- Less severe headaches can cause diagnostic difficulties.
- Consider an angioma rather than an aneurysm as the cause of SAH if previous episodes.

### Management

Immediate referral for possible surgical intervention is required. If there is lingering doubt, review the patient within 12–24 hours.

FIGURE 56.11 Third nerve palsy (right side)

## § Meningitis

The headache of meningitis is usually generalised and radiates to the neck. It is constant and severe and occasionally may begin abruptly. It is aggravated by flexion of the neck. Kernig sign is positive. Fever and neck stiffness is usually present. Urgent referral to hospital is necessary. If meningitis is suspected or if a child or adult has headache with fever and neck stiffness, antibiotics must not be given until a lumbar puncture has been performed.

## § Drug rebound headache

Rebound headaches are usually associated with analgesic and ergotamine dependence. A long list of over-the-counter and prescription medications can cause rebound, for example, aspirin, paracetamol, ibuprofen, opioids and caffeine. The headache is present on waking and typically persists throughout the day but fluctuates in intensity. It is a mild to moderate, dull, bilateral ache with a distribution similar to tension headache. Drug rebound headaches should be suspected in any patient who complains of headache 'all day every day'. A careful drug history should be taken. Treatment includes gradual withdrawal of the drugs and the substitution of antiemetics and amitriptyline or beta blocker over about 14 days.

## § Chronic paroxysmal hemicrania

This is a rare headache syndrome that overlaps with cluster headache and facial pain. The unilateral pain, which can be excruciating, is located in the area of the temple, forehead, eye and upper face. It can radiate to the ear, neck and shoulder. It differs from cluster headaches in that the patients are invariably female, the paroxysms are short (average 20–30 minutes) and more frequent, with attacks occurring up to 14 times a day. The disorder resembles cluster headaches in nature and distribution and associated autonomic features, such as ipsilateral nasal stuffiness or rhinorrhoea, lacrimation, conjunctival injection and ptosis. The aetiology is unknown but the headache often responds dramatically to indomethacin (25 mg (o) tds).<sup>10</sup>

## § Post-traumatic headache

This is a continuous, diffuse type of headache with associated psychological symptoms such as dizziness, irritability and depression. It can persist for 6–12 months and is best treated with aspirin or paracetamol. If unresponsive and persistent, amitriptyline or sodium valproate can be tried.<sup>9</sup>

## § Post-lumbar-puncture headache<sup>9</sup>

This is common and is usually present when standing or sitting and rapidly improves with lying flat. It is a form of low-pressure headache, possibly due to CSF leakage. It can be severe with nausea and vomiting. In most resolution occurs within 2–7 days. Treatment includes bed rest until resolution. If persistent, referral for an epidural blood patch is recommended.

## § Trigeminal neuralgia

The pain of trigeminal neuralgia comes in excruciating paroxysms, which last for seconds to minutes only and usually affect the face rather than the head (see CHAPTER 52). The lightning-like jabs of searing or burning pain usually last 1 to 2 minutes but can last as long as 15 minutes.

## § Icepick headache

Icepick headaches are similar sudden stabbing pains lasting a few seconds usually at the temple (often bilateral) and are more common in migraine sufferers. They can occur unpredictably 30 or more times a day. Treatment is with indomethacin 25 mg tds.<sup>9</sup>

## § Hypertension headache

It tends to occur only in severe hypertension such as malignant hypertension or hypertensive encephalopathy. The headache is typically occipital, throbbing and worse on waking in the morning.

The headache may be psychogenic in origin, developing after the diagnosis of hypertension is disclosed to the patient. However, the occasional patient has genuine headache related to milder hypertension and this serves as an accurate indicator of their blood pressure level.

## § Benign intracranial hypertension (pseudotumour cerebri)

This is a rare but important sinister headache condition that typically occurs in young obese women mainly in the second to fifth decades but can occur at any age. Key features are headache, visual blurring and obscurations, nausea and papilloedema. It is considered to be due to a disturbance in the CSF circulation. The CT and MRI scans are normal but lumbar puncture reveals increased CSF pressure and normal CSF analysis.

It is sometimes linked to drugs, including tetracyclines (most common), nitrofurantoin, oral

contraceptive pill, steroids and vitamin A preparations. The main concern is visual deficits from the high intracranial pressure. Urgent referral is essential. Medical treatment includes weight reduction, corticosteroids and diuretics. The treatment of choice to alleviate symptoms is repeated lumbar puncture. Surgery, which involves decompression of the optic nerves or lumbo-peritoneal shunting, is sometimes required for failed medical therapy.

**DxT** headache + visual obscurations + nausea → benign intracranial hypertension

## HEADACHES RELATED TO SPECIFIC ACTIVITIES

### § Sex headache

This can manifest as a dull or explosive headache, provoked by sexual arousal and activity, especially with orgasm. Some are clearly a form of exertional headache. Sometimes sex headache is mistaken for SAH but if the severe headache coincided with orgasm, was not associated with vomiting or neck stiffness, or settled within hours, SAH is unlikely. Treatment is with prophylactic beta blockers or ergotamine 1 mg (o) 1–2 hours before activity.

### § Cough and exertional headache

Some people experience a severe transient pain with factors such as coughing, sneezing, stooping, straining, lifting and various sporting activities. It is usually benign and examination is normal. A CT scan is indicated if there are focal signs or if the symptoms do not settle.

Treatment is indomethacin 25 mg (o) 2–3 times daily for cough headache and 1–2 hours before exertional activity.

### § Gravitational headache

Occipital headache, coming on when standing upright and relieved by lying down, is characteristic of a post-lumbar puncture, an epidural block or low pressure headache. It can last for several weeks after the procedure.

### § 'Ice-cream' headache

Frontal or global headache can be provoked by the rapid ingestion of very cold food and drink. It is a form of vascular headache.

## When to refer

- Evidence or suspicion of SAH or intracerebral haematoma
- Complicated migraine
- Uncertain diagnosis
- Positive neurological signs despite typical headaches

## Practice tips

- A patient >55 years presenting with unaccustomed headache has an organic disorder such as TA, intracerebral tumour or subdural haematoma until proved otherwise.
- The ESR is an excellent screening test to diagnose TA but occasionally can be normal in the presence of active TA.
- If a patient presents twice within 24 hours to the same practice or hospital with headache and vomiting, consider other causes apart from migraine before discharging the patient.<sup>8</sup>
- If migraine attacks are severe and unusual (e.g. always on the same side) consider the possibility of cerebral vascular malformation.
- CT scans and MRI have superseded other investigations in the diagnosis of cerebral tumours and intracranial haemorrhage but should be ordered sparingly and judiciously.
- If a headache is occipital in origin or accompanied by neck pain, consider the likely possibility of cervical dysfunction and refer to the appropriate therapist once the diagnosis is established.
- For recurrent migraine sufferers emphasise the importance of trigger factor avoidance and of taking aspirin and metoclopramide medication at the earliest warning of an attack.
- A severe headache of sudden onset is SAH until proved otherwise. It is overlooked sometimes.
- SAH is overlooked sometimes, mainly because it is not considered in the differential diagnosis. Suspect with very severe and protracted headache, drowsiness and neck stiffness.
- Medical evidence indicates that most headaches are related to fatigue, stress or migraine triggers and respond to application of heat or cold, exercise and common analgesics, including aspirin and ibuprofen.<sup>15</sup>
- If women with migraine demand the oral contraceptive, use a low-dose oestrogen preparation and monitor progress.
- The use of narcotics for migraine treatment (such as pethidine and codeine) is to be avoided whenever possible—the frequent use of ergotamine, analgesics or narcotics can transform episodic migraine into chronic daily headache.<sup>4</sup>

*Hoarseness results from imperfect phonation due to impairment of normal vocal cord mobility or vibration. It is an important symptom as it may signal a serious cause such as malignancy or a disease with potential for airway obstruction.<sup>1</sup>*

Raymond L Carroll 1996

Hoarseness (dysphonia) is defined as an altered voice due to a laryngeal disorder.<sup>2</sup> It is an important symptom of laryngeal disease presenting in general practice, and ranges from the very common, trivial, self-limiting condition of viral upper respiratory tract infection to a life-threatening disorder (see TABLE 57.1). It may be of sudden presentation lasting only a few days or develop gradually and persist for weeks or months. The cut-off point between acute and chronic hoarseness is three weeks duration, by which time most self-limiting conditions have resolved. Hoarseness pertains to harsh, raspy, gravelly or rough tones of voice rather than pitch or volume. Rarely, hoarseness can be a functional or deliberate symptom referred to as 'hysterical aphonia'.<sup>3</sup> In this condition, patients purposely hold the cords apart while speaking.

**Table 57.1** Hoarseness: diagnostic strategy model

Q. Probability diagnosis
A. Viral URTI: acute laryngitis Non-specific irritative laryngitis (Reinke oedema) Vocal abuse (shouting, screaming, etc.) Nodules and polyps of cords Presbyphonia in elderly: 'tired' voice Acute tonsillitis
Q. Serious disorders not to be missed
A. Cancer: larynx, lung, including recurrent laryngeal nerve palsy, oesophagus, thyroid Imminent airway obstruction (e.g. acute epiglottitis, croup) Other rare severe infections (e.g. TB, diphtheria) Foreign body Motor neurone disease Aortic arch aneurysm Myasthenia gravis
Q. Pitfalls
A. Toxic fumes Vocal abuse Benign tumours of vocal cords (e.g. polyps, 'singer's nodules', papillomas)

Gastro-oesophageal reflux → pharyngolaryngitis  
Goitre  
Vocal cord palsy  
Dystonia  
Physical trauma (e.g. post-intubation), haematoma  
Fungal infections (e.g. *Candida* with steroid inhalation, immunocompromised)  
Allergy (e.g. angioedema)  
Leucoplakia  
Systemic autoimmune disorders (e.g. SLE, Wegener granulomatosis)

- Q. Masquerades
- A. Consider:
- drugs: antipsychotics, anabolic steroids
  - smoking → non-specific laryngitis
  - hypothyroidism, acromegaly
- Q. Is the patient trying to tell me something?
- A. Consider:
- functional aphonia
  - functional stridor

## Key facts and checkpoints

- In acute hoarseness the diagnosis is usually obvious from the history alone. Examples include acute upper respiratory tract infection (URTI) or vocal overuse.
- Think 'hypothyroidism' if unusual hoarseness develops.
- Laryngeal cancer must be excluded if hoarseness persists for longer than 3 weeks in an adult. It can arise intrinsic or extrinsic to the vocal cords.
- Intermittent hoarseness is invariably secondary to a benign disorder. Constant or progressive hoarseness suggests malignancy.
- Non-malignant vocal cord lesions, which include polyps, vocal nodules, contact ulcers, granulomas, other benign tumours and leucoplakia, account for about half of all voice disorders.

*continued*

*continued*

- In cases of chronic hoarseness the larynx must be visualised for diagnosis but the following are common:
  - children—'screamer's nodules'
  - adults—non-specific irritant laryngitis
- Acute laryngeal oedema may develop as a component of the life-threatening acute angioedemic allergic response.
- Elderly or debilitated patients may exhibit a shaky or soft 'pseudohoarse' voice due to a weakened respiratory effort. This is termed phonaesthesia or presbyphonia.
- Contact ulcers of the larynx occur on the posterior third of the vocal cords where the mucosa is thin. The resultant weak hoarse voice may be accompanied by painful phonation. The ulcers may develop into granulomas. Apart from intubation, the condition is usually found in forceful orators who misuse their larynx when attempting to lower the pitch of their voice.<sup>3</sup>

## The clinical approach

### History

Note the nature and duration of the voice change. Inquire about corticosteroid inhalations, excessive or unaccustomed voice straining (especially singing), recent surgery, possible reflux, smoking or exposure to environmental pollutants. Elicit associated respiratory or general symptoms such as cough and weight loss. Consider symptoms of hypothyroidism.

### Examination

Palpate the neck for enlargement of the thyroid gland or cervical nodes. Perform a simple oropharyngeal examination except if epiglottitis is suspected. Check for signs of hypothyroidism, such as coarse dry hair and skin, slow pulse and mental slowing. Perform indirect laryngoscopy if skilled in the procedure.

### Investigations

The following need to be considered:

- Thyroid function tests.
- Chest X-ray if it is possibly due to lung cancer with recurrent laryngeal nerve palsy.
- Indirect laryngoscopy (the gag reflex may preclude this).
- Direct laryngoscopy with a flexible fibre-optic endoscope with possible biopsy (the most sensitive investigation).
- The choice of imaging to detect suspected neoplasia or laryngeal trauma is special CT scan.

## Management principles

### Acute hoarseness

- Treat according to cause.
- Advise vocal rest or minimal usage at normal conversational level.
- Avoid irritants (e.g. dust, tobacco, alcohol).
- Consider inhalations and cough suppressants in cases of acute URTI and coughing paroxysms.

### Chronic hoarseness

- Establish the diagnosis.
- Consider referral to ENT specialist.

## Hoarseness in children

- It is worth bearing in mind that stridor in infants can be caused by a congenital abnormality of the larynx, including laryngomalacia (congenital laryngeal stridor), which is particularly noticeable when the child is asleep; laryngeal stenosis (congenital laryngeal narrowing); and laryngeal paralysis due to birth trauma of the vagus nerve. Vocal cord paralysis/palsy is the most common laryngeal abnormality in children (20% of cases) after laryngomalacia.<sup>3</sup>
- In children exclude the acute infections—laryngotracheobronchitis (croup), tonsillitis and epiglottitis.
- Persistent hoarseness in children is due commonly to vocal cord nodules related to vocal abuse, such as screaming and yelling, often due to noisy children's games.
- It is important to exclude a juvenile papilloma in a hoarse child.<sup>4</sup>

## SPECIFIC CONDITIONS

### § Acute laryngitis

Most cases are caused by the respiratory viruses—rhinovirus, influenza, para-influenza, Coxsackie, adenovirus and respiratory syncytial virus, resulting in vocal cord oedema (be cautious of group A *Streptococcus*). The main symptom is hoarseness, which usually persists for 3–14 days and leads to loss of voice. Even speaking can be painful. Aggravating factors include smoking, excessive alcohol drinking, and exposure to irritants and pollutants, air-conditioning systems and very cold weather.

### Management

- Rest at home, including voice rest (the best treatment).

- Use the voice sparingly, avoid whispering.
- Use a warm sialagogue (e.g. hot lemon drinks).
- Drink ample fluids, especially water.
- Avoid smoking, passive smoke and alcohol.
- Have hot, steamy showers as humidity helps.
- Use steam inhalations (e.g. 5 minutes, three times a day).
- Use cough suppressants, especially mucolytic agents.
- Use simple analgesics, such as paracetamol or aspirin, for discomfort.
- Antibiotics are of no proven use unless there is evidence of bacterial infection. Corticosteroids are rarely indicated.

### § Chronic laryngitis: 'barmaid syndrome'

This typically occurs in a heavy smoker who works in a heavy smoking environment, who is a heavy drinker and continually talks or sings. It is a combination of vocal abuse and chemical irritation. Hoarseness often comes and goes. Treatment involves modification of these factors and screening for vocal cord tumours.

Chronic laryngitis due to laryngopharyngeal reflux is treated with an 8–12 week empirical course of proton-pump inhibitors as well as dietary and lifestyle modification.<sup>2</sup>

### § Benign tumours of the vocal cords

These include nodules (most common) (see FIG. 57.1), polyps (number 2), cysts and papules. Vocal cord nodules, including 'singer's nodules',

FIGURE 57.1 Vocal cord nodules

may respond well to conservative measures such as a voice rest and vocal therapy. If not, they can be removed by microlaryngeal surgery or laser therapy. Dependent polyps and papillomas are removed by microsurgery.

### § Laryngeal cancer

Squamous cell carcinoma usually occurs in patients with a history of chronic laryngitis, smoking and alcohol use. Symptoms include hoarseness, stridor, haemoptysis and dysphagia. It may be preceded by leucoplakia, which is treated by vocal cord stripping under microsurgery. The diagnosis based on persistent hoarseness is made after fibre-optic laryngoscopy and biopsy by a specialist. The patient may present with an unexplained cervical lymph node. The condition is curable if detected early. Small local tumours can be treated by radiotherapy or laser therapy. Larger tumours usually require laryngectomy and perhaps dissection of the cervical lymph nodes (Commando operation). Such radical surgery demands considerable patient support, including education about speech, eating and tracheostomy care.

### When to refer<sup>1</sup>

- Acute cases that are unexplained, fail to respond by 3–4 weeks or recur.
- All chronic cases.
- Any case with stridor or non-tender cervical lymphadenopathy.
- Patients requiring voice therapy when vocal abuse is identified.

### Practice tips

- Consider intubation as a possible cause of transient hoarseness, especially in these times of day surgery.<sup>5</sup>
- Consider gastro-oesophageal reflux disease in the elderly but avoid such a diagnosis without specialist investigation for other causes.
- If stridor is present with acute hoarseness, the airway is compromised. Be on stand-by for possible emergency intervention.
- Prevention is the best treatment for laryngeal cancer (i.e. quit smoking).
- Recurrent laryngeal nerve palsy may be associated with cancer of the lung and mediastinum, or diabetes, or may be idiopathic.

*The disease is produced by black bile when it flows into the liver. The symptoms are these: 'an acute pain in the liver, also below the breast, a feeling of suffocation is strong during these days and becomes less strong later'. The liver is tender to palpation and the complexion of the patient is somewhat livid. These are symptoms that occur in the beginning but as the disease progresses, the fever diminishes in strength and the patient feels sated after ingesting a little amount of food. He must drink melikration [a mixture of water and honey].*

Hippocrates on hepatitis

Jaundice is a yellow discolouration of the skin and mucosal surfaces caused by the accumulation of excessive bilirubin.<sup>1</sup> It is a cardinal symptom of hepatobiliary disease and haemolysis. Important common causes include gallstones, hepatitis A, hepatitis B, hepatitis C, drugs, alcohol and Gilbert syndrome. The commonest clinical encounter with jaundice, especially physiological jaundice, is in the newborn. As for all patients, the history and examination are paramount, but investigations are essential to clinch the diagnosis of jaundice.

The three major categories of jaundice are (see FIG. 58.1):

- obstructive:
  - extrahepatic
  - intrahepatic
- hepatocellular
- haemolytic

## Key facts and checkpoints

- Jaundice is defined as a serum bilirubin level exceeding  $19 \mu\text{mol/L}$ .<sup>2</sup>
- Clinical jaundice manifests only when the bilirubin level exceeds  $50 \mu\text{mol/L}$ .<sup>1</sup>
- However, jaundice is difficult to detect visually below  $85 \mu\text{mol/L}$  if lighting is poor.
- It can be distinguished from yellow skin due to hypercarotenaemia (due to dietary excess of carrots, pumpkin, mangoes or pawpaw) and hypothyroidism by involving the sclera.
- The most common causes of jaundice recorded in a general practice population are (in order) viral hepatitis, gallstones, pancreatic cancer, cirrhosis, pancreatitis and drugs.<sup>3</sup>
- Always take a full travel, drug and hepatitis contact history in any patient presenting with jaundice.
- Acute hepatitis is usually self-limiting in patients with hepatitis A and in adults with hepatitis B but

progresses to chronic infections with hepatitis C and children with hepatitis B.<sup>4</sup>

- A fatty liver (steatosis) can occur not only with alcohol excess but also with obesity, diabetes and starvation. There is usually no liver damage and thus no jaundice.

**Table 58.1** Abbreviations used in this chapter

Hepatitis A virus	HAV
Hepatitis A antibody	anti-HAV
Immunoglobulin M	IgM
Immunoglobulin G	IgG

Hepatitis C virus	HCV
Hepatitis C virus antibody	anti-HCV
Hepatitis D (Delta) virus	HDV
Hepatitis E virus	HEV
Hepatitis F virus	HFV
Hepatitis G virus	HGV

## A diagnostic approach

A summary of the diagnostic strategy model is presented in TABLE 58.2.

## Probability diagnosis

The answer depends on the age and social grouping of the patient, especially if the patient indulges in risk-taking behaviour or has travelled overseas.

FIGURE 58.1 The jaundice pathway

Viral hepatitis A, B or C account for the majority of cases of jaundice.

In the middle-aged and elderly group, a common cause is obstruction from gallstones or cancer. It is common for older people to have painless obstructive jaundice; bear in mind that the chances of malignancy increase with age.

Alcoholic liver disease is common and may present as chronic alcoholic cirrhosis with liver failure or as acute alcoholic hepatitis. It is worth emphasising that such patients can make a dramatic recovery when they cease drinking alcohol.

In family practice we encounter many cases of drug-induced jaundice, especially in the elderly. These drugs are outlined later in the chapter, under 'Seven masquerades checklist'.

### Serious disorders not to be missed

Malignancy must always be suspected, especially in the elderly patient and those with a history of chronic active hepatitis (e.g. post hepatitis B or C infection). The former is more likely to have carcinoma of the

head of the pancreas and the latter, hepatocellular carcinoma (hepatoma).

Metastatic cancer must be kept in mind, especially in those with a history of surgery, such as large bowel cancer, melanoma and stomach cancer. An enlarged, knobbly, hard liver is a feature.

Hepatic failure can be associated with severe systemic infection (e.g. septicaemia and pneumonia), and after surgery in critically ill patients. A patient who has the classic Charcot triad of upper abdominal pain, fever (and chills) and jaundice should be regarded as having ascending cholangitis until proved otherwise. Wilson syndrome, although rare, must be considered in all young patients with acute hepatitis. A history of neurological symptoms, such as a tremor or a clumsy gait, and a family history is important. If Wilson syndrome is suspected an ocular slit lamp examination, serum ceruloplasmin levels (low in 95% of patients) and a liver biopsy should be performed. Early diagnosis and treatment mean a better prognosis.

Reye syndrome is a rare and severe complication of influenza and some other viral diseases, especially

**Table 58.2** Jaundice (adults): diagnostic strategy model

Q.	Probability diagnosis
A.	Hepatitis A, B, C (mainly B, C) Gallstones in common bile duct Alcoholic hepatitis/cirrhosis

Malignancy: <ul style="list-style-type: none"> <li>• pancreas</li> <li>• biliary tract</li> <li>• hepatocellular (hepatoma)</li> <li>• metastases</li> </ul> Severe infections: <ul style="list-style-type: none"> <li>• septicaemia</li> <li>• ascending cholangitis</li> <li>• fulminant hepatitis</li> <li>• HIV/AIDS</li> </ul> Rarities: <ul style="list-style-type: none"> <li>• Wilson syndrome</li> <li>• Reye syndrome</li> <li>• acute fatty liver of pregnancy</li> </ul>
Q.	Pitfalls (often missed)
A.	Gallstones Gilbert syndrome Cardiac failure Primary biliary cirrhosis Autoimmune chronic active hepatitis Primary sclerosing cholangitis Chronic viral hepatitis Haemochromatosis Viral infections (e.g. CMV, EBV) Leptospirosis
Q.	Seven masquerades checklist
A.	Drugs Anaemia
Q.	Is the patient trying to tell me something?
A.	Not usually applicable.

in children when given aspirin. There is rapid development of hepatic failure and encephalopathy.

## Pitfalls

Gallstones, especially in the absence of upper abdominal pain, can be overlooked, so this possibility should be kept in mind in the elderly.

Gilbert syndrome is worth considering, especially as it is the commonest form of unconjugated hyperbilirubinaemia. It affects at least 3% of the population.

Cardiac failure can present as jaundice with widespread tenderness under the right costal

margin. It can be insidious in onset or manifest with gross acute failure. It can be confused with acute cholecystitis. The biochemical abnormalities seen are very variable. Usually there is a moderate rise in bilirubin and alkaline phosphatase and sometimes, in acute failure, a marked elevation of transaminase may occur, suggesting some hepatocellular necrosis.

There are many other pitfalls for a family doctor, who may encounter the conditions very rarely, if at all. Such disorders include:

- inherited conjugated hyperbilirubinaemias (Dubin–Johnson and Rotor syndromes) caused by faulty excretion by liver cells
- haemochromatosis (associated pigmentation and diabetes)
- chronic active hepatitis
- primary biliary cirrhosis
- primary sclerosing cholangitis (associated with ulcerative colitis)

## General pitfalls

- Excluding jaundice by examining the sclera in artificial light
- Not realising that the sclera in elderly patients often have an icteric appearance (without jaundice)
- Omitting to take a careful history, including illicit drugs
- A liver biopsy is essential in all patients with chronic hepatitis

## Seven masquerades checklist

Of this group the haemolytic anaemias and drugs have to be considered.

## Drug-related jaundice

Drug-induced jaundice is common and many drugs are implicated. The patterns of drug-related liver damage include cholestasis, necrosis ('hepatitis'), granulomas, chronic active hepatitis, cirrhosis, hepatocellular tumours and veno-occlusive disease.<sup>4,5</sup> Some drugs, such as methyl dopa, can initiate haemolysis.

The important drugs to consider are presented in **TABLE 58.3**. Antibiotics, especially flucloxacillin, amoxycillin + clavulanate and erythromycin, are commonly implicated.

## Haemolysis

The patient may present with the symptoms of underlying anaemia and jaundice with no noticeable change in the appearance of the urine and stool. The degree of haemolysis may vary from the

**Table 58.3** Drugs that can cause jaundice

## Haemolysis

## Methyldopa

## Hepatocellular damage

## Dose-dependent:

- paracetamol (can cause acute hepatic necrosis)
- salicylates
- tetracycline

## Dose-independent:

- anaesthetics (e.g. halothane)
- antidepressants (e.g. MAOIs)
- anti-epileptics (e.g. phenytoin, sodium valproate, carbamazepine)
- antibiotics (e.g. penicillins, sulphonamides)
- antimalarials (e.g. Fansidar)
- antituberculosis (e.g. isoniazid)
- anti-inflammatories (e.g. NSAIDs, various)
- carbon tetrachloride
- cardiovascular (e.g. amiodarone, methyldopa, perhexiline)
- statins (e.g. simvastatin)

## Cholestasis

## Antithyroid drugs

## Chlorpromazine

## Erythromycin estolate

## Penicillins, esp. flucloxacillin

## Gold salts

## Oral contraceptives/oestrogens

## Synthetic anabolic steroids (e.g. methyltestosterone)

## Hypoglycaemic drugs (e.g. chlorpropamide)

## Amitriptyline

## Others

## Allopurinol

## Cimetidine (aggravated by alcohol)

## Cytotoxics (e.g. methotrexate, azathioprine)

## Etretnate

## Hydralazine

## Nitrofurantoin

## Vitamin A (mega dosage)

## Various complementary medicines (e.g. herbal agents)

lemon-yellow tinge of pernicious anaemia in an elderly patient to a severe haemolytic crisis precipitated by drugs or broad beans (favism) in a patient with an inherited red cell deficiency of glucose-6-phosphate dehydrogenase (G6PD). More common causes include the hereditary haemolytic anaemias, such as congenital spherocytosis and thalassaemia major. Acquired causes include incompatible blood transfusions, malignancies (such as lymphoma), severe sepsis and some drugs.

Splenomegaly occurs in most patients with haemolytic anaemia, and decreased red cell survival can be measured.

## Psychogenic considerations

This is not really applicable for an organic problem such as jaundice. Nevertheless, the cause may be related to factors in the patient's lifestyle, such as homosexuality, sexual promiscuity or intravenous drug abuse, and the patient may be reluctant to offer this information. Discreet, concerned probing will be necessary.

## Red flag pointers for jaundice

- Unexplained weight loss
- Progressive jaundice including painless jaundice
- Oedema
- Cerebral dysfunction (e.g. confusion, somnolence)

## The clinical approach

### History

The history should include questioning about the following:

- any episodes of jaundice
- change in colour of faeces and urine
- anorexia, sore throat, weight loss, pruritus
- abdominal pain
- residence and members of household
- contact with patients with hepatitis or jaundice
- recent overseas travel
- exposure to blood or blood products
- needle-stick injuries or exposure to needles, such as acupuncture, tattooing and intravenous drugs
- dietary history—shellfish, drinking water
- sexual history—evidence of promiscuity
- drug history, including alcohol, paracetamol
- recent medical history, including surgery
- family history—family contacts who have had jaundice, haemolytic disease and other genetic liver diseases

- ethnic history—liable to haemolytic disease, contact with hepatitis B
- occupational history—exposure to hazards

### Significance of various symptoms

- Pain in the right hypochondrium:
  - gallstones
  - acute hepatitis (a constant ache)
  - cholecystitis
- Anorexia, dark urine, fever:
  - viral hepatitis probable
  - alcoholic liver disease possible
  - drug-induced hepatitis possible
- Pruritus:
  - cholestasis probable
  - possible with all liver diseases
- Arthralgia, rash:
  - viral hepatitis
  - autoimmune hepatitis

### Examination

The abdominal examination is very important. The liver should be palpated carefully for enlargement, consistency and tenderness under the right costal margin. Search for enlargement of the gall bladder and the spleen. The gall bladder lies in the transpyloric line. A palpable gall bladder indicates extrahepatic biliary obstruction, and splenomegaly may indicate haemolytic anaemia, portal hypertension or viral hepatitis. Test for ascites.

Skin excoriation may indicate pruritus, which is associated with cholestatic jaundice. Look for evidence of chronic liver disease, such as palmar erythema, easy bruising, spider naevi and muscle

wasting, and testicular atrophy and gynaecomastia. Test for hepatic flap (asterixis) and fetor, which indicate liver failure. Search for lymphadenopathy, which may be indicative of malignancy.

The examination should include dipstick urine testing for bilirubin and urobilinogen.

A summary of the possible findings is presented in [FIGURE 58.2](#).

### Investigations

The main investigations are FBE and the standard LFTs and viral serology for the infective causes, particularly hepatitis A, B and C virus (also EBV and CMV).

A summary of the general findings for liver function tests is shown in [TABLE 58.4](#). Consideration should be given to ordering fractionalisation of bilirubin to determine whether it is conjugated or unconjugated (important in diagnosis of Gilbert syndrome).

### Diagnostic markers for hepatitis

- Hepatitis A: IgM antibody (HAV Ab)
- Hepatitis B: surface antigen (HBsAg)
- Hepatitis C: HCV antibody (HCV Ab)

### Hepatobiliary imaging

Tests to identify causes such as malignancy or gallstones are now sophisticated and should be chosen with care.

- X-ray: a plain abdominal X-ray shows up to 10% of gallstones
- Transabdominal ultrasound (US): the most useful investigation for detecting gallstones

**Table 58.4** Characteristic liver function tests for selected types of liver disease

Liver function tests (serological)	Hepatocellular (viral) hepatitis	Haemolytic jaundice	Obstruction	Gilbert syndrome	Liver metastases/ abscess	Alcoholic liver disease
<b>Bilirubin</b>	↑ to ↑↑↑	↑ unconjugated	↑ to ↑↑↑	↑ up to 50 unconjugated	↑ to N	↑ to N
<b>Alkaline phosphatase</b>	↑ <2N	N	↑↑↑ >2N	N	↑↑ to ↑↑↑	↑
<b>Alanine transferase (ALT)</b>	↑↑↑ >5N	N	N or ↑	N	↑	↑

**FIGURE 58.2** Possible findings on examining the jaundiced patient

and dilatation of the common bile duct; also detects liver metastases and other diffuse liver diseases

- HIDA scintiscan: useful in diagnosis of acute cholecystitis
- CT scan: for diagnosis of enlargement of the head of the pancreas and other pathology; indicated if US unsatisfactory
- PTC: percutaneous transhepatic cholangiography: shows imaging of biliary tree
- ERCP: endoscopic retrograde cholangiopancreatography; PTC and ERCP (best) determine the cause of the obstruction and relieves it by sphincterotomy and removal of CBD stones

- MRCP: magnetic resonance cholangiography provides non-invasive planning for obstructive jaundice
- Liver isotopic scan: useful for liver cirrhosis, especially of the left lobe

### Specific tests

Some specific tests include:

- autoantibodies for autoimmune chronic active hepatitis and primary biliary cirrhosis
- carcinoembryonic antigen to detect liver secondaries, especially colorectal
- serum iron studies, especially transferrin saturation—elevated in haemochromatosis

- alpha-fetoprotein—elevated in hepatocellular carcinoma; mild elevation with acute or chronic liver disease (e.g. cirrhosis)
- serum ceruloplasmin level—low in Wilson syndrome
- liver biopsy
- EBV/cytomegalovirus serology (consider if hepatitis serology negative)

## Jaundice in children

### JAUNDICE IN THE INFANT

Jaundice in the newborn is clinically apparent in 50% of term babies and more than 80% of preterm.<sup>6</sup> Icterus is therefore common and invariably physiologically benign. However, it is a cause for concern as there are many other causes and investigation is needed to determine whether the bilirubin is conjugated (always pathological) or unconjugated. If conjugated, consider the serious biliary atresia (stools are white); also a cyst obstructing the bile duct or neonatal hepatitis. Prompt referral is essential.

Jaundice occurring in the first 24 hours after birth is not due to immature liver function but is pathological and usually due to haemolysis consequent on blood group incompatibility. In primigravidae it is usually due to ABO incompatibility.

### Bilirubin encephalopathy

Unconjugated bilirubin can be regarded as a neurological poison. With increasing serum levels an encephalopathy (which may be transient) can develop, but if persistent can lead to the irreversible brain damage known as kernicterus. The level of bilirubin causing kernicterus is totally unpredictable, but a guideline as a cause for concern in babies with Rh disease is a serum unconjugated bilirubin of 340  $\mu\text{mol/L}$  (20 mg/dL).

Guidelines for treatment for hyperbilirubinaemia (at 24–36 hours)—an example

- >285  $\mu\text{mol/L}$ —phototherapy
- >360  $\mu\text{mol/L}$ —consider exchange transfusion

An example of a normogram is presented in FIGURE 58.3.

### Physiological jaundice

This mild form of jaundice, which is very common in infants, is really a diagnosis of exclusion. In a term infant the serum bilirubin rises quickly after birth to reach a maximum by day 3–5, then declines rapidly over the next 2–3 days before fading more

FIGURE 58.3 Typical normogram for decision making in healthy infants with jaundice

slowly for the next 1–2 weeks. Management includes phototherapy.

### Pathological jaundice

There are many causes of pathological jaundice, including:

- haemolysis (e.g. blood grouping incompatibilities, ABO or Rhesus, G6PD deficiency, hereditary spherocytosis)
- polycythaemia (e.g. intrauterine growth retardation)
- inherited conjugation defects (e.g. uridyl diphosphate glucuronyl transferase deficiency)
- breast milk jaundice
- drugs
- sepsis
- hypothyroidism
- biliary atresia

Such cases require referral for evaluation and management.

### § ABO blood group incompatibility

This is antibody-mediated haemolysis (Coomb test positive):

- Mother is O
- Child is A or B

Jaundice develops within first 24 hours.

### Treatment

- Perform a direct Coomb test on infant.
- Phototherapy is required immediately.
- These children require follow-up developmental assessment including audiometry.

### § Breast milk jaundice

If the secondary causes of prolonged jaundice are excluded, the baby is well and breastfeeding, the likely cause of unconjugated elevated bilirubin is breast milk jaundice. It occurs in 2–4% of breastfed infants. It usually begins late in the first week and peaks at 2–3 weeks. Diagnosis is confirmed by suspending (not stopping) breastfeeding for 24–48 hours. The serum bilirubin falls and then breastfeeding can continue. The mother, who can express milk for this short period, must be reassured that there is nothing wrong with the milk and advised to resume. Some doctors recommend continuation of breastfeeding.

### JAUNDICE IN OLDER CHILDREN

Viral infection is the commonest cause of jaundice in the older child, especially hepatitis A and hepatitis B. It is uncommon for viral hepatitis to become chronic in childhood.

### Jaundice in the elderly

If an elderly person presents with jaundice the usual causes and investigations have to be considered. Obstructive jaundice is the commonest form of jaundice in the elderly and may be caused by gallstones blocking the common bile duct (may be painless) and carcinoma of the head of the pancreas, the biliary tract itself, the stomach or multiple secondaries for other sites. While it is not uncommon for a gallstone to produce marked obstructive jaundice and yet be painless, it is appropriate to adhere to the old adage that painless obstructive jaundice is due to neoplasm—particularly if the gall bladder is palpable (Courvoisier's law).

Alcoholic liver disease, although most frequently affecting patients between 40 and 60 years, can present for the first time over age 60 years. The commonest cause of hepatocellular jaundice in the elderly is probably alcoholic cirrhosis; hepatitis A is still relatively uncommon in old persons.

Drugs do not cause jaundice in the elderly as frequently as they once did, particularly as phenothiazines, especially chlorpromazine, are not prescribed as often as previously. However, drugs should be considered as a potential cause and a careful check of the drug history is important.

### Infective causes of jaundice

A generation ago hepatitis A (infectious hepatitis or yellow jaundice) was the commonest recognised form of viral hepatitis, presenting usually with an abrupt onset of fever, anorexia, nausea and vomiting. It usually occurred in epidemics and hence was common in overcrowded institutions and camps. Now hepatitis B and C are the most commonly reported types of viral hepatitis with an onset that is more insidious and with a longer incubation period.<sup>4,7</sup> Symptoms include malaise, anorexia, nausea and polyarthritides. Acute hepatitis C is often subclinical.

The various forms of hepatitis are summarised in TABLE 58.5. All forms of hepatitis are common in developing countries and travellers are at risk of contracting these infections: hepatitis A and E from faeco-oral transmission; and hepatitis B, C, D and G from intravenous drugs and bodily fluids (from sexual transmission, in particular, for hepatitis B).

Evidence points to more viruses causing non-ABC hepatitis.<sup>8</sup> Hepatitis F virus has been claimed to be transmitted enterically while the newly designated hepatitis G virus (HGV) is transmitted parenterally. It does not appear to cause a severe illness in recipients. It can be predicted that the hepatitis alphabet will continue to expand.

In hepatitis A, liver damage is directly due to the virus, but in hepatitis B and C it is due to an immunologic reaction to the virus.

Other infections that can present with jaundice as part of a systemic disease are malaria, Epstein-Barr mononucleosis, cytomegalovirus, Q fever, toxoplasmosis, leptospirosis and, rarely, measles, varicella, yellow fever, rubella, herpes simplex, dengue fever, Lassa fever and Marburg and Ebola virus.

### § Hepatitis A

Hepatitis A is becoming relatively less prevalent in first world countries. It is enterically transmitted and arises from the ingestion of contaminated food, such as shellfish, or water. There is no carrier state and it does not cause chronic liver disease. Hepatitis A most often causes a subclinical or self-limited clinical illness.

### Clinical features

Pre-icteric (prodromal) phase:

- anorexia, nausea  $\pm$  vomiting
- malaise
- headache
- distaste for cigarettes in smokers

**Table 58.5** Characteristic profiles of viral hepatitis A–E

Characteristic	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
<b>Pseudonyms</b>	Infectious hepatitis	Serum hepatitis	Parenterally transmitted non-A, non-B	Delta hepatitis	Enterically transmitted non-A, non-B
<b>Agent (virus)</b>	27 nm RNA	42 nm DNA	50 nm RNA	35 nm RNA	30 nm RNA
<b>Transmission</b>	Faecal–oral	Blood and other body fluids	Blood ? Other body fluids	Blood and other body fluids	Faecal–oral
<b>Incubation period</b>	15–45 days	40–180 days	14–180 days	30–50 days	15–45 days
<b>Severity of acute illness</b>	Mild to moderate; often subclinical—no jaundice	Mild to severe; jaundice common; arthralgia and rash common	Mild to moderate; often subclinical	Moderate to severe; high mortality; usually jaundice	Mild to moderate; often subclinical
<b>Chronic liver disease</b>	No	Yes 5–10%	Yes 20–50%	Yes Potentially worst	No
<b>Carrier state</b>	No	Yes	Yes	Yes	No
<b>Risk in travellers</b>	Yes, applies to all A–E: East and South-East Asia, Asian subcontinent (e.g. India), South Pacific Islands (e.g. Fiji), sub-Saharan Africa, Mexico, Russia, other developing countries. A and E with poor sanitation; B, C, D also with IV drug use; B, D sexual contact.				
<b>Antigens</b>	HAV Ag	HBsAg, HBcAg, HBeAg	HCV Ag	HDV Ag	?
<b>Serology</b>	IgM anti-HAV diagnosis (HAV IgM)	HBsAg diagnosis anti-HBs—exposure immunity	anti-HCV (antibody) HCV-RNA (PCR) HCV genotype	HBsAg +ve HDsAg +ve anti-HDV (antibody)	HEV IgM
<b>Immuno-prophylaxis</b>	Normal Ig	HB Ig	? Ig effective	None	None
<b>Vaccine</b>	Hepatitis A vaccine	Hepatitis B vaccine	None	Hepatitis B vaccine	None

- mild fever
- $\pm$  diarrhoea
- $\pm$  upper abdominal discomfort

Icteric phase (many patients do not develop jaundice):

- dark urine
- pale stools
- hepatomegaly
- splenomegaly (palpable in 10%)

Recovery usually in 3–6 weeks.

Fulminant hepatitis with liver coma and death may occur but is rare.

## Investigations

LFTs and viral markers confirm the diagnosis. The antibodies to HAV are IgM, which indicates active

infection, and IgG antibodies, which means past infection and lifelong immunity and which is common in the general population. Ultrasound is useful to exclude bile duct obstruction, especially in an older patient.

## Outcome and treatment

Hepatitis A has an excellent prognosis with most patients making a complete recovery, and patients should be reassured. The mortality is less than 0.5%. Admission to hospital is not usually necessary. There is no specific treatment, so management is as follows.

- Provide appropriate reassurance and patient education.
- Rest as appropriate.
- Follow a fat-free diet.

- Avoid alcohol, smoking and hepatotoxic drugs (until recovery).
- Advise on hygiene at home to prevent spread to close contacts and family members.
- Wash hands carefully after using the toilet and disinfect them with antiseptic.
- Do not handle food for others with your fingers.
- Do not share cutlery and crockery during meals.
- Do not use tea-towels to dry dishes.

### Prevention

Simple health measures such as good sanitation, effective garbage disposal and hand washing are probably responsible for the major decrease in the disease. Immune serum globulin (0.03–0.06 mL/kg IM) confers satisfactory passive immunity for close contacts (within 2 weeks of contact) and for travellers to endemic areas for up to 3 months. An active vaccine consisting of a two-dose primary course is the best means of prevention.

### § Hepatitis B

Hepatitis B has protean clinical manifestations. Transmission is by blood spread, percutaneous, sexual transmission, perinatal spread or by close prolonged family contact. Infection may be subclinical or self-limited acute hepatitis. Fulminant hepatitis is rare. Five per cent of subjects go on to become chronic carriers of the virus. Most are 'healthy carriers' but some may develop chronic active hepatitis, cirrhosis and hepatoma. The serology of hepatitis B involves antibody responses to the four main antigens of the virus (core, DNA polymerase, protein X and surface antigens). Passive and active vaccines are available, and should be used freely in groups at risk, including babies of infected mothers. High-risk groups are presented in TABLE 58.6. The clinical features are the same as those found in hepatitis A infection but may be less abrupt in onset but more severe in the long term.<sup>7</sup> A serum sickness-like immunological syndrome may be seen with transient rashes (e.g. urticaria or a maculopapular rash), and polyarthrititis affecting small joints in up to 25% of cases in the prodromal period.

### Investigations<sup>5,9,10</sup>

The main viral investigation for HBV is HBsAg (surface antigen), which is searched for routinely. If detected, indicating hepatitis B positive or carrier, a full viral profile is then formed.

HBsAg may disappear or persist. Its presence indicates a current or chronic infection as well as

**Table 58.6** Higher-risk groups for contracting hepatitis B (vaccination advisable)<sup>7</sup>

Babies born to hepatitis B positive (carrier) mothers
Garbage collectors
Health care workers
Household contacts of hepatitis B carriers
Institutionalised intellectually disabled patients
Intravenous drug users
Kidney dialysis patients
Male homosexuals
Prisoners
Recipients of blood or blood products (prior to testing)
Sex industry workers
Sexual partners of hepatitis B carriers (especially acute HBV)
Travellers to endemic areas

a carrier state (see FIG. 58.4). Chronic hepatitis B (carriage) is defined as the presence of HBsAg for at least 6 months.

HBeAg is a soluble protein from the pre-core and core. Antibodies develop to both HBsAg and HBeAg.

### Serological patterns

#### Acute hepatitis

HBsAg +ve, anti-HBcIgM + anti-HBs –ve

#### Chronic hepatitis

HBsAg +ve, anti-HBcIgG + anti-HBs –ve

**FIGURE 58.4** Time course of acute hepatitis B infection

## Monitoring and outcome<sup>9,10</sup>

The possible course of events is shown in **FIGURE 58.5**. The majority of patients recover completely with the outcome depending on several factors, including the virulence of the virus and the immune state and age of the patient. Some will develop chronic hepatitis, some will develop a fulminant course, and others will become asymptomatic carriers and present a health risk to others.

Monitor progress with 6–12 monthly LFTs, HBeAg and HBV DNA.

- Negative HBsAg and HBV DNA (with anti-HBe) = resolving, with anti-HBs = full recovery.
- Positive HBsAg and HBV DNA = replicating and infective—refer.
- Monitor LFTs every 6 months. Refer if ALT elevated.

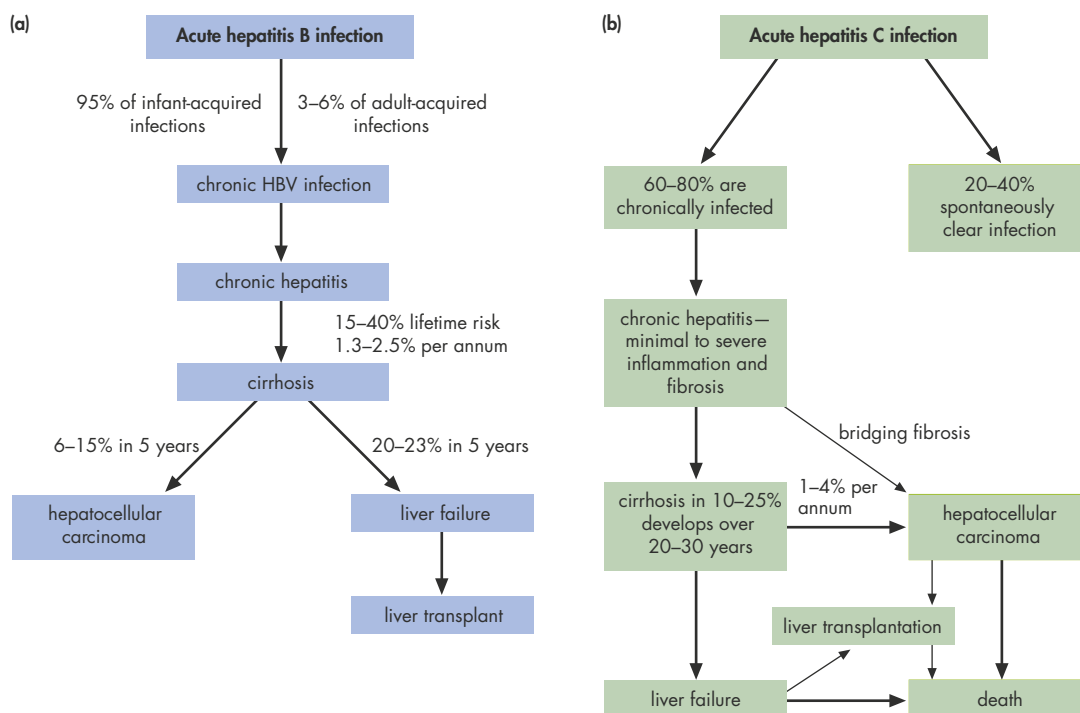

## Treatment<sup>5</sup>

There is no specific treatment initially—appropriate reassurance and patient education are necessary. Advise avoidance of alcohol. Avoid certain drugs, e.g. sedatives, NSAIDs, OCP, until recovery (normal LFTs). Advise about prevention of transmission

especially safe sex and sharing needles. Treatment of chronic hepatitis B infection (abnormal LFTs) is with the immunomodulatory and antiviral agents—pegylated interferon alpha and entecavir or tenofovir. This is expensive but it achieves permanent remission in 25% of patients, and temporary remission in a further 25%.<sup>7</sup> Liver transplantation has been performed, but is often followed by recurrence of hepatitis B in the grafted liver. Follow up with regular LFTs and alpha-fetoprotein screening. It is appropriate to refer any HBsAg positive patient with an abnormal ALT and/or signs of chronic liver disease to a specialist since the evaluation of chronic hepatitis B can be complex.<sup>4</sup>

## Serology guidelines

HBsAg = acute or persistent infection  
 anti-HBs = past infection and immunity  
 HBeAg = highly infectious  
 HBV DNA = circulating and replicating virus  
 anti-HBc IgM = recent and continuing infection  
 anti-HBc IgG = past infection  
 anti-HBe = seroconversion

**FIGURE 58.5** Natural history of (a) hepatitis B infection; (b) hepatitis C infection.

Source: W Sievert, B Katz, Department of Gastroenterology, Monash Medical Centre

## Prevention

Active immunisation through hepatitis B vaccination has been a major breakthrough in the management of this serious illness. There is a course of three injections. If there is a negative antibody response after 3 months, revaccinate with a double dose. If the response is positive, consider a test in 5 years with a view to a booster injection.

For non-immune patients at risk (e.g. after a needle-stick injury), hepatitis B immunoglobulin (HBIG), which contains a high level of HBV surface antibody, is appropriate.

Prenatal screening of pregnant women and appropriate use of HBIG and HB vaccine is useful in preventing perinatal vertical transmission of HBV. Refer **CHAPTER 109**.

## § Hepatitis C<sup>5,9,11,12</sup>

Hepatitis C virus is responsible for most cases of viral hepatitis in Australia. It is primarily contracted from intravenous drug use or tattooing. It does not seem to be spread very readily by sexual contact although there is a small risk during heterosexual and homosexual intercourse. It is also not readily spread perinatally.

Clinical symptoms of hepatitis C are usually minimal (often asymptomatic), and the diagnosis is often made after LFTs are found to be abnormal. An important feature is that there are at least six major genotypes of HCV and treatment decisions are based on the genotype; thus, patients with acute hepatitis C should have HCV genotype testing.

Hepatitis C infection may be self-limiting, but more commonly (in about 70% of cases) causes a slow, relentless progression to chronic hepatitis, cirrhosis (20%) and also hepatoma.<sup>7</sup> See **FIGURE 58.6**. The severity of hepatic fibrosis can be assessed by liver biopsy or, preferably, by a non-invasive device called a FibroScan that assesses 'hardness or stiffness' of the liver via the technique of transient elastography. A raised ALT level that is tested three times over the next 6 months implies disease activity. HCV RNA (a PCR test) is present when the ALT becomes abnormal while the anti-HCV rises more slowly and may not be detectable for several weeks. If the PCR test is negative, the hepatitis C infection has resolved.

## Diagnosis and progress

This is by serology:

- HCV Ab (anti-HCV) +ve = exposure (current or past)

**FIGURE 58.6** Time course of active hepatitis C infection

- HCV-RNA +ve = chronic viraemia  
-ve = spontaneous clearance
- CD<sub>4</sub>/HCV = viral load
- ALTs on LFTs indicate disease activity (tested 3 times over next 6 months)  
ALT persistently normal = good prognosis  
ALT ↑ ↑ = requires referral for treatment
- If PCR +ve + significant viral load + ALT ↑ perform HCV genotype—determines treatment
- PCR -ve, ALT -ve = infection clear

## Treatment<sup>5,12</sup>

The current standard treatment for chronic hepatitis C is ribavirin orally daily and pegylated alpha-interferon by weekly SCI—genotypes 1, 4, 5, 6 for 48 weeks; genotypes 2, 3 for 24 weeks. The combination therapy, which can cure many cases of hepatitis C, has considerable side effects, ranging from flu-like symptoms to depression to significant anaemia. At present the determination of the genotype and the viral load will identify those groups most likely to respond to therapy, for example, genotype 1 infected patients will have a good response while an excellent response including cure can be expected in genotypes 2 and 3. Acute hepatitis C can be treated with pegylated alpha-interferon but the acute stage is difficult to recognise clinically. There is no vaccine yet available. These patients should be tested for hepatitis A and B and immunised if not immune. They should avoid alcohol.

## Those at increased risk of having hepatitis B and C

- Blood transfusion recipients (prior to HBV and HCV testing)

- Intravenous drug users (past or present)
- Male homosexuals who have practised unsafe sex
- Kidney dialysis patients
- Sex industry workers
- Those with abnormal LFTs with no obvious cause
- Tattooed people/body piercing

### Prevention of transmission of hepatitis B and C viruses

Advice to those who are positive for HCV:

- Do not donate blood or any body organs or tissues.
- Do not share needles.
- Advise health care workers, including your dentist.
- Do not share intimate equipment such as toothbrushes, razors, nail files and nail scissors.
- Wipe up blood spills in the home with household bleach.
- Cover up cuts or wounds with an adequate dressing.
- Dispose of bloodstained tissues, sanitary napkins and other dressings safely.
- Use safe sex practices such as condoms.
- Avoid tattooing.

### § Hepatitis D

Hepatitis D is a small defective virus that lacks a surface coat. This is provided by hepatitis B virus, and so hepatitis D infection occurs only in patients with concomitant hepatitis B.

It is usually spread parenterally and if chronic is usually associated with progressive disease with a poor prognosis. Treatment with interferon has a poor success rate. Antibodies to the delta virus, both anti-HDV and anti-HDV IgM (indicating a recent infection) as well as HDV Ag can be measured.<sup>13</sup>

### § Hepatitis E

Hepatitis E is an enterically transmitted virus that occurs in outbreaks in certain countries with a poor water supply, such as some Asian subcontinent countries. Epidemiologically, HEV behaves like HAV, with well-documented water-borne epidemics in areas of poor sanitation. There is a high case fatality rate (up to 20%) in pregnant females.

### § Hepatitis F

Researchers claim to have identified HGF virus, which is spread enterically.<sup>14</sup>

## Hepatitis G

HGV has been identified as a transfusion-spread virus. It has subsequently been found to be prevalent among Queensland blood donors.<sup>10,15</sup>

### § Cholestatic jaundice

Cholestasis refers to the syndrome of biliary obstructive jaundice whereby there is obstruction to the flow of bile from the hepatocyte to the duodenum, thus causing bilirubin to accumulate in the blood. It is classified into two main groups:

- intrahepatic cholestasis—at the hepatocyte or intrahepatic biliary tree level
- extrahepatic cholestasis—obstruction in the large bile ducts by stones or bile sludge

The significant causes are listed in [TABLE 58.7](#).

**Table 58.7** Significant causes of cholestasis in adults

Intrahepatic
Alcoholic hepatitis/cirrhosis
Drugs
Primary biliary cirrhosis
Viral hepatitis
Extrahepatic
Cancer of bile ducts
Cancer of pancreas
Other cancer: primary or secondary spread
Cholangitis
Primary sclerosing cholangitis (? autoimmune)
Common bile duct gallstones
Pancreatitis
Post-surgical biliary stricture or oedema

## Symptoms

- Jaundice (greenish tinge)
- Dark urine and pale stools
- Pruritus—worse on palms and soles
- Pain varies from nil to severe

## Gallstones and jaundice

Gallstones can be found in the following (see [FIG. 58.7](#)):

- gall bladder (asymptomatic up to 75%)—the majority remain here

FIGURE 58.7 Clinical presentation of gallstones

- neck of gall bladder (biliary 'colic' or acute cholecystitis)
- cystic duct (biliary 'colic' or acute cholecystitis)
- common bile duct—may cause severe biliary 'colic', cholestatic jaundice or cholangitis

Acute cholecystitis is accompanied by mild jaundice in 25% of cases, due to accompanying common duct stones.<sup>13</sup>

Common bile duct stones may be asymptomatic or may present with any one or all of the triad of abdominal pain, jaundice and fever. The jaundice varies, depending on the amount of obstruction. The liver is moderately enlarged if the obstruction lasts for more than a few hours.

The investigations of choice for cholestatic jaundice are ultrasound and ERCP.

### § Acute cholangitis

This is due to bacterial infection of the bile ducts secondary to abnormalities of the bile duct, especially gallstones in the common duct. Other causes are neoplasms and biliary strictures.

Charcot triad (present in 70%) is shown in the diagnosis box.

**DxT** fever (often with rigor) + upper abdominal pain + jaundice → acute cholangitis

Older patients can present with circulatory collapse and Gram-negative septicaemia. Urgent referral is necessary.

### § Carcinoma of head of the pancreas

Pancreatic cancer is the fourth commonest cause of cancer death in the UK and US.<sup>13</sup>

#### Clinical features

- M > F
- Mainly >60 years of age
- Obstructive jaundice
- Pain (over 75%)—epigastric and back
- Enlarged gall bladder (50–75%)

#### Possible features

- Weight loss, malaise, diarrhoea
- Migratory thrombophlebitis
- Palpable hard, fixed mass
- Metastases (e.g. left supraclavicular gland of Troisier)
- Occult blood in stool
- Glycosuria

#### Diagnosis

- Scanning by ultrasound or CT scan may show mass
- ERCP

**DxT** jaundice + constitutional symptoms (malaise, anorexia, weight loss) + epigastric pain (radiating to back) → pancreatic cancer

#### Prognosis

Prognosis is very poor: 5-year survival is 5%.

### § Cirrhosis of the liver

Cirrhosis is accompanied by jaundice as a late and serious manifestation with the exception of primary biliary cirrhosis, where jaundice appears before advanced liver failure. The development of jaundice usually indicates that there is minimal hepatic reserve and is therefore found in conjunction with other signs of liver failure (see FIG. 58.8).

#### Causes

Common:

- alcohol excess
- chronic viral hepatitis (esp. HBV, HCV)

FIGURE 58.8 Possible features of chronic alcoholic liver disease

#### Others:

- autoimmune chronic active hepatitis
- primary biliary cirrhosis (autoimmune)
- haemochromatosis
- Wilson syndrome
- drugs (e.g. methotrexate)
- cryptogenic (no cause found)

#### Clinical features

- Anorexia, nausea  $\pm$  vomiting
- Swelling of legs
- Abdominal distension
- Bleeding tendency
- Drowsiness, confusion or coma (if liver failure)

#### Signs

- Spider naevi (distribution of superior vena cava)
- Palmar erythema of hands
- Peripheral oedema and ascites
- Jaundice (obstructive or hepatocellular)
- Enlarged tender liver (small liver in long-term cirrhosis)
- Ascites
- Gynaecomastia
- $\pm$  Splenomegaly (portal hypertension)

#### Complications

- Ascites
- Portal hypertension and GIT haemorrhage

- Portosystemic encephalopathy
- Hepatoma
- Kidney failure

### § Autoimmune chronic active hepatitis (ACAH)<sup>5</sup>

Also termed idiopathic ACAH, this usually affects young females (10–40 years) who present insidiously with progressive fatigue, anorexia and jaundice. Diagnosis is made by abnormal LFTs, positive smooth muscle antibodies, a variety of other autoantibodies and a typical liver biopsy. If untreated, most patients die within 3–5 years. Treatment is with prednisolone orally, monitored according to serum alanine aminotransferase levels, and supplemented with azathioprine or mercaptopurine. About 80% respond while 20% develop chronic liver disease.

### § Primary sclerosing cholangitis<sup>5</sup>

This uncommon inflammatory disorder of the biliary tract presents with progressive jaundice and other features of cholestasis such as pruritus. It is often associated with ulcerative colitis. Diagnosis is based on characteristic cholangiopancreatography findings. There is no specific therapy, but refer for possible ERCP.

### § Primary biliary cirrhosis<sup>5</sup>

This is an uncommon cause of chronic liver disease that often presents with pruritis, malaise and an obstructive pattern of liver biochemistry. Treatment is with ursodeoxycholic acid orally.

### § Alcoholic liver disease

The main effects of alcohol excess on the liver are:

- acute alcoholic liver disease
- fatty liver
- alcoholic hepatitis (progresses to cirrhosis if alcohol consumption continues)
- alcoholic cirrhosis

If diagnosed, patients are advised to stop drinking alcohol for life except for fatty liver when small amounts can be drunk later.

### § Fatty liver

Alcohol can cause hepatic steatosis (fatty liver), which is almost universal in obese alcoholics. Non-alcoholic causes include obesity, diabetes mellitus,

hypertriglyceridaemia and corticosteroids. A significant number with this very common condition (one in five Australians) will develop cirrhosis. Fatty liver is usually asymptomatic but some complain of malaise and tiredness. Serology is unhelpful. Diagnosis is by liver biopsy and perhaps CT scan. The treatment is weight loss through diet, which improves liver function and reduces fatty deposits.

## Special patient groups

### The returned overseas traveller

The overseas traveller presenting with jaundice may have been infected by any one of the viruses—hepatitis A, B, C, D or E. All are prevalent in developing countries, especially in south-eastern and eastern Asia, some Pacific islands and Africa.

Other causes to consider are malaria, ascending cholangitis and drug-induced hepatic damage due to, for example, the antimalarials, including mefloquine (Lariam) and Fansidar. Refer [CHAPTERS 14 and 15](#).

### The pregnant patient

Important hepatic disorders in pregnancy leading to jaundice are cholestasis of pregnancy, acute fatty liver of pregnancy and severe pre-eclampsia. Refer to [CHAPTER 109](#).

### Postoperative jaundice

There are many possible causes of postoperative jaundice either in the immediate or the long-term postoperative phase. Hypoxia associated with shock in a severely ill patient or in a patient with cardiopulmonary disease may lead to transient abnormalities in liver function. Other causes include:

- post-transfusion hepatitis
- coincident viral hepatitis
- drugs, including anaesthetics
- transfusion overload (haemolysis)
- sepsis
- unmasked chronic liver disease and biliary tract disease
- cholestasis: post major abdominal surgery

### Neonates of HBeAg positive mothers

The neonates should have the following (see [CHAPTER 109](#)):

- hepatitis B immunoglobulin IM within 24 hours of birth
- hepatitis B vaccine at birth, 1 month and 6 months

This is not 100% effective because some infants can be infected in utero.

## When to refer

- All patients with fulminant hepatitis
- All patients with chronic liver disease
- Painless obstructive jaundice
- Evidence of malignancy
- Symptomatic gallstones
- Patients with cirrhosis
- Acute fatty liver of pregnancy (very urgent)
- Suspected rare conditions (e.g. Wilson syndrome)

## Practice tips

- All drugs should be suspected as potential hepatotoxins.
- With hepatitis A the presence of IgM antibodies reflects recent infection, and IgG antibody indicates past infection and lifelong immunity.
- There is no chronic carrier state of hepatitis A and E.
- All patients with jaundice should be tested for hepatitis B surface antigen (HBsAg).
- Hepatitis B infection is usually benign and short-lived, but it can be fatal if chronic hepatitis develops, which may lead later to cirrhosis and hepatocellular carcinoma.
- Up to 5% of patients with hepatitis B will become chronic carriers (especially drug addicts).
- Such carriers are identified by persistent titres of HBsAg and possibly HBeAg, the latter indicating the presence of the whole virus, and active replication and high infectivity.
- A raised gamma glutamyl transferase accompanied by a raised MCV is a good screening test for alcohol abuse.
- A systolic murmur may be heard over the liver in alcoholic hepatitis and hepatoma.
- A distaste for smoking (with jaundice) suggests acute viral hepatitis.

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Gallstones
- Hepatitis A
- Hepatitis B
- Hepatitis C

*The face of Mrs Gamp—the nose in particular—was somewhat red and swollen, and it was difficult to enjoy her society without becoming conscious of the smell of spirits.*

Charles Dickens (1812–70), *Mar tin Chuzzlewit*

Disorders of the nose, which include the everyday problems of rhinitis, postnasal drip, epistaxis, folliculitis and disorders of smell, are very common in everyday general practice.

The main functions of the nose are:

- airflow
- filtration—of dust, organisms and other air-borne particles
- olfaction (smell)
- self-cleansing and moisturising of the mucous membrane
- humidification and warming of air in its passage to the lungs
- vocal resonance

The main symptoms of nasal disorders are discharge, blockage, sneezing, anosmia, itching, postnasal drip, bleeding and snoring (see TABLE 59.1).<sup>1</sup>

Nasal discharge is a common and important symptom to evaluate. The characteristics of nasal discharge are summarised in TABLE 59.2.

**Table 59.1** Typical symptoms for nasal disorders<sup>2</sup>

<b>Foreign body</b>	Unilateral discharge, unilateral blockage
<b>Acute sinusitis</b>	Facial pain, toothache, nasal discharge, postnasal drip
<b>Allergic rhinitis</b>	Sneezing, rhinorrhoea, itch, eye irritation
<b>Infective rhinitis</b>	Blockage, purulent discharge, postnasal drip
<b>Deviated septum</b>	Blockage, postnasal drip
<b>Nasal polyps</b>	Blockage, reduced sense of smell
<b>Nasal tumour</b>	Blockage, unilateral discharge, epistaxis
<b>Adenoidal hypertrophy</b>	Bilateral blockage, snoring, halitosis
<b>Nasal vestibulitis</b>	Local pain, crusting, malodour

**Table 59.2** Characteristics of nasal discharge

Nature of discharge	Think of:
Blood	Neoplasia, trauma, bleeding disorder, rhinitis, infection, hypertension
Mucopurulent	Bacterial rhinitis, foreign body
Serosanguineous	Neoplasia, foreign body
Watery/mucoid	Viral rhinitis, allergic rhinitis, vasomotor rhinitis, CSF

A major presenting problem is nasal obstruction with the complaint of a blocked or 'stuffy' nose. Common causes are physiological (the nasal cycle), rhinosinusitis (allergic or non-allergic), polyps, adenoid hypertrophy and mechanical such as septal deformity.

### Red flag pointers for nasal disorders

- Unilateral nasal 'polyp'
- Unilateral blood-stained discharge
- Toddler with offensive nasal discharge esp. unilateral
- Post-traumatic periseptal swelling
- Rhinitis medicamentosa
- Chronic sinusitis + LRTI = ? Wegener granulomatosis

### Disorders of smell

The basic sense of smell is detected in the olfactory region by the olfactory nerve (cranial nerve I) while irritant sensors in the nose, mediated by the maxillary branch of the trigeminal nerve (cranial nerve V), detect some noxious odours.

The disorders can be classified as:<sup>3</sup>

- anosmia—no smell
- hyposmia—reduced smell

- hyperosmia—increased sensitivity to odours
- dysosmia—distortion of smell perception
  - cacosmia—normal odours seem foul or unpleasant
  - parosmia—a perverse sense of smell

Disorders of smell can be caused by conductive or sensorineural disturbances or considered as idiopathic (see **TABLE 59.3**). Conductive disorders present as anosmia or hyposmia, while sensorineural disorders can present with all of the above disorders.<sup>3</sup> Most cases of idiopathic anosmia are considered to be viral neuropathies and may last from a few days to several months. Head trauma, which can cause conductive or sensorineural disturbances, is considered to be caused either from a fracture of the skull involving the cribriform plate or, more commonly, by posterior head trauma. Some patients will never recover their sense of smell. Patients with anosmia lack flavour discrimination and often have accompanying loss of sense of taste. They are also vulnerable to an unawareness of smoke, gas, dangerous chemicals and unhealthy food.

**Table 59.3** Causes of reduced sense of smell

Conductive defects
Head trauma
Nasal polyps
Septal deviation
Rhinitis and sinusitis
Rare (not to be missed)
Nasal tumour
Wegener granulomatosis
Central/sensorineural defects
Ageing
Chemicals (e.g. benzene, chlorine, formaldehyde, cement dust)
Cigarette and other smoking/inhalation
Drugs
Endocrine disorders (e.g. diabetes, hypothyroidism)
Frontal lobe tumour
Parkinson disease
Head trauma
Kallmann syndrome (anosmia + hypogonadism)
Nutritional deficiencies
Viral infections

## The clinical approach

- History: head injury or surgery, recent URTI, drugs, occupation including chemical exposure

- Physical examination, including inspection via a Thudicum nasal speculum
- Sniff test—qualitative and quantitative odours (e.g. coffee, cloves, lemon, peppermint, water placebo). Ammonia (for irritant sensation)
- Investigations (e.g. CT scan for sinus disease, nasal polyps)

## Treatment<sup>2,4</sup>

- Explanation and reassurance
- Education about smoke detectors, caution about chemicals including gas, excessive perfume, food safety including milk and meat contamination
- Consider dietary supplement with daily zinc sulphate, vitamin A and thiamine

For chronic anosmia following an URTI:

- prescribe a nasal decongestant such as Spray-Tish Menthol for 5–7 days

## Rhinitis

Rhinitis is inflammation of the nose causing sneezing, nasal discharge or blockage for more than an hour during the day. Rhinitis is subdivided into various types:

- According to time span:
  - seasonal rhinitis: occurs only during a limited period, usually springtime
  - perennial rhinitis: present throughout the year
- According to pathophysiology:
  - allergic rhinitis: an IgE-mediated atopic disorder
  - vasomotor rhinitis: due to parasympathetic overactivity

Both allergic and vasomotor rhinitis have a strong association with asthma.

The classification can be summarised as:

- seasonal allergic rhinoconjunctivitis = hay fever
- perennial rhinitis
  - allergic (usually due to house dust mites)
  - non-allergic = vasomotor: eosinophilic, non-eosinophilic

*Note:* allergic rhinitis (hay fever) is presented in detail in **CHAPTER 80**.

## Clinical features

Nasal symptoms:

- sneezing
- nasal obstruction and congestion
- hypersecretion—watery rhinorrhoea, postnasal drip

- reduced sense of smell
- itching nose (usually allergic)

Throat symptoms:

- dry and sore throat
- itching throat

Irritated eyes (allergic)

Abnormal nasal mucous membrane—pale, boggy, mucoid discharge. A transverse nasal crease indicates nasal allergy, especially in a child.

### Allergens

- Pollens from trees (spring) and grass (in summer)
- Moulds
- House dust mites (perennial rhinitis)
- Hair, fur, feathers (from cats, dogs, horses, birds)
- Some foods (e.g. cow's milk, eggs, peanuts, peanut butter)

### Diagnosis

Allergic rhinitis—nasal allergy:

- detection of allergen-specific IgE antibodies (not specific)
- RAST test or skin testing for specific allergens (can get false negatives)

Vasomotor rhinitis—a diagnosis of exclusion.

### Other causes of rhinitis

- Chronic infection (viral, bacterial, fungal)
- Rhinitis of pregnancy
- Rhinitis medicamentosa—following overuse of OTC decongestant nasal drops or oxymetazoline sprays
- Drug-induced rhinitis:
  - various antihypertensives
  - aspirin
  - phenothiazines
  - oral contraceptives
  - cocaine, marijuana
- Chemical or environmental irritants (vasomotor rhinitis):
  - smoke and other noxious fumes
  - paints and sprays
  - cosmetics

### Factors aggravating rhinitis (vasomotor)

- Emotional upsets
- Fatigue
- Alcohol
- Chilly damp weather
- Air-conditioning
- Sudden changes in temperature and humidity

## RHINOSINUSITIS

### § Acute sinusitis

Acute sinusitis is acute inflammation in the mucous membranes of the paranasal sinuses. About 5% of URTIs are complicated by an acute sinusitis,<sup>4</sup> which is mainly viral initially while secondary bacterial infection commonly follows. Any factor that narrows the sinus openings into the nasal cavity (the ostia) will predispose to acute sinusitis.

The two prime clinical presentations are:

- 1 an URTI persisting for longer than 10 days
- 2 an URTI that is unusually severe with pyrexia and a purulent nasal discharge

Refer to **CHAPTER 52** for features of acute maxillary sinusitis.

### § Chronic sinusitis

Chronic sinusitis is the most common complication of acute sinusitis. In chronic sinusitis the symptoms and signs of inflammation persist for more than 8–12 weeks and are more likely to be associated with factors that impair drainage via the osteomeatal complex, including nasal polyps.

### Treatment

- Amoxycillin 500 mg (o) 8 hourly for 10–14 days, possibly for longer periods of 3–6 weeks<sup>5</sup>
- Consider decongestant spray (e.g. xylometazoline) for maximum of 5 days and intranasal steroids
- Steam inhalations three times daily
- Nasal saline sprays

### Chronic rhinosinusitis

If the above therapies are ineffective a mechanical saline sinus irrigation procedure to remove stagnant mucus is beneficial.<sup>6</sup>

Refer urgently:

- for surgical drainage if there is no response to the above regimen
- those with orbital or facial cellulitis

### § Nasal polyps

Nasal polyps are round, soft, pale, pedunculated outgrowths arising from the nasal or sinus mucosa. They are basically prolapsed, congested, oedematous mucosa, described by some as 'bags of water' (**FIG 59.1**). They occur in patients with all types of rhinitis, but

**FIGURE 59.1** Nasal polyp in right nasal cavity in a patient with inflamed mucosa from allergic rhinitis

**FIGURE 59.2** Cross-section of nose, demonstrating origin of nasal polyps

especially in allergic rhinitis (see **FIG. 59.2**). Polyps usually arise from the middle meatus and turbinates.

Symptoms include nasal obstruction, watery discharge, postnasal drip and loss of smell.

*Note:*

- Nasal polyps may be associated with asthma and aspirin sensitivity.
- Cystic fibrosis should be considered in any child with nasal polyps.
- A polyp that does not have the typical smooth pale appearance may be malignant.
- A unilateral 'polyp' may be a neoplasm.
- If there is a purulent discharge, swab and give antibiotics.

## Treatment

The initial treatment should be medical.<sup>7</sup> A medical 'polypectomy' can be achieved with oral steroids, for example, prednisolone 50 mg daily for 7 days. Supplement this with a corticosteroid spray such as betamethasone, starting simultaneously and continuing for at least 3 months. Give antibiotics for any purulent nasal discharge.

Simple polyps can be readily snared and removed, but referral to a specialist surgeon is advisable for surgical intervention since the aim is to remove the polyp with the mucosa of the sinuses (often ethmoidal cells) from which it arises. This complex procedure reduces the incidence of recurrence.

## § Epistaxis

This common emergency should, in some instances, be treated as a life-threatening problem. The common situation is intermittent anterior bleeding from Little area, seen in children and the young adult (90% of episodes), while posterior epistaxis (10%) is more common in the older hypertensive patient. It has a strong association with higher URTI (rhinitis, sinusitis), hot dry climates and trauma. Neoplasms should be kept in mind. Bleeding often occurs at night due to vascular vasodilation. Systemic factors include hypertension, atherosclerotic vascular disease, bleeding disorders and the rare hereditary haemorrhagic telangiectasia (see **TABLE 59.4**). The secret

**Table 59.4** Causes of epistaxis

Local causes
Idiopathic (spontaneous)
Intracranial tumours
Rhinitis
Trauma including nose picking, nasal fracture
URTIs:
• common cold
• influenza
• sinusitis
Systemic causes
Blood disorders (e.g. leukaemia, thrombocytopenia)
Cardiovascular disorders:
• arteriosclerosis
• hypertension
Drugs: anticoagulants, aspirin, others
Hereditary haemorrhagic telangiectasia
Systemic febrile infections (e.g. malaria)
Toxic agents

of good management is to have the right equipment, good lighting and effective local anaesthesia.

### Ideal equipment

Head light, Thudicum nasal speculum, Tilley nasal packing forceps, suction cannula and tubing, Co-Phenylcaine forte spray  $\pm$  5% cocaine solution.

### Tamponade options (for difficult bleeding)

Merocel expandable pack, Kaltostat, BIPP (bismuth iodoform paraffin paste) with ribbon gauze, Foley catheter (no. 12, 14 or 16) with a 30 mL balloon and self-sealing rubber stopper, anterior/posterior balloon, Epistat catheter with or without Kaltostat.

### Treatment

Simple tamponade:

- Pinch 'soft' part of nose below the nasal septum between thumb and finger for 5 minutes
- Apply ice packs to bridge of nose

Simple cautery of Little area (see FIG. 59.3) (under local anaesthetic e.g. Co-Phenylcaine forte nasal spray  $\pm$  5% cocaine solution):

- use one of three methods: electrocautery trichloroacetic acid or silver nitrate stick (preferred)

### Persistent anterior bleed

Merocel (surgical sponge) nasal tampon or Kaltostat pack

'Trick of the trade' for intermittent minor anterior epistaxis:

topical antibiotic (e.g. Aureomycin ointment) bd or tds for 10 days

or (better option)

Nasalate nasal cream tds for 7–10 days

or

Rectinol ointment or Vaseline

Avoid digital trauma and nose blowing.

### Severe posterior epistaxis

Use a Foley catheter or an Epistat catheter.

### Nasal vestibulitis

Infection of the nasal vestibule can cause a tender, irritating, crusty problem. Low-grade infections and *folliculitis*, which are evident on inspection, cause localised pain, crusts and bleeding, especially if picked from habit. Treatment is with bacitracin or preferably mupirocin (intranasal) ointment topically for 5–7 days.

*Furunculosis* of the nasal vestibule is usually due to *Staphylococcus aureus*. It starts as a small superficial abscess in the skin or the mucous membrane and may develop into a spreading cellulitis of the tip of the nose. The affected area becomes tender, red and swollen. It is best treated by avoidance of touching, hot soaks and systemic antibiotics such as dicloxacillin or as determined by culture from swabs of the vestibule.

FIGURE 59.3 Little area on the nasal septum where several blood vessels anastomose. Bleeding is common here, especially in young people

*Tip:* *Staphylococcus aureus* colonises the nose of 20–30% of the population.<sup>8</sup> Carriers are prone to transmit nosocomial infection and have an increased risk of serious infections in the presence of serious medical disorders. Treatment includes strict hygiene and eradication with an agent such as mupirocin ointment (match-head size) 2–3 times daily for 5–7 days (max. 10 days).<sup>6</sup>

*Fissure:* Painful fissures often develop at the mucocutaneous junction. They may become crusted and chronic. Fissures can be treated by keeping the area moist with petroleum jelly (Vaseline) or saline gel, using hot compresses and the use of an antibiotic or antiseptic ointment if necessary.

### Offensive smell from nose

This may be caused by vestibulitis but ensure no foreign body is present.

### Treatment

- Take nasal swab for culture.  
consider mupirocin 2% nasal ointment,  
instilled 2 to 3 times a day for 10 days  
or  
Kenacomb ointment, instil 2 to 3 times a day

## § Rhinophyma

This disfiguring swelling of the nose is due to hypertrophy of the nasal sebaceous glands. There is no specific association with alcohol. It is almost exclusive to men over the age of 40 years. Rhinophyma may be associated with rosacea.

### Treatment

- Good control of rosacea may reduce the risk (see CHAPTER 123).
- If surgical correction is warranted refer to a specialist.
- Carbon dioxide laser therapy is the treatment of choice.
- Shave excision is another effective therapy.

## § Nasal septal deviation

This causes blockage as a solitary symptom. Mild septal deviation tends to cause alternating blockage while severe deviation causes persistent blockage on one side.

The septum can be divided into anterior and posterior segments. The anterior portion is necessary to support the cartilaginous pyramid of the nose whereas the posterior portion has no supporting role and can be removed without disturbing the support of

the nose. The classic submucous resection operation is therefore suitable for posterior septal deviations. Repair of anterior septal deviations is more complex.

### Nasal cosmetic surgery

Rhinoplasty is undertaken to improve the function of an obstructed nasal airway or for cosmetic reasons. In counselling for rhinoplasty it is important to undertake careful planning with realistic anticipated outcomes. The GP should provide non-judgmental support for the patient's decision for cosmetic surgery before referral to an expert in rhinoplasty. Each case has to be assessed individually and the surgery tailored to the deformity. Attention to surgery to the airway is important, otherwise the nose may become partially obstructed and stuffy after cosmetic surgery alone.

## § Septal perforation

A hole in the nasal septum is caused commonly by chronic infection including tuberculosis, repeated trauma such as vigorous nose 'picking' or following nasal surgery. It is a known occupational hazard particularly among chrome workers and is seen in drug users who sniff cocaine. In about 5–10% of cases perforation is a result of malignant disease.<sup>4</sup> The condition may be asymptomatic depending on the cause, but there is often an irritating nasal crust and a whistling sound on nasal inspiration. It can be demonstrated by looking in one nares while a light is shone in the opposite one. The cartilaginous part is usually involved.

If not due to a serious cause, treat with Vaseline or saline gel and topical antibiotics for any infection. Refer if malignancy is suspected, otherwise treat symptomatically.

## § Nasal fractures<sup>2,9</sup>

Fractures of the nose can occur in isolation or combined with fractures of the maxilla or zygomatic arch. They may result in nasal bridge bruising, swelling, non-alignment and epistaxis. Always check for a compound fracture or head injury and, if present, leave alone and refer. If the patient is seen immediately (such as on a sports field) with a straightforward lateral displacement, reduction may be attempted 'on the spot' with digital manipulation before distortion from soft tissue swelling. This involves simply using the fingers to push laterally on the outside of the nose towards the injured side.<sup>2</sup>

*Tips:*

- X-rays are generally unhelpful unless excluding other facial skeletal injuries.

- If a deformity is present refer the patient within 7 days, ideally from days 3–5.
- Skin lacerations, i.e. compound fracture, usually require early repair.
- The optimal time to reduce a fractured nose is about 10 days after injury. There is a window period of 2–3 weeks before the fracture unites.
- Closed reduction under local or general anaesthetic is the preferred treatment.
- Open reduction is more suitable for bilateral fractures with significant septal deviation, bilateral fractures with major dislocations or fractures of the cartilaginous pyramid.

Refer:

- uncontrolled epistaxis
- recurrent epistaxis
- concern about cosmetic alignment

### § Haematoma of nasal septum

Septal haematoma following injury to the nose can cause total nasal obstruction. It is easily diagnosed as a marked swelling on both sides of the septum when inspected through the nose (see FIG. 59.4).

It results from haemorrhage between the two sheets of mucoperiosteum covering the septum. It may be associated with a fracture of the nasal septum.

FIGURE 59.4 Inferior view of nasal cavity showing bilateral swelling of septal haematoma

**Note:** This is a most serious problem as it can develop into a septal abscess. The infection can pass readily to the orbit or the cavernous sinus through thrombosing veins and may prove fatal, especially in children. Otherwise it may lead to necrosis of nasal septal cartilage followed by collapse and nasal deformity.

### Treatment

- Remove blood clot through an incision, under local anaesthetic.
- Prescribe systemic (oral) antibiotics (e.g. penicillin or erythromycin).
- Treat as a compound fracture if X-ray reveals a fracture.
- ENT specialist advice as necessary.

### § Stuffy, running nose in adults

For simple post-URTI rhinitis, blow the nose hard into disposable paper tissue or a handkerchief until clear, instil a nasal decongestant for 2 to 3 days and also have steam inhalations with Friar's Balsam or menthol preparations.

### RHINORRHOEA

This can be normal or abnormal. There is a 'nasal cycle' in which there is nasal congestion and decongestion that alternates from side to side and leads to rhinorrhoea. Other causes of normal discharge include vasomotor reactions to external environmental stimuli, such as cold wind and irritants, and postnasal drip (2 L of mucus pass down the back of the nose each day).

### § Senile rhinorrhoea

This is a common, distressing problem in the elderly, caused by failure of the vasomotor control of the mucosa. It may be associated with a deviated septum and dryness of the mucosa. There are few physical signs apart from the nasal drip. The treatment is to keep the nasal passages lubricated with an oily based preparation, for example, insufflation with an oily mixture (a sesame oil based preparation, e.g. Nozoil, is suitable) or petroleum jelly. Topical decongestants cause serious side effects in the elderly.

### § CSF rhinorrhoea

Following head injury, clear dripping fluid (+ve for glucose) may indicate a fracture of the roof of the ethmoid. Refer for assessment although spontaneous healing can occur.

### § Neoplasia

Malignant nasal disease, which is uncommon, may cause nasal discharge which may be clear at first, becoming thick and offensive. Malignancy should be suspected in the presence of blood. The growth may be in the nasal fossa, sinus or nasopharynx.

Benign tumours include papilloma, fibroma, osteoma, fibroangioma of puberty and nasal polyps. Fibroangiomas occur exclusively in males between the ages of 9 and 24. Patients present with unilateral nasal obstruction and recurrent epistaxis.

Malignant tumours include nasopharyngeal carcinoma, with the maxillary sinus being the most common site. Squamous cell carcinoma is the most common, followed by adenocarcinoma melanoma and lymphoma. Malignant or non-healing granuloma, sometimes called 'midline granuloma', is a slowly progressing ulceration of the face starting in the region of the nose.<sup>4</sup> It may represent a form of T cell malignant lymphoma, which responds to radiotherapy. The differential diagnosis is Wegener granulomatosis (see CHAPTER 32). Diagnosis is by CT scan and biopsy. Treatment of nasopharyngeal and sinonasal carcinoma depends on the site, size and histology, but usually involves a combination of surgery and postoperative radiotherapy.

## NASAL DISORDERS IN CHILDREN

Nasal problems, especially nasal discharge (rhinorrhoea), are very common in children but the pattern of presentation is usually different from that of adults. Sinusitis is uncommon in children under the age of 10 and allergic nasal polyps are relatively rare. If a child presents with polyps, consider the possibility of cystic fibrosis or neoplasia. Rhinitis, epistaxis and nasal foreign bodies are common.

### Abnormal causes

- Adenoid hypertrophy causing post-nasal space obstruction
- Foreign body in nose—usually unilateral discharge
- Allergic rhinitis
- Unilateral choanal atresia
- Sinusitis (possible but rare)
- Tumour (also rare—consider fibroangioma)

Diagnosis may be enhanced by spraying with a vasoconstricting agent and getting the child to blow the nose. A tumour, foreign body or polyp may become visible.

### § Choanal atresia

Acute bilateral nasal obstruction may occur in newborns with congenital bilateral choanal atresia. This leads to anterior nasal discharge and to acute respiratory distress. Immediate investigation and relief are essential and a finger in the corner of the mouth can be life-saving as can passing a nasal probe down one nostril and perforating the membrane.

### § Sinusitis

Although rare, sinusitis can represent a serious emergency. Red flags requiring consideration include a sick child, pyrexia, rapid onset, unilateral and deteriorating airway obstruction.

### § Blocked nose and snoring

The above causes of nasal blockage may lead to snoring, mouth breathing, reduced sense of smell, dribbling and possibly obstructive sleep apnoea.

### § Nasal trauma and fractures<sup>10</sup>

Areas of concern associated with nasal fractures, which are uncommon, are possible child abuse, open fracture, septal haematoma or abscess and eye or facial changes. If a fracture is undisplaced the treatment is pain relief, ice compresses and rest. If displaced refer for closed reduction under general anaesthetic within 1–2 weeks (ideally at 10 days).<sup>10</sup> If associated epistaxis does not settle with pressure, temporary packing may be required.

### § Epistaxis

Epistaxis is usually intermittent anterior bleeding from Little area and may follow trauma including nose picking. Bleeding often occurs at night due to vascular vasodilatation. At first, try correction with simple measures (see earlier in chapter) such as pinching below the nasal septum for 5 minutes, supplemented by cold packs. Vaseline applied in the nose at night tends to prevent bleeding while an antibiotic ointment twice daily for 7–10 days may help.

If problematic, refer for an ENT appointment.

*Tip:* Think of a bleeding disorder or a tumour, e.g. juvenile angiofibroma.

### § Snoring and obstructive sleep apnoea

In normal children these problems are almost always due to adenotonsillar hypertrophy and most cases are relieved by surgery; CPAP is rarely necessary. Sleep studies are performed to confirm clinical features and allay parental concerns. See CHAPTER 71.

### § The snuffling infant

Snuffling in infants is usually caused by rhinitis due to an intercurrent viral infection. The presence of yellow or green mucus should not usually be cause for concern.

## Treatment

Reassure the parents.

- Paracetamol mixture or drops for significant discomfort.
- Get the parents to perform nasal toilet with a salt solution (1 teaspoon of salt dissolved in some boiled water); using a cotton bud, gently clear out nasal secretions every 2 waking hours.
- Once the nose is clean, saline nose drops or spray (e.g. Narium nasal mist) can be instilled.
- Stronger decongestant preparations are not advised unless the obstruction is causing a significant feeding problem, when they can be used for up to 4–5 days.

## § Foreign bodies in the nose

The golden rule is 'a child with unilateral nasal discharge has a foreign body (FB) until proved otherwise'. Such foreign bodies usually consist of beads, pebbles, peas, pieces of rubber, plastic and paper or other small objects handled by the child. A rhinolith may develop in time on the foreign body. In adults, foreign bodies are often rhinoliths, which are sometimes calcium deposits on pieces of gauze or other material that has been used to pack the nose.

## Removal of foreign bodies

Removal of FBs from the nose in children is a relatively urgent procedure because of the risks of aspiration. A disc/button battery such as a hearing aid battery in the nose is a medical emergency requiring urgent removal under anaesthetic.<sup>10</sup>

The nose should be examined using a nasal speculum under good illumination. The tip of the nose should be raised and pressed with the tip of a thumb. At first spray a topical decongestant into the nose and see if the child can blow it out after waiting 10 minutes. Do not attempt to remove FBs from the nose by grasping with 'ordinary forceps'.

## Methods of removal

- 1 Spray with decongestant, wait 10 minutes, then ask the child to blow out the FB.
- 2 It is best to pass an instrument behind the FB and pull or lever it forward.  
Examples of instruments are:
  - a Eustachian catheter
  - a probe to roll out the FB

- a bent hairpin
- a bent paperclip

## 3 Snaring the FB

This is the appropriate method for soft irregular FBs such as paper, foam rubber and cottonwool that are clearly visible. Examples of instruments are:

- a foreign-body remover
- crocodile forceps
- fine nasal forceps

## 4 Glue on a stick

Apply SuperGlue to the plastic end of a swab stick. Apply it to the FB, wait about 1 minute and then gently extract the FB.

## 5 Rubber catheter suction technique

The only equipment required is a straight rubber catheter (large type) and perhaps a suction pump. The method involves cutting the end of the catheter at right angles, smearing the rim of the cut end with petroleum jelly and applying this end to the FB, then providing suction. Oral suction may be applied for a recently placed or 'clean' object, but gentle pump suction, if available, is preferred.

## 6 Irritation of the nose

Some practitioners sprinkle white pepper into the nose to induce sneezing.

## 7 The 'kiss and blow' technique

This mouth-to-mouth method is used for a cooperative child with a firm, round foreign body such as a bead impacted in the anterior nares. It is best to supervise the child's mother to perform the technique, but the practitioner or practice nurse can perform it.

## Method

- Use a nasal decongestant spray.
- After 20 minutes lay the child on an examination couch with a pillow under the head.
- Obstruct the normal nostril with a finger from the side.
- Place the mouth over the child's mouth, blowing into it until a slight resistance is felt (this indicates that the glottis is closed).
- Then blow hard with a high velocity puff to cause the FB to 'pop out'.

To encourage cooperation with the technique the child can be asked to give mother (or other) a 'kiss'. More than one attempt may be needed but it is usually very successful and avoids the necessity for a general anaesthetic.

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Hay fever
- Nosebleed
- Nose: stuffy, running nose
- Sinusitis

*Nausea, retching and hypersalivation frequently precede the act of vomiting, which is a highly integrated sequence of involuntary visceral and somatic motor events.*

*Harrison's Principles of Internal Medicine, 1994*

Vomiting or emesis is a rather dramatic event with a diverse number of causes. It is usually preceded by nausea.

## Definitions

**Haematemesis** Vomiting of blood. It is presented in **CHAPTER 55**.

**Nausea** The unpleasant sickly sensation that can herald the onset of vomiting or can be present without vomiting.

**Regurgitation** The effortless passage of gastric contents into the mouth in the absence of nausea and without diaphragmatic muscular contractions.

**Retching** An involuntary act with all the movements of vomiting without the expulsion of gastric contents because the cardiac orifice remains closed.

**Rumination** The effortless regurgitation of recently ingested food into the mouth, followed by rechewing and reswallowing or spitting out.<sup>1</sup>

**Vomiting** The forceful expulsion of gastric contents through a relaxed upper oesophageal sphincter and out of the mouth.

## Key facts and checkpoints

- Nausea and vomiting have a wide range of potential causes emanating from every body system.
- The common cause of acute nausea and vomiting in most age groups is gastroenteritis.
- The most common causes of vomiting in children are infections—viral (especially) and bacterial—including otitis media and urinary infection.
- Drug ingestion is a common cause of nausea and vomiting; thus, a drug history is vital in assessment.
- Vomiting is commonly associated with migraine and may be the only symptom of a variety of migraine. Children with cyclical vomiting syndrome may have a genetic association with migraine.
- The nature of the vomitus provides a clue:
  - faeculent = intestinal obstruction
  - blood = bleeding from oesophagus, stomach or duodenum (mostly)
  - coffee-grounds = bleeding from stomach or duodenum

## The clinical approach

### History

A careful history is essential with an emphasis on drug intake, possible psychogenic factors, including self-induced emesis, weight loss, other GIT symptoms or symptoms suggestive of systemic disease.

### Examination

If fever is present possible sources of infection (e.g. middle ear, meninges and urinary tract) should be checked.

A careful abdominal examination is appropriate in most instances and this includes urinalysis. Look

particularly for scars indicating previous surgery. Look for a succussion splash—this indicates pyloric obstruction.

A neurological examination needs to be considered, including ophthalmoscopy. Consider raised intracranial pressure.

No examination is complete without assessment of the patient's physical fitness, including the level of hydration, especially in infants and the very old. In these age groups the history may be difficult to obtain and the consequences of fluid loss are more complicated. Always be mindful of the possibility of pregnancy in the female patient. Look for acid dental erosion as a marker of bulimia.

## Investigations

These should consider the underlying cause and also biochemical abnormalities resulting from fluid and electrolyte loss.

The following need to be considered:

- pregnancy test (all females of child-bearing age)
- microscopy and culture of stools
- radiology of GIT
- endoscopy
- oesophageal motility studies
- neurological investigation for suspected intracranial pressure (e.g. CT scan, MRI)
- drug toxicity studies
- biochemistry
- cortisol/short synacthen test

## Red flags for vomiting

- Marked pallor
- Signs of hypovolaemia
- Peritoneal signs
- Headache, stiff neck, confusion
- Distended tympanic abdomen

## Diagnostic guidelines

- Surgical GIT causes are unlikely in the absence of abdominal pain.
- Vomiting without bile-stained vomitus = pyloric obstruction.
- Vomiting of bile = obstruction below duodenal ampulla.
- Vomiting of ingested food = oesophageal obstruction.
- Vomiting without nausea and possibly projectile = ↑ intracranial pressure.

A summary of the diagnostic strategy model is presented in **TABLE 60.1**.

## Vomiting in infancy

### Is the vomiting bile-stained?

- Green vomiting = urgent surgical referral for possible intestinal malrotation with volvulus (6 hours leeway before gangrene of bowel)<sup>2</sup>  
Other causes: meconium ileus, small bowel atresia
- Non bile-stained vomitus (curdled milk): consider pyloric stenosis, GORD, feeding problems, concealed infection (e.g. UTI, meningitis). Both pyloric stenosis and GORD cause projectile vomiting.

**Table 60.1** Vomiting: diagnostic strategy model

Q. Probability diagnosis
A. All ages: acute gastroenteritis, motion sickness, drugs, various infections Neonates: feeding problems Children: viral infections/fever, otitis media, UTI Adults: gastritis, alcohol intoxication, other toxins, pregnancy, migraine
Q. Serious disorders not to be missed
A. Bowel obstruction: <ul style="list-style-type: none"> <li>• oesophageal atresia (neonates)</li> <li>• pyloric obstruction &lt;3 months</li> <li>• intestinal malrotation</li> <li>• intussusception</li> <li>• malignancy (e.g. oesophagus, stomach)</li> </ul> Severe infection: <ul style="list-style-type: none"> <li>• botulinum poisoning</li> <li>• septicaemia</li> <li>• meningitis/encephalitis</li> <li>• infective endocarditis</li> <li>• others (e.g. acute viral hepatitis)</li> </ul> Malignancy Intracranial disorders: malignancy, cerebellar haemorrhage Acute appendicitis Acute pancreatitis Acute myocardial infarction (e.g. painless)
Q. Pitfalls (mainly adults)
A. Pregnancy (early) Organ failure: liver, kidney (uraemia), heart, respiratory Labyrinthine disorders: Meniere syndrome, labyrinthitis Poisoning: food, chemicals Gut motility disorders: achalasia Paralytic ileus Substance abuse Radiation therapy Hypercalcaemia Functional obstruction: diabetic gastroparesis, idiopathic gastroparesis
Q. Seven masquerades checklist
A. Depression (possible) Diabetes (ketoacidosis) Drugs Anaemia Thyroid and other endocrine disorders (Addison disease) UTI
Q. Is the patient trying to tell me something?
A. Possibly: extreme stress (e.g. panic attacks). Consider bulimia (self-induced vomiting) and functional (psychogenic).

## Important warning signs in neonates

- Excessive drooling of frothy secretions from mouth
- Bile-stained vomitus—always abnormal
- Delayed passage of meconium (beyond 24 hours)
- Inguinal hernias

## Specific conditions

### Oesophageal atresia

- Vomiting occurs with the first feeding.
- There is excessive drooling of frothy secretions from the mouth.
- Pass a French gauge 10 catheter through the mouth to aid diagnosis.

### Congenital hypertrophic pyloric stenosis

- Usually sudden onset 3rd–6th week
- Projectile vomitus
- Failure to thrive
- Male:female = 5:1
- Gastric peristalsis during test feeding (L → R):
  - feel for pyloric tumour either during test feeding or immediately after vomiting (deep in right epigastrium)—see FIGURE 60.1; once felt, further investigation is not necessary
- biochemistry:
  - metabolic alkalosis: sodium usually <130 mmol/L, chloride <100 mmol/L
- special investigations (if necessary):
  - barium meal (string sign)—concern about aspiration
  - abdominal ultrasound
- treatment:
  - correct fluid and electrolyte deficiency (hypochloraemic alkalosis) before surgery
  - appropriate fluid is  $\frac{N}{2}$  or half normal saline with 5% dextrose
  - surgical management (longitudinal pyloromyotomy)

### Acute gastroenteritis

See CHAPTER 44.

### Gastroparesis (adults)<sup>3</sup>

Gastroparesis (gastropathy) or severely delayed gastric emptying is a moderately common condition, which is a cause of nausea and vomiting.

Causes include:

- diabetic gastroparesis
- postsurgical gastroparesis, e.g. vagotomy (complete or partial), fundoplication
- trauma

FIGURE 60.1 Signs of pyloric stenosis

- idiopathic (de novo)
- Less common causes include:
- connective tissue disorders (e.g. scleroderma)
  - vasculitides
  - myopathic disorders (e.g. muscular dystrophy)
  - thyroid dysfunction
  - hypokalaemia
  - pancreatitis

### Symptoms

- Upper abdominal discomfort/bloating
- Early satiety
- Nausea
- Postprandial vomiting (1–3 hours after meals)
- Abdominal pain

### Diagnosis

- Endoscopy → significant gastric residue
- Barium swallow with follow through
- Nuclear medicine gastric emptying test (gastric retention of 60% after 2 hours is abnormal)

### Special problems

- Malnutrition
- Dehydration

### Management

- Advise patients to eat small, frequent meals, with careful chewing of food.
- Avoid large pieces of bread especially doughy bread (encourage toasting).
- Avoid fat, especially French fries, raw fruit and vegetables.
- Refer diabetic patients to a dietitian for advice.

### Medications<sup>4,5</sup>

domperidone 10–20 mg (o) tds, 15–30 minutes before meals  
*or*  
 metoclopramide 5–10 mg (o) tds, 30 minutes before meals  
*or*  
 erythromycin (has prokinetic properties) 125 mg (o) tds, 15 minutes before meals (rapidly develops tolerance)  
 consider cisapride 10 mg (o) tds before meals (with caution)

### Other measures

- Injection of botulinum toxin into the pylorus
- Gastric pacing with internally implanted neurostimulators<sup>6</sup>

### § Cyclical vomiting<sup>7</sup>

Features:

- severe, unexplained vomiting or nausea occurring at varying intervals in a normal healthy person
- lasts hours to days
- most common in children (mean age 5 years)
- ± severe abdominal pain, photophobia, headache
- regarded as a migraine variant
- usually remits in adulthood—may persist
- treated with antimigraine therapy

### Complications of vomiting

These include dehydration, metabolic alkalosis, hypokalaemia, aspiration, mucosal tear of gastro-oesophageal junction, rupture of the oesophagus (Boerhaave syndrome).

### Symptomatic relief of vomiting

The first-line management is to ensure that any fluid and electrolyte imbalance is corrected and that any underlying cause is identified and treated. Various anti-emetics can give symptomatic relief.

*Note:* Avoid the use of centrally acting dopamine antagonist drugs (DADS, e.g. metoclopramide and prochlorperazine) in children because of risk of extrapyramidal side effects (EPSE), usually acute dystonic reactions. Elderly also at risk. EPSE rare with domperidone because it does not cross the blood–brain barrier. Other DADS include haloperidol and droperidol (limited use).

### Serotonin 5-HT<sub>3</sub> antagonists

These include ondansetron, granisetron, dolasetron, palonosetron and tropisetron and are effective at preventing chemotherapy- and radiotherapy-induced emesis when initiated prior to treatment. Dexamethasone enhances the effect of 5-HT<sub>3</sub> agents. Ondansetron can be used in children with gastroenteritis, preferably in wafer format.

### Drug-induced nausea and vomiting<sup>4</sup>

metoclopramide 10 mg (o) or IM 8 hourly prn

For cytotoxic drugs (e.g. cisplatin) and radiotherapy: metoclopramide 10 mg (o) or IM 1 to 2 hours prior to therapy then 8 hourly (if mild)

For severe cases:

ondansetron 8 mg (o) or IV prior to therapy then two doses 6 hourly

*plus*

dexamethasone 8 mg IV 30 minutes prior to therapy, then two doses 6 hourly

*Note:* Restrict ondansetron to 8 mg daily for those with hepatic dysfunction.

A list of some drugs that can cause nausea and vomiting is presented in [TABLE 60.2](#).

**Table 60.2** Some drugs that can cause nausea and vomiting

Alcohol (including binge drinking)
Antibiotics (various) esp. erythromycin
Antidepressants (e.g. serotonin reuptake inhibitors)
Antidiabetic agents (e.g. metformin, acarbose)
Antihypertensives
Bromocriptine
Codeine
Corticosteroids
Cytotoxic agents
Digoxin
Iron preparations
Levodopa, other anti-parkinsonism drugs
Nicotine and nicotine gum
NSAIDs (e.g. indomethacin)
Opioids (e.g. morphine, codeine)
Oral contraceptives
Salicylates
Theophylline

## Motion sickness

Refer CHAPTER 14.

promethazine theoclate 25 mg (o) 60 minutes prior to travel  
*or*  
 dimenhydrinate 50 mg (o) 60 minutes prior to travel  
*or*  
 hyoscine 300–600 mcg (o) 30 minutes prior to travel  
*or*  
 hyoscine 1.5 mg dermal disc: applied to dry hairless skin behind the ear 5–6 hours before travel (effective for 72 hours)<sup>4</sup>

For treatment: repeat oral presentations 4–6 hourly during trip (max. 4 doses in 24 hours).

## Vestibular disturbances<sup>4</sup>

The phenothiazine derivatives are the most effective, while the dopamine D<sub>2</sub>-receptor antagonists are relatively ineffective. Refer to CHAPTER 46.

prochlorperazine 5–10 mg (o) or 10 mg rectally, SC or IM 4 times daily prn  
*or*  
 promethazine theoclate 25 mg (o) or IM 4 hourly prn (max. 100–150 mg per 24 hours)

*Note:* Beware of tardive dyskinesia with prolonged use.

## Gastroenteritis

For severe cases in adults:

metoclopramide 10 mg (o) or IM 8 hourly prn

## Pregnancy

pyridoxine hydrochloride 25–50 mg (o) tds *if still ineffective add*  
 metoclopramide 10 mg (o) tds or IM (if oral intolerance)  
*if response still unsatisfactory*  
 ondansetron tablet or wafer 4–8 mg (o) bd to tds

## Postoperative vomiting<sup>4</sup>

metoclopramide 10 mg IM or IV (slowly), 8 hourly prn  
*or*  
 prochlorperazine 12.5 mg IM, 8 hourly prn

## Chemotherapy and radiotherapy

ondansetron 4 mg (o or SL) bd *plus*  
 dexamethasone 4 mg (o) daily

Table 60.3 Anti-emetic medications in common use

Anti-emetic	Receptor antagonist	Route
Promethazine	H <sub>1</sub>	O, IM, IV
Metoclopramide	D <sub>2</sub> + 5-HT <sub>3</sub>	O, IV, IM
Prochlorperazine	D <sub>2</sub> (central)	O, IM, PR
Domperidone	D <sub>2</sub> (peripheral)	O
Haloperidol	D <sub>2</sub> (central)	O, IM
Ondansetron	5-HT <sub>3</sub>	O, IV

Important side effects: dystonia, dyskinesia, drowsiness, anticholinergic, hyperprolactinaemia

5-HT<sub>3</sub> = 5 hydroxytryptamine type 3, D<sub>2</sub> = dopamine D<sub>2</sub>

## Practice tips

- Consider the possibility of anorexia nervosa and bulimia in adolescent females with a history of vomiting immediately after meals, especially after binge eating.
- If weight loss accompanies nausea and vomiting, consider GIT malignancy and obstruction as well as the above psychogenic conditions.
- Early morning nausea and vomiting can be caused typically by alcohol, pregnancy, kidney failure and raised intracranial pressure.
- Intracranial space-occupying lesions can cause vomiting without associated anorexia or nausea.
- Gastroparesis commonly occurs in longstanding diabetes, following surgery or may be idiopathic. Intense nausea and anorexia are features.
- Anti-emetic drug therapy should not be used in infants and children with gastroenteritis.
- Anti-emetic treatment (see TABLE 60.3) must be tailored to the specific cause of the problem.
- The major complications of severe vomiting include trauma of the distal oesophagus, such as a Mallory–Weiss tear, and severe fluid and electrolyte disturbances.

# 61 Neck lumps

*There are approximately 800 lymph nodes in the body; no fewer than 300 of them lie in the neck and inflammation of these is exceedingly common.*

McNeil Love, Co-editor of *Bailey & Love's Short Practice of Surgery*, 1965

In the management of lumps in the neck it is important to distinguish between the various midline and lateral causes, especially cervical lymphadenopathy, which may be caused by occult malignancy, such as in the aerodigestive tract. With increasing ageing in the population the number of patients presenting with a malignant neck lump is also increasing. The neck is divided into anterior and posterior triangles by the sternomastoid muscle and the anatomical areas are helpful in identifying the origin of the primary lesion (see FIG. 61.1).

- Other investigations are chest X-ray and FBE. Bone marrow biopsy or fine-needle aspiration of thyroid nodule or other masses may be considered. Fine-needle aspiration biopsy (FNAB) which is a relatively simple procedure, is the single most helpful investigation for diagnosing the cause.<sup>3</sup> If cytology reveals malignant squamous cells, the primary lesion may lie in the skin, lung, larynx, pharynx, ear or oesophagus.

## Key facts and checkpoints

- Most neck lumps are reactive lymph nodes—to concurrent infection.
- Lymph nodes are normally palpable in children between 3 and 8 years of age; soft, mobile nodes up to 1 cm in diameter are commonly felt in the anterior and posterior triangle. A node >2 cm is considered to be enlarged. Some cervical glands are very prominent, especially tonsillar nodes.
- These prominent nodes often enlarge during intercurrent viral infection.
- Causes of neck swellings are lymph nodes 85%, goitres 8%, others 7%.<sup>1</sup>
- Solitary nodules in the thyroid move on swallowing.
- Consider the possibility of tuberculosis, especially with exposure in endemic areas and in immunocompromised people.
- A knowledge of the areas drained by lymph nodes is important (see FIG. 61.1).
- Examination must extend beyond the neck for lymphadenopathy.
- To examine cervical nodes slightly rotate head and palpate with palmar aspect of fingers.
- Palpate submental area with head slightly flexed.
- Biopsy of a complete lymph node is necessary to establish diagnosis for unknown or suspicious causes but do not consider it as the first step in diagnosis.<sup>2</sup>

## A diagnostic approach

A summary of the diagnostic strategy model is presented in TABLE 61.1.

The key components of the history, examination and investigations follow.

## History

This depends on the age of the patient but should include in all ages a history of upper respiratory infection, lower respiratory infection, possible Epstein-Barr, HIV, cytomegalovirus and tuberculosis infection. Consider red flags such as weight loss, dysphagia, history of cancer and increasing size of the lump. Note any response to antibiotics given for a throat or upper airways infection.

## Examination

- Careful palpation of lymph node areas and matching the site of any lymphadenopathy with a 'map' of areas drained by the nodes
- Examine the lump according to the classic rules of look, feel, move, measure, auscultate and transilluminate
- Palpate the midline anterior area for thyroid lumps and the submental area for submandibular swellings
- Note the consistency of the lump: soft, firm, rubbery or hard

**Table 61.1** Neck lumps: diagnostic strategy model

## Probability diagnosis

## Lymphadenitis (reaction to local infection)

- acute: viral or bacterial
- chronic: MAIS (atypical tuberculosis), viral (e.g. EBM, rubella)

## Prominent normal lymph nodes

## Goitre

## Sebaceous cyst

## Lipoma

## Sternomastoid tumour (neonates)

## Serious disorders not to be missed

## Vascular:

- carotid body tumour or aneurysm

## Infection:

- 'collar stud' abscess (atypical TB)
- tuberculosis of cervical nodes (scrofula)
- HIV/AIDS of nodes
- actinomycosis

## Cancer/tumour

- lymphoma (e.g. Hodgkin)
- leukaemia
- thyroid nodule (adenoma, cancer, colloid cyst)
- metastatic nodes
- salivary gland tumours

## Pitfalls (often missed)

## Parotitis

## Thyroglossal cyst

## Lymphatic malformation (children)

## Cervical rib

## Rarities:

- sarcoidosis
- cyst hygroma
- bronchial cyst (child)
- torticollis

**Investigations**

- FBE
- ESR/CRP
- CXR
- TFTs (of thyroid swelling)
- Fine needle aspiration biopsy of thyroid nodules
- Lymph node biopsy

Thyroid and primary tumours: imaging techniques (if necessary to assist diagnosis) include:

- ultrasound

- axial CT scan (esp. in fat necks)
- MRI scan (distinguishes a malignant swelling from scar tissue or oedema)
- tomogram of larynx (malignancy)
- barium swallow (pharyngeal pouch)
- sialogram
- carotid angiogram

**Red flag pointers for neck lumps**

- >40 years, esp. >70 years
- Nodes >2.5 cm
- Nodes >3–4 cm ? malignancy
- Tender mass
- Purple discolouration (collar-stud abscess)
- Single, gradually enlarging node
- Fixed to skin without punctum
- Associated dysphagia
- Hard midline thyroid lump
- Patient at risk of malignancy and HIV
- Exposure to tuberculosis

**The 20:40 and 80:20 rules<sup>3</sup>**

- The age of the patient is a helpful guide, as causes of neck lumps can be roughly categorised by the '20:40 rule':
  - 0–20 years: congenital, inflammatory, lymphoma, tuberculosis
  - 20–40 years: inflammatory, salivary, thyroid, lymphoma
  - >40 years: lymphoma, metastases
- Most neck lumps (80%) are benign in children while the reverse applies to adults.
- Imaging techniques that may assist diagnosis include axial CT scan (especially in fat necks), MRI scan (distinguishes a malignant swelling from scar tissue or oedema), tomogram of larynx (laryngocele or malignancy), barium swallow (pharyngeal pouch), sialogram and carotid angiogram.<sup>4</sup>

A basic suggested approach for the patient presenting with a neck lump is summarised in **FIGURE 61.2**.

**CERVICAL LYMPHADENOPATHY**

- There are many causes, varying from local infections to lymphoproliferative disorders.
- Most malignant nodes in the supraclavicular area have their primary tumour below the clavicle.
- Eighty-five per cent of malignant nodes in the anterior triangle have their primary tumour in the head and neck.<sup>2</sup>

FIGURE 61.1 Lymph glands (site of the nodes) of the neck including common sources of adenopathy (excluding lymphomas)

FIGURE 61.2 A basic approach for patients presenting with a neck lump<sup>4</sup>

- Always search for:
  - other nodes at distant sites
  - possible primary source of infections or neoplasia
  - hepatosplenomegaly

- Hodgkin lymphoma usually presents with rubbery, painless nodes in the neck.
- Most swellings are lateral.

### Consistency of enlarged nodes

Rules of thumb are:<sup>5</sup>

- hard: secondary carcinoma
- rubbery: lymphoma
- soft: sarcoidosis or infection
- tender and multiple: infection

### Causes of cervical lymph node enlargement (lateral cervical swelling)

#### Acute cervical lymphadenitis

- Acute viral lymphadenitis
- Acute bacterial lymphadenitis—coccal infection

#### Chronic lymph node infection

- MAIS lymphadenitis (atypical tuberculosis)
- Tuberculosis
- Viral infection, for example, EBM (see FIG. 61.3), rubella, cytomegalovirus, HIV

**FIGURE 61.3** Cervical lymphadenopathy associated with Epstein–Barr mononucleosis

- *Toxoplasma gondii* infection
- Cat scratch disease—*Bartonella henselae* infection

### Neoplastic lymphadenopathy

- Lymphomas, esp. Hodgkin lymphoma
- Leukaemia

### Metastatic

- Check mouth, pharynx, sinuses, larynx, scalp, oesophagus, stomach, breast, lungs, thyroid and skin. A working rule is upper neck—from skin to upper aerodigestive tract; lower neck—from below clavicles (e.g. lung, stomach, breast, colon).
- Examples:
  - occipital or pre-auricular—check scalp
  - submental—check mouth, tongue, teeth
  - submandibular—check floor of mouth
  - left supraclavicular (under sternomastoid)—consider stomach (Troisier sign)
  - deep anterior cervical—consider larynx, thyroid, oesophagus, lungs

## NECK LUMPS NOT DUE TO LYMPH NODE SWELLING<sup>6</sup>

### Types and causes

#### Widespread

- Sebaceous cysts
- Lipomas

#### Midline

- Thyroid nodule (moves upon swallowing)
- Thyroglossal cysts (moves upwards on tongue protrusion)
- Dermoid cyst (beneath chin)

### Anterior triangle

- Branchial cyst (in upper part):
  - usually adulthood (20–25 years)
- Carotid body tumour:
  - opposite thyroid cartilage
  - smooth and pulsatile
  - can be moved laterally but not vertically
  - usually 40–60 years
  - requires excision (with care)
- Carotid aneurysm
- Lateral thyroid tumours

### Posterior triangle

- Developmental remnants:
  - cystic hygroma
  - bronchial sinuses and cysts
- Pancoast tumour (from apex lung)
- Cervical rib

### Submandibular swellings

- Submandibular salivary gland
- Cervicofacial actinomycosis (lumpy jaw syndrome):
  - chronic granulomatous infection due to Gram-positive *Actinomyces israelii*
  - forms a multilocular abscess (pus has ‘sulphur granules’)
  - infection follows dental extraction or poor dental hygiene, esp. severe caries
  - treat with high-dose penicillin G, 4 months

### Sternomastoid tumour

Refer **CHAPTER 91**.

### Pharyngeal pouch

- A soft, squelchy, indefinite mass
- Base of left neck
- History of difficulty in swallowing

### Thyroid nodule

The most likely cause of a solitary thyroid nodule is the dominant nodule in a multinodular goitre.

Other causes include a true solitary nodule—adenoma, follicular carcinoma or solitary carcinoma—and a colloid cyst. Malignancy must be excluded.

### Investigations

- Ultrasound
- FNAB (may resolve a cystic lesion)
- TFTs

## Neck lumps in children

Eighty per cent of neck lumps are benign while 20% are malignant. Benign lumps usually occur in the anterior triangle, while malignant lumps are more likely in the posterior triangle. The common midline lump in children is the thyroglossal cyst.<sup>3</sup> Consider sternomastoid tumour (fibrosis) in infants (see CHAPTER 92).

## Lymphadenopathy

- Most enlarged lymph nodes are either 'normal' or local infections (mainly viral), especially if <2 cm diameter, and not hard or fixed.
- Inflammatory nodes may be caused by infection in the tonsils, the teeth or other oral or nasopharyngeal cavities.
- They are of concern if supraclavicular node enlargement and fever <1 week.
- Suspicious nodes are >2.5 cm, with firmer consistency than normal and less mobility (investigate especially with biopsy).
- Consider bacterial infection with abscess formation in infants and children with large (2–4 cm) tender masses.

## MAIS lymphadenitis<sup>4,7</sup>

- Child usually 2–3 years of age
- Caused by *Mycobacterium avium-intracellulare-scrofulaceum* (MAIS) infection
- Produces chronic cervical lymphadenitis and collar stud abscesses
- A relatively common infection of cervical nodes, yet often unrecognised
- Painless swelling due to development of a cold abscess in healthy child
- Nodes enlarge over 4–6 weeks prior to erupting into a 'cold' abscess and the overlying skin has a purplish discolouration, which is an indication for surgical treatment

- Common sites are submandibular, tonsillar and pre-auricular nodes
- Invariably unilateral, confined to one lymph node group
- No pulmonary involvement
- Unresponsive to antimicrobials: treatment is by surgical excision of abscess and underlying lymph nodes

## Acute bacterial lymphadenitis

- Usually coccal infections—*Staphylococcus*, *Streptococcus*
- Can progress to abscess formation (fluctuant): requires drainage

## When to refer

- A persisting lump, depending on its location and size
- A lymph node or group of nodes that are abnormally enlarged and fail to respond to antibiotics

William Heberden (1710–1801)

Neck pain is a very common symptom in both sexes at all ages and although most pain is experienced in the posterior aspect of the neck, anterior neck pain can occur from causes that overlap between front and back. The main cause of neck pain is a disorder of the cervical spine, which usually manifests as neck pain but can refer pain to the head, shoulders and chest. Such pain usually originates from the facet (apophyseal) joints but can arise from other musculoskeletal structures, such as the intervertebral discs and the muscles or ligaments (see FIG. 62.1). The other major symptom is limited movement or stiffness.

General causes of neck pain are presented in TABLE 62.1.

## Key facts and checkpoints

- According to an Australian study, about 18% of people wake with some degree of neck pain and 4% experience neck pain or stiffness for all of the day.<sup>1</sup>

- The commonest cause of neck pain is idiopathic dysfunction of the facet joints without a history of injury.
- Disorders of the intervertebral discs are common, especially in the lower cervical spine, and may cause unilateral pain, paraesthesia or anaesthesia in the arm.
- In a UK study radiological cervical disc degeneration was present in 40% of males and 28% of females<sup>2</sup> between 55 and 64 years.
- Strains, sprains and fractures of the facet joints, especially after a 'whiplash' injury, are difficult to detect and are often overlooked as a cause of persistent neck pain.
- Cervical spondylosis is a disorder of ageing: radiological signs occur in 50% of people over the age of 50 and in 75% over the age of 65 years.<sup>3</sup>
- In cervical spondylosis, osteophytic projections may produce nerve root and spinal cord compression,

*continued*

FIGURE 62.1 Transverse section illustrating the functional unit and nervous network of the cervical spine

*continued*

- resulting in radiculopathy and myelopathy respectively.
- Radiculopathy can be caused by a soft disc protrusion (usually unilateral), a hard, calcified lump and osteophytes (may be bilateral).
- Cervical disorders are aggravated by vibration (e.g. riding in a motor vehicle).
- Always determine the C2, C6 and C7 levels by finding the relevant spinous processes (easily palpable landmarks) prior to palpation.
- Palpation of the neck is the cornerstone of cervical management. Palpate gently—the more one presses the less one feels.
- Most episodes of neck pain, including acute torticollis, are transient, lasting from about 2 to 10 days.
- In one study 70% of people with neck pain who sought medical attention had recovered or were recovering within one month.<sup>2</sup>
- Effective management of neck pain is based on the theoretical principle that stiff dysfunctional joints are painful and restoration of normal movement may be associated with resolution of pain.
- The optimal treatment for dysfunctional joints (without organic disease or radiculopathy) is active and passive mobilisation, especially as exercises.

**Table 62.1** Causes of neck pain (a pathological classification)

#### Musculoskeletal/structural

##### Joint dysfunction:

- apophyseal
- intervertebral disc

##### Muscular/ligamentous strains or sprains

##### Trauma:

- 'whiplash'
- fracture
- other disorders

#### Inflammation

##### Osteoarthritis\*

##### Rheumatoid arthritis

##### Spondyloarthropathies (e.g. ankylosing spondylitis, psoriasis, reactive arthritis)

##### Polymyalgia rheumatica

##### Thyroiditis

#### Infective

##### Spinal:

- osteomyelitis
- tuberculosis
- herpes zoster

#### Extraspinal:

- epidural abscess
- cervical adenitis
- poliomyelitis
- tetanus

#### Extracervical:

- meningitis
- febrile states (e.g. meningism, malaria)

#### Degenerative

##### Spondylosis\*

#### Metabolic

##### Paget disease

#### Neoplasia

##### Benign

##### Malignant

#### Fibromyalgia syndrome

#### Psychogenic

#### Referred visceral

##### Heart:

- IHD

##### Oesophagus

##### Lung cancer

#### Referred cranial

##### Haemorrhage (e.g. subarachnoid)

##### Tumour

##### Abscess

\* Osteoarthritis, or spondylosis, is inflammatory and degenerative.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in **TABLE 62.2**.

## Probability diagnosis

The main causes of neck pain are vertebral dysfunction, especially of the facet joints, and traumatic strains or sprains affecting the musculoligamentous structures of the neck. The so-called myofascial syndrome is mainly a manifestation of dysfunction of the facet joints. Acute wry neck (torticollis), which is quite common, is yet another likely manifestation of apophyseal joint dysfunction. Spondylosis, known also as degenerative osteoarthritis and osteoarthritis, is also a common cause, especially in the elderly patient.

**Table 62.2** Neck pain: diagnostic strategy model

Q. Probability diagnosis
A. Vertebral dysfunction
Traumatic 'strain' or 'sprain'
Cervical spondylosis
Q. Serious disorders not to be missed
A. Cardiovascular:
• angina
• subarachnoid haemorrhage
• arterial dissection
Neoplasia:
• primary
metastasis
• Pancoast tumour
Severe infections:
• osteomyelitis
• meningitis
Vertebral fractures or dislocation
Q. Pitfalls (often missed)
A. Disc prolapse
Myelopathy
Cervical lymphadenitis
Fibromyalgia syndrome
Outlet compression syndrome (e.g. cervical rib)
Polymyalgia rheumatica
Ankylosing spondylitis
Rheumatoid arthritis
Oesophageal foreign bodies and tumours
Paget disease
Q. Seven masquerades checklist
A. Depression
Thyroid disorder (thyroiditis)
Spinal dysfunction
Q. Is the patient trying to tell me something?
A. Highly probable. Stress and adverse occupational factors relevant.

Intervertebral disc disruption is also a relatively common phenomenon in the cervical spine, especially at the lower levels C5–6 and C6–7.<sup>4</sup>

## Serious disorders not to be missed

Conditions causing neck pain and stiffness may be a sign of meningitis or of cerebral haemorrhage, particularly subarachnoid haemorrhage, or of a cerebral tumour or retropharyngeal abscess.

Angina and myocardial infarction should be considered in anterior neck pain. Other visceral disorders can refer pain to the neck.

Arterial dissection of the internal carotid artery or vertebral artery should be kept in mind in patients

presenting with acute neck pain, especially without musculoskeletal symptoms or signs.

Tumours are relatively rare in the cervical spine but metastases do occur and should be kept in mind, especially with persistent neck pain present day and night.

Metastasis to the spine occurs in 5–10% of patients with systemic cancer, making it the second most common neurological complication of cancer. The cervical spine accounts for some 15% of spinal metastases.<sup>3</sup>

The commonest primary tumours are the breast, prostate or lung. Other primaries include the kidney, thyroid and melanoma.

## Red flag pointers for neck pain

- History of major trauma
- Age >50 years
- Constant pain (day and night)
- Fever >38°C
- Anterior neck (throat) pain
- History of cancer
- Unexplained weight loss
- Neurological deficit
- Radicular pain in arm
- Rheumatoid arthritis
- Down syndrome

## Pitfalls

There are many pitfalls in the clinical assessment of causes of neck pain, many of them related to inflammation.

Rheumatoid arthritis is the prime severe inflammatory arthropathy that involves the neck but the neck can be affected by the seronegative spondyloarthropathies, particularly ankylosing spondylitis, psoriasis and the inflammatory bowel disorders.

While polymyalgia rheumatica affects mainly the shoulder girdle, pain in the lower neck, which is part of the symptom complex, is often overlooked. Diffuse neck pain in myofascial soft tissue with tender trigger areas is part of the uncommon but refractory fibromyalgia syndrome.

## General pitfalls

- Failing to appreciate how often the benign problem of facet joint dysfunction occurs in the neck, causing pain and limited movement. This involves failure to appreciate the value of physical therapy, especially exercise programs, in alleviating the problem.

- Failing to adhere to the idiom: one disc—one nerve root. Involvement of more than one nerve root in the upper limb may mean a neoplastic disorder such as metastatic disease, lymphoma in the thoracic outlet and similar serious diseases.
- Missing the insidious onset of myelopathy, especially the spasticity component, caused by rheumatoid arthritis, osteophytic overgrowth or, rarely, a soft disc prolapse.

### Seven masquerades checklist

Cervical spinal dysfunction is the obvious outstanding cause. Thyroiditis may cause neck pain, as in the extremely rare cases of acute specific infection in the thyroid (e.g. syphilis, pyogenic infections), which cause severe pain; non-specific thyroiditis (de Quervain thyroiditis) produces painful swelling with dysphagia. The association between depression and neck pain is well documented.

### Psychogenic considerations

The neck is one of the commonest areas for psychological fixation following injury. This may involve perpetuation or exaggeration of pain because of factors such as anxiety and depression, conversion reaction and secondary gain.

The psychological sequelae that can follow a whiplash injury and chronic neck problems such as spondylosis serve as a reminder that the state of the patient's cervical spine can profoundly affect his or her life and that we should always be aware of the whole person. A feeling of depression is a very common sequel to such an injury and these patients demand our dutiful care and understanding.

## The clinical approach

### History

It is important to analyse the pain into its various components, especially the nature of its onset, its site and radiation, and associated features. The diurnal pattern of the pain will provide a lead to the diagnosis (refer to FIG. 38.3: the patterns are similar to low back pain).

### Key questions

- Can you point to exactly where in your neck you get the pain?
- Do you wake up with pain in the morning?
- Does the pain come on when you have to look up for a while?
- Do you have trouble reversing your car?
- Can you recall an injury to your head or neck such as hitting your head on an overhead bar?
- Does your neck grate or get stiff?
- Do you get headaches or feel dizzy?
- Is the pain present day and night?
- Do you get pain or pins and needles or numbness in your arms?
- Does the pain come on with activity?
- Does the pain wake you at night?
- Do you feel pain on both sides of your neck and over your shoulders?
- Do your hands or arms feel weak or clumsy?

### Examination

It is appropriate to follow the traditional rule for examination of any joint or complex of joints: *look, feel, move, measure, test function, look elsewhere* and *X-ray*. Careful examination of the cervical spine is essential for the correct diagnosis and for specific treatment at the painful level.

Three objectives of the examination are to:

- reproduce the patient's symptoms
- identify the level of lesion or lesions
- determine the cause (if possible)

A neurological examination is essential if radicular pain is present, or weakness or other upper limb symptoms, including any pain or paraesthesia that extends below the elbow.

### Inspection

The patient should be examined sitting on a couch, rather than on a chair. The body should be fully supported with the hands resting on the thighs. The following should be noted:

- willingness to move the head and neck
- level of the shoulders
- any lateral flexion
- contour of the neck from the side

In the patient with torticollis the head is held laterally flexed with, perhaps, slight rotation to one side—usually away from the painful side. Patients suffering from whiplash injury and severe spondylosis tend to hold the neck stiff and the head forward, and tend to turn the trunk rather than rotate the neck.

### Palpation

For this vital component of the examination it is essential to know the surface anatomy of the neck so that the affected level can be determined.

## Method

The patient lies prone on the examination couch with the forehead resting on the hands (palms up). The neck should be flexed forward and the shoulders relaxed.

### 1 Central digital palpation

Systematically palpate the first spinous processes of the cervical vertebrae.

- C2 (axis) is the first spinous process palpable beneath the occiput.
- C7 is the largest 'fixed' and most prominent process—situated at the base of the neck.
- C6 is also prominent but usually 'disappears' under the palpating finger with extension of the neck.
- The spinous processes of C3, C4 and C5 are difficult to palpate because of cervical lordosis but their level can be estimated (see FIG. 62.2).

Standing at the patient's head, place opposed pulps of the thumbs on the spinous processes (starting at C2) and then move down the middle line to C7. Press firmly over each and with arms straight oscillate with moderate firmness three or four times to assess pain, stiffness or muscle spasm.

### 2 Lateral digital palpation

The facet joints lie in sequence (called the articular pillar) about 2 to 3 cm from the midline. Press with opposed thumbs against this pillar in a systematic manner on either side of the midline (top to base) to determine any painful area. Palpation should be extended to include the anterior neck, searching for evidence of lymphadenitis, muscle spasm, thyroid disorder and other problems.

FIGURE 62.2 Relative sizes of spinous processes of the cervical spine

## Movement

Active movements are observed with the patient sitting on the couch. The movements are as follows with normal range indicated:

- flexion—45°
- extension—50°
- lateral flexion (R and L)—45°
- rotation (R and L)—75°

If there is a full range of pain-free movement, apply overpressure slowly at the end range and note any pain.

The range of movements can be plotted on a special grid called a direction of movement (DOM) diagram (see FIG. 62.3). This provides a ready reference for serial assessments.

FIGURE 62.3 Direction of movement diagram to record movements of the neck. This record shows restricted and painful movements (indicated by ||) in right lateral flexion and right rotation; the other movements are free.

## Neurological examination

A neurological examination for nerve root lesions (C5 to T1) is indicated if the clinical assessment identifies the presence of neurological symptoms and signs such as pain, paraesthesia or anaesthesia in the arm. Nerve root pressure is indicated by:

- pain and paraesthesia along the distribution of the dermatome
- localised sensory loss
- reduced muscular power (weakness or fatigue or both)
- hyporeflexia (reduced amplitude or fatigue or both)

It is necessary to know the sensory distribution for each nerve root and the motor changes. This is summarised in TABLE 62.3. The dermatomes are illustrated in FIGURE 62.4.

**Table 62.3** Cervical nerve root syndromes

Nerve root	Sensory change	Muscle power	Power loss	Reflex
<b>C5</b>	Outer arm	Deltoid	Abduction arm	Biceps jerk (C5, 6)
<b>C6</b>	Outer forearm/thumb/ index finger	Biceps	Elbow flexion Extension wrist	Biceps + brachioradialis (C5, 6)
<b>C7</b>	Hand/middle and ring fingers	Triceps	Elbow extension	Triceps (C7–8)
<b>C8</b>	Inner forearm/little finger	Long flexors finger, long extensors thumb	Grip	Fingers (C8)
<b>T1</b>	Inner arm	Interossei	Finger spread	

**FIGURE 62.4** Dermatomes of the upper limb, head and neck

## Investigations

The investigations are directed to diagnosing the painful condition and determining if suspected or true organic disease is present in the spine. It is inappropriate to perform sophisticated investigations such as CT scans on most patients. Scanning should be reserved where surgery is contemplated and serious disease is suspected but not confirmed by plain X-ray.

Investigations to consider include:

- haemoglobin, film and WCC
- ESR/CRP
- rheumatoid arthritis factor

- HLA-B<sub>27</sub> antigen
- radiology:
  - plain X-ray (not indicated in absence of red flags and major trauma)
  - CT scan (good for bone definition)
  - CT scan and myelogram (if cervical disc surgery contemplated)
  - radionuclide bone scan (for suspected metastatic disease)
  - MRI: the investigation of choice for cervical radiculopathy, myelopathy, suspected spinal infection and tumour

These should be selected conservatively. CT imaging has high radiation levels.

## Neck pain in children

In children and adolescents, neck pain, often with stiffness, may be a manifestation of infection or inflammation of cervical lymph nodes, usually secondary to an infected throat—for example, tonsillitis or pharyngitis. However, it is vital to consider the possibility of meningitis. Sometimes a high fever associated with a systemic infection or pneumonia can cause meningism. In the presence of fever the rare possibility of poliomyelitis should be kept in mind. In both children and adults the presence of cerebral pathology, such as haemorrhage, abscess or tumour are uncommon possibilities.<sup>5</sup> Acute torticollis is quite common in this age group and the neck may be involved in chronic juvenile arthritis.

## Neck pain in the elderly

In adults the outstanding causes are dysfunction of the joints and spondylosis, with the acute febrile causes encountered in children being rare. However, cerebral and meningeal disorders may cause pain and stiffness in the neck.<sup>5</sup>

Rheumatoid arthritis is the prime severe inflammatory arthropathy that involves the neck, but the neck can be affected by the spondyloarthropathies (e.g. ankylosing spondylitis). The painful, acute wry neck can affect all ages and is considered to be caused mainly by acute disorders of the apophyseal joints rather than disc prolapse. However, disc lesions do occur and can cause referred pain or radicular pain. In the elderly, radicular pain can also be caused by impingement of the nerve root in the intervertebral foramen that has become narrowed from the degenerative changes of longstanding spondylosis.

Problems with a higher probability with increasing age include:

- cervical spondylosis with radiculopathy or myelopathy
- atlantoaxial subluxation complicating rheumatoid arthritis
- polymyalgia rheumatica
- metastatic cancer
- Pancoast tumour of the lung
- angina and myocardial infarction
- pharyngeal and retropharyngeal infection and tumour

## Clinical problems of cervical spinal origin

Pain originating from disorders of the cervical spine is usually, although not always, experienced in the neck. The patient may experience headache, or pain around the ear, face, arm, shoulder, upper anterior or posterior chest.<sup>5</sup>

Possible symptoms include:

- neck pain
- neck stiffness
- headache
- migraine-like headache
- facial pain
- arm pain (referred or radicular)
- myelopathy (sensory and motor changes in arms and legs)
- ipsilateral sensory changes of scalp
- ear pain (peri-auricular)
- scapular pain
- anterior chest pain
- torticollis
- dizziness/vertigo
- visual dysfunction

FIGURE 24.1 in CHAPTER 24 indicates typical directions of referred pain from the cervical spine. Pain in the arm (brachialgia) is common and tends to cover the shoulder and upper arm as indicated.

## CERVICAL DYSFUNCTION

Dysfunction of the 35 intervertebral joints that comprise the cervical spine complex is responsible for most cases of neck pain. The problem can occur at all ages and appears to be caused by disorder (including malalignment) of the many facet joints, which are pain-sensitive. Dysfunction of these joints, which may also be secondary to intervertebral disc disruption, initiates a reflex response of adjacent muscle spasm and myofascial tenderness.

### § Acute neck pain

Acute neck pain (ANP) is most commonly idiopathic or due to a whiplash accident. Serious causes are rare.<sup>6</sup> Dysfunction can follow obvious trauma such as a blow to the head or a sharp jerk to the neck, but can be caused by repeated trivial trauma or activity such as painting a ceiling or gentle wrestling. People often wake up with severe neck pain and blame it on a 'chill' from a draught on the neck during the night. This is incorrect because it is usually caused by an unusual twist on the flexed neck for a long period during sleep.

### Clinical features

- Typical age range 12–50 years
- Dull ache (may be sharp) in neck
- May radiate to occiput, ear, face and temporal area (upper cervical)
- May radiate to shoulder region, especially suprascapular area (lower cervical)
- Rarely refers pain below the level of the shoulder
- Pain aggravated by activity, improved with rest
- Various degrees of stiffness
- Neck tends to lock with specific movements, usually rotation
- Localised unilateral tenderness over affected joints
- Variable restriction of movement but may be normal
- X-rays usually normal: plain X-rays are not indicated for the investigation of ANP in the absence of 'red flags' and a history of trauma<sup>6</sup>

### Management

The aim of treatment is to reduce pain, maintain function and minimise the risk of chronicity.

- Provide appropriate reassurance, information and support.

- Give advice to the patient about rules of living including the following:  
Do:
  - Stay active and resume normal activities.
  - Keep your neck upright in a vertical position for reading, typing and so on.
  - Keep a good posture—keep the chin tucked in.
  - Sleep on a low firm pillow or a special conforming pillow.
  - Sleep with your painful side on the pillow.
  - Use heat and massage: massage your neck firmly three times a day using an analgesic ointment.
 Don't:
  - Look up in a strained position for long periods.
  - Twist your head often towards the painful side (e.g. when reversing a car).
  - Lift or tug with your neck bent forwards.
  - Work, read or study with your neck bent for long periods.
  - Become too dependent on 'collars'.
  - Sleep on too many pillows.
- Monitor the patient's progress without overtreatment.
- Analgesia:<sup>7</sup>
  - first line: paracetamol 1 g (o) qid
  - second: paracetamol + codeine or an NSAID (o)
  - third: tramadol 50 mg tds (avoid opioids if possible)
  - $\pm$  tricyclic antidepressant for night pain
- Prescribe an exercise program as early as possible; start with gentle exercises and maintain them at home. Suitable exercises are shown in **FIGURE 62.5**.
- Refer to an appropriate therapist for cervical mobilisation for persisting pain. Mobilisation combined with exercises can be effective treatment. Occasionally, manipulation may help with a stubborn 'locked' neck but should be left to an expert. If manipulation, which carries the rare but real risk of vertebral artery dissection and stroke, is to be performed, informed consent and an experienced therapist are required.<sup>8</sup>

### Evidence of benefit (in summary)<sup>6</sup>

- Staying active: resuming normal activities
- Exercises
- Combined cervical passive mobilisation/ exercises
- Pulsed electromagnetic therapy (up to 12 weeks)

**FIGURE 62.5** Examples of exercises for the neck: (a) resisted side bending, (b) rotation, (c) chin retraction

Approximately 40% of patients recover fully from acute idiopathic ANP, about 30% continue to have mild symptoms while 30% continue to have moderate or severe symptoms.<sup>6</sup>

### Chronic pain (lasting more than 3 months)<sup>7</sup>

Additional treatment modalities to consider include:

- a course of antidepressants
- TENS, especially when drugs are not tolerated
- hydrotherapy
- acupuncture (may provide short-term relief)
- corticosteroid facet injections (ideally under image intensification)
- facet joint denervation with percutaneous radiofrequency (if nerve block provides relief)
- multidisciplinary rehabilitation program

## § Cervical spondylosis<sup>7</sup>

Cervical spondylosis following disc degeneration and apophyseal joint degeneration is far more common than lumbar spondylosis and mainly involves the C5–6 and C6–7 segments. The consequence is narrowing of the intervertebral foramen with the nerve roots of C6 and C7 being at risk of compression.

Cervical spondylosis is generally a chronic problem but it may be asymptomatic. In some patients the pain may lessen with age, while stiffness increases.

### Clinical features

- Dull, aching suboccipital neck pain (see FIG. 62.6)
- Stiffness
- Worse in morning on arising and lifting head
- Improves with gentle activity and warmth (e.g. warm showers)
- Deteriorates with heavy activity (e.g. working under car, painting ceiling)

FIGURE 62.6 Cervical spondylosis: typical pain distribution with direction of movement diagram indicating painful and restricted movements

- Usually unilateral pain—may be bilateral
- Pain may be referred to head, arms and scapulae
- May wake patient at night with paraesthesia in arms
- C6 nerve root most commonly involved
- Acute attacks on chronic background
- Aggravated by flexion (reading) and extension
- Associated vertigo or unsteadiness
- Restricted tender movements, especially rotation/lateral flexion
- Joints tender to palpation
- X-ray changes invariable

### Treatment

- Provide appropriate reassurance, information and support.
- Refer for physiotherapy, including warm hydrotherapy.
- Use regular mild analgesics (e.g. paracetamol).
- Use NSAIDs: a trial for 2 weeks and then review.
- Prescribe gentle mobilising exercises as early as possible.
- Give passive mobilising techniques.
- Outline general rules to live by, including advice regarding sleeping and pillows, and day-to-day activities.

### Complications

- Radiculopathy (unilateral or bilateral)
- Myelopathy—pressure on spinal cord
- Spinal canal stenosis

## § Acute torticollis

Torticollis (acute wry neck) means a lateral deformity of the neck. This is usually a transient self-limiting acutely painful disorder with associated muscle spasm of variable intensity.

### Clinical features

- Age of patient between 12 and 30 years
- Patient usually awakes with the problem
- Pain usually confined to neck but may radiate
- Deformity of lateral flexion and slight flexion/rotation
- Deformity usually away from the painful side
- Loss of extension
- Mid-cervical spine (C2–3, C3–4, C4–5)
- Any segment between C2 and C7 can cause torticollis
- Usually no neurological symptoms or signs

The exact cause of this condition is uncertain, but both an acute disc lesion and apophyseal joint lesion are implicated, with the latter the more likely cause. Acute torticollis is usually a transient and self-limiting condition that can recover within 48 hours. Sometimes it can last for about a week. Encourage heat massage and early mobility. Avoid cervical collars. Management by mobilisation and muscle energy therapy is very effective.

### Muscle energy therapy

This amazingly effective therapy relies on the basic physiological principle that the contracting and stretching of muscles leads to automatic relaxation of agonist and antagonist muscles.<sup>9</sup> Lateral flexion or rotation or a combination of movements can be used but treatment in rotation is preferred. The direction of contraction can be away from the painful side (preferred) or towards the painful side, whichever is most comfortable for the patient.

### Method

- 1 Explain the method to the patient, with reassurance that it is not painful.
- 2 Rotate the patient's head passively and gently towards the painful side to the limit of pain (the motion barrier).
- 3 Place your hand against the head on the side opposite the painful one. The other (free) hand can be used to steady the painful level—usually C3–4.
- 4 Request the patient to push the head (in rotation) as firmly as possible against the resistance of your hand. The patient should therefore be producing a strong isometric contraction of the neck in rotation away from the painful side (see FIG. 62.7A). Your counterforce (towards the painful side) should be firm and moderate (never forceful) and should not 'break' through the patient's resistance.
- 5 After 5–10 seconds (average 7 seconds) ask the patient to relax; then passively stretch the neck gently towards the patient's painful side (see FIG. 62.7B).
- 6 The patient will now be able to turn the head a little further towards the painful side.
- 7 This sequence is repeated at the new improved motion barrier. Repeat three to five times until the full range of movement returns.
- 8 Ask the patient to return the following day for treatment although the neck may be almost normal.

The patient can be taught self-treatment at home using this method.

**FIGURE 62.7** Muscle energy therapy for acute torticollis: (a) isometric contraction phase for problem on the left side, (b) relaxation phase towards the affected (left) side

### § Acceleration hyperextension (whiplash) injury

Patients with the whiplash syndrome, preferably referred to as an acceleration hyperextension injury, present typically with varying degrees of pain-related loss of mobility of the cervical spine, headache and emotional disturbance in the form of anxiety and depression. The problem can vary from mild temporary disability to a severe and protracted course.

The injury occurs as a consequence of hyperextension of the neck followed by recoil hyperflexion, typically following a rear-end collision between motor vehicles. There is reversal of sequence of these movements in a head-on collision. In addition to hyperextension, there is prolongation or anterior stretching plus longitudinal extension of the neck.<sup>8</sup> It can also occur with other vehicle accidents and in contact sports such as football.

Whiplash causes injury to soft tissue structures including muscle, nerve roots, the cervical sympathetic chain, ligaments, apophyseal joints and their synovial capsules and intervertebral discs. Damage to the apophyseal joints appears to be severe, with possible microfractures (not detectable on plain X-ray) and long-term dysfunction.

Pain and stiffness of the neck are the most common symptoms. The pain is usually experienced in the neck and upper shoulders but may radiate to the sub-occipital region, the interscapular region and down the arms. The stiffness felt initially in the anterior neck muscles shifts to the posterior neck.

Headache is a common and disabling symptom that may persist for many months. It is typically occipital but can be referred to the temporal region and the eyes.

Nerve root pain can be caused by a traction injury of the cervical nerve roots or by inflammatory changes or direct pressure subsequent to herniation of a disc.

Paraesthesia of the ulnar border of the hand, nausea and dizziness are all relatively common symptoms.

Delayed symptoms are common. A patient may feel no pain until 24 (sometimes up to 96) hours later; most experience symptoms within 6 hours. Complications of whiplash are summarised in **TABLE 62.4**.

**Table 62.4** Complications of whiplash

Referred pain (headache, arm pain)
Visual problems
Vertigo
Dysphagia
Depression
Compensation neurosis
Disc rupture increasing to nerve root pain
Osteoarthritis becomes symptomatic

The Canadian guidelines (1995) for whiplash are:

- Grade I—neck pain, stiffness or tenderness
- Grade II—neck symptoms + musculoskeletal signs (e.g. decreased range of motion, point tenderness)
- Grade III—neck symptoms + neurological signs
- Grade IV—neck symptoms + fracture or dislocation

### Management principles

The objective of treatment is to obtain a full range of free movement of the neck without pain by attending to both the physical and the psychological components of the problem. Other objectives include an early return to work and discouragement of unnecessary and excessive reliance on cervical collars and legal action.

### Treatment

- Establish an appropriate empathy and instil patient confidence with a positive, professional approach. Discourage multiple therapists.

- Provide appropriate reassurance and patient education.
- Encourage normalisation of activities as soon as possible.
- Compare the problem with a sprained ankle, which is a similar injury.
- Inform that an emotional reaction of anger, frustration and temporary depression is common (lasts about 2 weeks).
- X-ray is required.
- Prescribe rest only for grades II and III (max. 4 days).
- Use a cervical collar (limit to 2 days) for grades II and III. Provide collar and refer for grade IV.
- Use analgesics (e.g. paracetamol)—avoid narcotics.
- Use NSAIDs for 14 days.
- Use tranquillisers, mild—up to 2 weeks.
- Refer for physiotherapy.
- Provide neck exercises (as early as possible).
- Use heat and massage—‘spray and stretch’—or ice.
- Give passive mobilisation (not manipulation).

Recovery can take any time from 1 to 2 weeks up to about 3 months. A valuable reference is *Update Quebec Task Force Guidelines for the Management of Whiplash—Associated Disorder* at <[www.nhmrc.gov.au/guidelines/](http://www.nhmrc.gov.au/guidelines/)>

### § Cervical disc disruption

Disruption of a cervical disc can result in several different syndromes.

- 1 Referred pain over a widespread area due to pressure on adjacent dura mater.  
Note: A disc disruption is capable of referring pain over such a diffuse area (see **FIG. 62.8**) that the patient is sometimes diagnosed as functional (e.g. hysterical).
- 2 Nerve root or radicular pain (radiculopathy). The pain follows the dermatomal distribution of the nerve root in the arm.
- 3 Spinal cord compression (myelopathy).

### § Radiculopathy

Apart from protrusion from an intervertebral disc, nerve root pressure causing arm pain can be caused by osteophytes associated with cervical spondylosis. Uncommon causes include various tumours involving the vertebral segment, the meninges and nerves or their sheaths. The pain follows neurological patterns

**FIGURE 62.8** Zone of possible referred pain distribution caused by a cervical disc lesion on the right side

down the arm, being easier to localise with lower cervical roots, especially C6, C7 and C8.

- 1 The cervical roots exit above their respective vertebral bodies. For example, the C6 root exits between C5 and C6 so that a prolapse of C5–6 intervertebral disc or spondylosis of the C5–6 junction affects primarily the C6 root (see FIG. 62.4).
- 2 One disc—one nerve root is the rule.
- 3 Spondylosis and tumours tend to cause bilateral pain (i.e. more than one nerve root).

### Clinical features

- A sharp aching pain in the neck, radiating down one or both arms
- Onset of pain may be abrupt, often precipitated by a sudden neck movement on awakening
- Paraesthesia in the forearm and hand (in particular)—in 90% with proven disc prolapse<sup>9</sup>
- Stiffness of neck with limitation of movement
- Nocturnal pain, waking patient during night
- Pain localised to upper trapezius and possible muscle spasm

### Investigations

- Plain X-ray (AP, lateral extension and flexion, oblique views to visualise foramina); not good for diagnosis or for surgery
- Plain CT scan
- CT scan and myelogram—excellent visualisation of structures but invasive
- MRI—excellent but expensive, sometimes difficult to distinguish soft disc from osteophytes
- Electromyography—may help delineate lesions requiring surgery

### Treatment

Many patients respond to conservative treatment, especially from a disc prolapse. It is basically a self-limiting disorder—about 10% remain severely disabled.<sup>10</sup>

- bed rest
- soft cervical collar
- analgesics (according to severity—see CHAPTER 38)
- consider a course of corticosteroids for severe neck radicular pain
- tranquillisers, especially at night
- traction (with care)
- careful mobilisation (manipulation is contraindicated)

### CERVICAL SPONDYLITIC MYELOPATHY

Sometimes the presence of large or multiple osteophytes or in the presence of a narrowed spinal canal symptoms of spinal cord involvement may develop.<sup>11,12</sup> The common cause is a hard mass of material projecting from the posterior aspect of the vertebral body to indent the spinal cord and possibly the nerve roots at the exit foramina. This resultant spinal cord compression may result in several different clinical presentations, notably myelopathy in particular, but also central cord and anterior cord syndrome. A full neurological assessment is necessary.

### Clinical features

- Older patients, typically men >50 years
- Insidious onset—symptoms over 1–2 years
- Numbness and tingling in fingers
- Leg stiffness
- Gait disturbance
- Numb, clumsy hands, especially with a high cervical lesion

- Signs of UMN: spastic weakness, increased tone and hyper-reflexia (arms > legs)  $\pm$  clonus
- Neurological deficit, which predicts the level with reasonable accuracy
- Bowel and bladder function usually spared

*Note:* LMN signs occur at the level of the lesion, and UMN signs and sensory changes occur below this level.

### Causes

- Cervical spondylosis
- Atlantoaxial subluxation: rheumatoid arthritis, Down syndrome
- Primary spinal cord tumours (e.g. meningiomas)
- Metastasis to cervical spine  $\rightarrow$  epidural spinal cord compression

### Investigations

- MRI scan
- CT scan with myelogram (most accurate)

## § Central cord syndrome<sup>12</sup>

This rather bizarre condition occurs classically in a patient with a degenerative cervical spine following a hyperextension injury that causes osteophytes to compress the cord anteriorly and posteriorly simultaneously.

The maximum damage occurs in the central part of the cord, leading to sensory and motor changes in the upper limbs with relative sparing of the lower limbs due to the arrangements of the long tracts in the cord.

Fortunately, the prognosis is good with most patients achieving a good neurological recovery.

## § Anterior cord syndrome

The anterior cord syndrome occurs with hyperflexion injuries that produce 'tear drop' fractures of the vertebral bodies or extrusion of disc material. The syndrome can also be produced by comminuted vertebral body fractures.

It is characterised by complete motor loss and the loss of pain and temperature discrimination below the level of the injury, but deep touch, position and vibration sensation remain intact.

Because it is probably associated with obstruction of the anterior spinal artery, early surgical intervention to relieve pressure on the front of the cord may enhance recovery. Otherwise the prognosis for recovery is poor.

## § Down syndrome

One of the more sinister problems with trisomy 21 syndrome is hypoplasia of the odontoid process, leading to C1–2 subluxation and dislocation. If unrecognised in the early stages, sudden death can occur in these children. If suspected, flexion–extension lateral views of the cervical spine will highlight the developing instability and the need for early specialist opinion.

## § Rheumatoid arthritis<sup>7</sup>

Involvement of the cervical spine is usually a late manifestation of rheumatoid arthritis (RA). It is important to be aware of the potentially lethal problem of C1–2 instability due to erosion of the major odontoid ligaments in the rheumatoid patient. These patients are especially vulnerable to disasters when under general anaesthesia and when involved in motor vehicle accidents. Early cervical fusion can prevent tragedies, especially with inappropriate procedures such as cervical manipulation. It is imperative to perform imaging of the cervical spine of all patients with severe RA before major surgery to search for C1–2 instability. Lateral plain X-rays in flexion and extension may reveal increased distance in the atlanto–dens interval. This can be assessed further with MRI or CT scanning in a specialist clinic.

### Treatment of spondylitic myelopathy

Conservative (may help up to 50%):<sup>2</sup>

- soft cervical collar
- physiotherapy for muscle weakness
- analgesics and/or NSAIDs

Surgery is indicated when the myelopathy interferes with daily activities. One procedure is the 'Cloward' method, which is anterior decompression with discectomy and fusion. The aim of surgery is to halt deterioration.

### When to refer

- Persisting radicular pain in an arm despite conservative treatment
- Evidence of involvement of more than one nerve root lesion in the arm
- Evidence of myelopathy, such as weakness, numbness or clumsiness of the upper limbs
- Evidence, clinical or radiological, of cervical instability in post-accident victims, or people with Down syndrome or rheumatoid arthritis

### Practice tips

- 'One disc—one nerve root' is a working rule for the cervical spine.
- The patient should sit on the couch with the thighs fully supported for inspection and movements of the neck.
- Be alert for patients with RA and Down syndrome who have cervical instability. Physical treatments such as cervical manipulation may easily cause quadriplegia.
- All acutely painful conditions of the cervical spine following trauma should be investigated with a careful neurological examination of the limbs, sphincter tone and reflexes. Plain film radiology is mandatory.
- In conscious patients, flexion and extension lateral cervical spinal plain films are useful for diagnosing instability of spinal segments with or without associated spinal fractures.
- The so-called 'whiplash' syndrome is a diagnosis of exclusion of spinal fractures or severe ligamentous disruption causing instability, and even then, for medicolegal and psychological reasons, would best be termed a 'soft tissue injury of the cervical spine'.
- Most 'soft tissue cervical spine injuries' heal within 3 months with conservative treatment. If severe pain persists, follow-up investigations may be required.
- Dysfunction of the cervical spine is an underestimated cause of headache.
- Always consider dysfunction of the cervical spine as a possible cause of shoulder pain.
- Strains and fractures of the apophyseal joints, especially after a whiplash injury, are difficult to detect, and are often overlooked causes of neck and referred pain.

### Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Exercises for your neck
- Neck: painful neck
- Whiplash
- Wry neck (torticollis)

*Search for clues—difficulty reaching into the hip pocket to remove a wallet may indicate loss of function due to total rupture of the supraspinatus tendon, while a complete rotator-cuff tear may lead the patient to lift the affected limb to the clothes line and leave it suspended there by the hand while hanging out the laundry.*

Michael Hayes 1996

The painful shoulder is a relatively common and sometimes complex problem encountered in general practice. The diagnostic approach involves determining whether the disorder causing the pain arises from within the shoulder structures or from other sources such as the cervical spine (see FIG. 63.1), the acromioclavicular (AC) joint or diseased viscera, especially the heart, lungs and sub-diaphragmatic structures.

- Injections of local anaesthetic and long-acting corticosteroid produce excellent results for inflammatory disorders around the shoulder joint, especially for supraspinatus tendonopathy.
- The diagnosis is usually made on the history and examination. Blood tests are usually not necessary and imaging has a limited place and value.<sup>2</sup>

*Note:* The term tendonopathy or tendonosis is preferred to tendonitis since it has been shown that overuse tendon conditions generally have a non-inflammatory pathology.

## Key facts and checkpoints

- Virtually all shoulder structures are innervated by the fifth cervical vertebra (C5) nerve root. Pain present in the distribution of the C5 nerve can arise from the:
  - cervical spine
  - upper roots of brachial plexus
  - glenohumeral joint
  - rotator cuff tendons, especially supraspinatus
  - biceps tendon
  - soft tissue (e.g. polymyalgia rheumatica)
  - viscera, especially those innervated by the phrenic nerve (C3, C4, C5)
- The visceral diseases causing a painful shoulder include cardiac disorders, such as angina and pericarditis; lung diseases, especially Pancoast tumour; mediastinal disorders; and diaphragmatic irritation, as from intra-abdominal bleeding or a subphrenic abscess.
- A careful history should generally indicate whether the neck or the shoulder is responsible for the patient's pain.
- By the age of 50 about 25% of people have some wear and tear of the rotator cuff, making it more injury-prone.<sup>1</sup>
- Disorders of the rotator cuff are common, especially supraspinatus tendonopathy. The most effective tests to diagnose these problems are the resisted movement tests.<sup>1</sup>

**FIGURE 63.1** Typical pain zone arising from disorders of the shoulder joint and the lower cervical spine (C5 level)

## Functional anatomy of the shoulder

A working knowledge of the anatomical features of the shoulder is essential for understanding the various disorders causing pain or dysfunction of the shoulder. Apart from the AC joint there are two most significant functional joints—the glenohumeral (the primary joint) and the subacromial complex (the secondary joint) (see FIG. 63.2). The glenohumeral joint is a ball and socket

joint enveloped by a loose capsule. It is prone to injury from traumatic forces and develops osteoarthritis more often than appreciated. Two other relevant functional joints are the scapulothoracic and sternoclavicular joints.

The clinically important perihumeral space lies above the glenohumeral joint between the head of the humerus and an arch formed by the bony acromion, the thick coracoacromial ligament and the coracoid process. This relatively tight compartment houses the subacromial bursa and the rotator cuff, particularly the vulnerable supraspinatus tendon.<sup>3</sup> Excessive friction and pinching in this space render these structures prone to injury.

There is a critical zone of relative ischaemia that appears to affect the rotator cuff about 1 cm medial to the attachment of the supraspinatus tendon,<sup>4</sup> and this area is compromised during adduction and abduction of the arm due to pressure on the rotator cuff tendons from the head of the humerus. The so-called 'impingement interval' is the space between the undersurface of the acromion and the superior aspect of the humeral head. This space is normally narrow (6–14 mm), especially when the arm is abducted.

Such factors are largely responsible for the many rotator cuff syndromes, including subacromial bursitis and lesions of the supraspinatus tendon and also bicipital tendonopathy.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in TABLE 63.1.

## Probability diagnosis

The commonest causes of pain in the shoulder zone (see FIG. 63.1) are cervical disorders and periarthrosis (i.e. soft tissue lesions involving the tendons around the glenohumeral joint). The outstanding common disorders of the shoulder joint are the rotator cuff disorders and adhesive capsulitis. Of these, supraspinatus tendon disorders are the commonest. It is obvious that the supraspinatus tendon is subjected to considerable friction and wear and tear. For acute shoulder pain presentation consider rotator cuff disorders (including calcific tendonitis and an acute tear) and adhesive capsulitis.

## Serious disorders not to be missed

As usual it is important to exclude any malignancy or septic infection, be it septic arthritis or osteomyelitis. Lung cancer (Pancoast syndrome), myeloma and bony metastases should be kept in mind. For pain in the region of the left shoulder the possibility of myocardial ischaemia has to be considered. Referred pain to the right shoulder from myocardial ischaemia is rare, occurring about once for every 20 episodes of left shoulder referral.

FIGURE 63.2 The basic anatomical structures of the shoulder joint

**Table 63.1** Shoulder pain: diagnostic strategy model

Q.	Probability diagnosis
A.	Cervical spine dysfunction (referred pain) Rotator cuff tendonopathy $\pm$ a tear Adhesive capsulitis Glenoid labral tears
Q.	Serious disorders not to be missed
A.	Cardiovascular: • angina • myocardial infarction Neoplasia: • Pancoast tumour • primary or secondary in humerus Severe infections: • septic arthritis (especially children) • osteomyelitis Axillary vein thrombosis Rheumatoid arthritis Intra-abdominal pathology e.g. bleeding
Q.	Pitfalls (often missed)
A.	Polymyalgia rheumatica Cervical dysfunction Gout/pseudogout (uncommon) Osteoarthritis of acromioclavicular joint Winged scapula—muscular fatigue pain
Q.	Seven masquerades checklist
A.	Depression Diabetes Drugs Thyroid disorder (rarely) Spinal dysfunction
Q.	Is the patient trying to tell me something?
A.	Shoulder is prone to (uncommonly) psychological fixation for secondary gains, depression and conversion reaction.

Referred pain from the diaphragm and intra-abdominal disorders (e.g. biliary, perforated ulcer, splenic rupture) should be kept in mind.

With an acute onset of painful capsulitis the possibility of rheumatoid arthritis (or even gout) is worth considering.

## Pitfalls

The shoulder is notorious for diagnostic traps, especially for referred pain from visceral structures, but polymyalgia rheumatica is the real pitfall. A good rule is to consider it foremost in any older person (over 60) presenting with bilateral shoulder girdle pain that is worse in the morning.

Specific pitfalls include:

- misdiagnosing posterior dislocation of the shoulder joint
- misdiagnosing recurrent subluxation of the shoulder joint
- overlooking an avascular humeral head (post fracture)
- misdiagnosing rotator cuff tear or degeneration

## Seven masquerades checklist

Of the seven primary masquerades, spinal dysfunction and depression are those most likely to be associated with shoulder pain. The degree to which cervical spondylosis is associated with shoulder pain is not always appreciated.

It is important to realise that patients' perception of pain in the 'shoulder' may be amazing. For example, pain in the lower border of the scapula may be referred to as shoulder pain.

Diabetics have a higher incidence of adhesive capsulitis. Drugs are relevant as corticosteroids can cause avascular necrosis of the humeral head and anabolic steroids (weight-lifters) can cause osteolysis of the AC joint.

A summary of common shoulder conditions is presented in **TABLE 63.2**.

## The clinical approach

### History

In analysing the pain pattern it is appropriate to keep the various causes of shoulder pain in mind (see **TABLE 63.3**). Many of these conditions, such as rheumatoid arthritis, osteoarthritis and gout, are relatively uncommon.

A careful history should generally indicate whether the neck or the shoulder (or both) is responsible for the patient's pain. Enquire about features of movement:

- stiffness and restriction
- excessive movement/instability
- weakness
- rough versus smooth

### Red flag pointers for shoulder pain<sup>6</sup>

- Fever (septic arthritis, osteomyelitis)
- Skin redness or swelling
- History of trauma (dislocation, fracture, rotary cuff tear)
- History of inflammatory arthritis
- Past history cancer
- Motor or sensory loss in arm

**Table 63.2** Common shoulder conditions (after Murrell)<sup>5</sup>

Problem	Structure affected	Typical age group	Symptoms	Diagnostic pointers
Instability	Labrum/capsule	15–35	Dislocations	History of dislocation, apprehension sign
Stiffness	Capsule	40–60	Pain, night pain, loss of movement	Loss of external rotation
Impingement	Rotator cuff (fatigue)	30–60	Night pain, pain with overhead activities	Impingement signs
Rotator cuff tear	Rotator cuff esp. supraspinatus	50 +	As above	Impingement signs, weakness external rotation, weakness supraspinatus
AC joint pain	AC joint cartilage	25–45	Localised AC joint pain	Paxinos sign
Arthritis	Glenohumeral joint cartilage	70 +	Pain, loss of movement	Crepitus

**Table 63.3** Causes of shoulder pain (excluding trauma, fractures and dislocations)

## Cervical:

- dysfunction
- spondylosis

## Cervical radiculopathy

## Polymyalgia rheumatica (bilateral)

## Acromioclavicular joint:

- dysfunction
- osteoarthritis

## Shoulder complex

## Extracapsular:

- subacromial bursitis
- rotator cuff disorders:
  - supraspinatus tendonopathy
  - infraspinatus tendonopathy
  - subscapularis tendonopathy
- bicipital tendonopathy

## Intracapsular (glenohumeral joint):

- adhesive capsulitis:
  - idiopathic
  - blunt trauma
  - diabetes
  - others
- rheumatoid inflammation:
  - rheumatoid arthritis
  - ankylosing spondylitis

## — psoriatic arthropathy

- osteoarthritis
- avascular necrosis
- septic arthritis

## Winged scapula—muscular fatigue pain

## Malignant disease:

- primary or secondary in humerus
- Pancoast (referred from lung)

## Referred pain

## Cardiac:

- ischaemic heart disease
- pericarditis

## Gall bladder

## Lung

- mediastinum, including oesophagus
- diaphragmatic irritation

## Herpes zoster

**Key questions**

- Did you have any injury, even very minor, before your pain started?
- Does the pain keep you awake at night?
- Do you have pain or stiffness in your neck?
- Do you have pain or restriction when clipping or handling your bra or touching your shoulder blades? (indicates painful internal rotation and a problem of capsular restriction or a disorder of the acromioclavicular joint)

- Do you have trouble combing or attending to your hair? (indicates problematic external rotation and also a disorder of the capsule, e.g. adhesive capsulitis)
- Is the pain worse when you wake in the morning? (indicates inflammation)
- Do you have aching in both your shoulders or around your hips?
- Do you get pain associated with sporting activity, including weight training, or with housework, dressing or other activities?
- Do you think you can throw a ball underhand for 10–20 m and/or overhead for 20–25 m with your affected arm?
- Can you lift a full 2 L container (e.g. milk) to the level of your shoulder without bending your elbow (or to the top of your head)?
- Can you carry a 20–30 kg weight (e.g. full suitcase) by your side?

## Examination

The diagnosis is based on systematic examination of the cervical spine followed by examination of the shoulder joint. For details of examination of the cervical spine, refer to **CHAPTER 62**.

### Examination of the shoulder<sup>3,6</sup>

For the examination of the shoulder it is important to understand the functional anatomy of all important tendons.

The tendon disorders are diagnosed by pain on resisted movement (see **TABLE 63.4**). A knowledge of the anatomical attachments of the rotator cuff tendons to the head of the humerus (see **FIG. 63.3**) provides an understanding of the shoulder movements powered by these muscles.

**FIGURE 63.3** The attachments of the rotator cuff tendons to the head of the humerus

Source: Reproduced with permission from C Kenna and J Murtagh. *Back Pain and Spinal Manipulation*. Sydney: Butterworths, 1989

**Table 63.4** Tendon disorders: determining resisted movements

Painful resisted movement at shoulder	Affected tendon
1 Abduction	Supraspinatus
2 Internal rotation	Subscapularis
3 External rotation	Infraspinatus Teres minor* Biceps*
4 Adduction	Pectoralis major Latissimus dorsi*

\* Lesser role

With tendon disorders (rotator cuff tendons or biceps) there is usually painful restriction of movement in one direction, but with capsulitis and subacromial bursitis there is usually restriction in most directions.

## Inspection

Observe the shape and contour of the shoulder joints and compare both sides. Note the posture and the position of the neck and scapula. The position of the scapula provides considerable clinical information. Note any deformity, swelling or muscle wasting.

## Palpation

Stand behind the patient and palpate significant structures such as the AC joint, the subacromial space, the supraspinatus tendon and the long head of biceps. The subacromial bursa is one area where it is possible to localise tenderness with inflammation. Feel also over the supraspinatus and infraspinatus muscles for muscle spasm and trigger points. The axilla should be palpated for lymphadenopathy.

## Movements

The movements of the shoulder joint are complex and involve the scapulothoracic joint as well as the glenohumeral joint, with each joint accounting for about half the total range. Significant signs of a painful capsular pattern can be gained by determining the movements of flexion, abduction, external rotation and internal rotation.

For each movement, note:

- the range of movement
- any pain reproduction
- any trick movement by the patient
- scapulothoracic rotation

Movements should be tested bilaterally and simultaneously wherever possible.

Look for impingement, which is the sign of fleeting interruption of free movement by 'catching' of a tendon upon bone.

### 1 Active movements

- Flexion (anterior elevation) 180°
- Extension (posterior elevation) 50°

With the palm facing medially the patient moves the arm upwards through 180° to a vertical position above the head and then backwards through this plane.

- Abduction—180°
- Adduction—50° (from neutral position)

Abduction, which is initiated by the deltoid, is possible only if the arm is fully externally rotated. It is a key combined glenohumeral and scapulohumeral movement, which should reach 180°, and these components should be differentiated if the movement is limited. This is done by fixing the scapula with one hand holding the scapula at its inferior angle and noting the degree of movement of each component (initial glenohumeral range 85–100°). Look for the presence of a painful arc, which occurs usually between 60° and 120° of abduction (see FIG. 63.4).

The commonest cause is supraspinatus tendonopathy. Other causes include infraspinatus tendonopathy and subacromial bursitis (milder degree).

- Internal rotation—90°
- External rotation—90°

These movements are tested with the arm by the side and the elbow flexed to 90° with the palm facing medially. The hand is carried outwards to test external rotation and inwards towards the abdomen for internal rotation.

### 2 Resisted movements<sup>3</sup>

Resisted movements (isometric contractions of a muscle) are important ways of testing capsulitis and for pinpointing tenderness of muscle insertions around the shoulder joint, and no examination of the shoulder is complete without them (see TABLE 63.4).

**Abduction (supraspinatus test).** With the arm abducted to no more than 15° the patient pushes the elbow away from the side while the examiner's hands resist and prevent the movement, holding for 5 seconds. Compare both sides and note any reproduction of the patient's pain.

A better and more specific test for supraspinatus impingement is testing resisted elevation in the

FIGURE 63.4 The painful arc syndrome

'emptying the can' position (90° of abduction, 30° horizontal flexion and full internal rotation).

**Internal rotation (subscapularis test).** The examiner stands behind the patient and grasps the palmar surface of the patient's wrists (with the arm by the side and elbow at 90°). The patient attempts to move the forearm internally (medially) against resistance.

**External rotation (infraspinatus test).** With the examiner and patient adopting a similar position to that for internal rotation, the examiner grasps the dorsal surface of the forearm near the wrist and asks the patient to press outwards, using the forearm as a lever to produce external rotation. This test is also positive for a C5 nerve root lesion.

### 3 Special tests

**Supraspinatus/infraspinatus rapid differentiation test.** A quick test that helps to differentiate between a lesion of either of these tendons causing a painful arc syndrome is the 'thumbs up/thumbs down' abduction test. To test the supraspinatus, perform abduction with thumbs pointing upwards, and then with the thumbs pointing downwards to test the infraspinatus.

**Long head of biceps test.** The best test is opposed forward elevation of the arm with the elbow at right angles. A positive test is reproduction of pain in the bicipital groove. Another useful test is resisted supination at the wrist (Yergason test).

**The brachial plexus tension test.** This test, devised by Elvey,<sup>8</sup> tests the nerve roots and sheaths of the brachial plexus without implicating the cervical spine and the glenohumeral joint. The upper cervical roots of the plexus are sometimes injured in accidents, so this test is an effective differentiation test.

**Impingement test for supraspinatus lesions.** See later in this chapter.

## Investigations

Appropriate investigations for shoulder pain include:

- ESR (especially for polymyalgia rheumatica)/CRP
- rheumatoid factor and anti-CCP
- serum uric acid (acute pain)
- ECG (if IHD suspected)
- radiology:
  - X-ray of a specific part of the shoulder—AC joint, axillary view of glenohumeral joint (best view to show osteoarthritis)
  - X-ray of cervical spine and chest (if relevant)
  - radionuclide bone scan—to assess bone tumours
  - shoot-through axillary views (posterior dislocation)
  - high-resolution ultrasound—modern techniques make this an appropriate test to assess shoulder pain due to rotator cuff lesions, especially tears and capsulitis, especially if surgery is contemplated. However this test as sometimes reported can be misleading.
  - arthrogram of shoulder (beware of false negatives)
  - CT scan (limited use)
  - MRI—a useful imaging method but not routinely required except for the unstable joint
  - arthroscopy

## Shoulder tip pain

Pain at the shoulder tip may be caused by local musculoskeletal trauma or inflammation or can be referred from blood or other irritants in the peritoneal cavity. Referred causes where the pain is unchanged by shoulder movement include:

- peptic ulceration
- diaphragmatic irritation (e.g. pneumonia)
- ruptured viscus (e.g. perforated ulcer)
- intraperitoneal bleeding (e.g. ruptured spleen)
- pneumothorax/pneumonia
- post laparoscopy (intraperitoneal gas)
- myocardial infarction/pericarditis
- ectopic pregnancy
- gall bladder disease

## Shoulder pain in children

Shoulder pain in children is not a common presenting problem but the following require consideration:

- septic arthritis/osteomyelitis
- swimmer's shoulder (supraspinatus dysfunction)

## Swimmer's shoulder

Although it occurs in adults, shoulder pain is the most common complaint in swimmers in the teenage years (over 12 years of age). American studies of college and national competition swimmers showed 40–60% had suffered significant pain.<sup>9</sup> Refer to **CHAPTER 136**.

The problem, which is considered to be associated with abnormal scapular positioning and cervicothoracic dysfunction, occurs in the supraspinatus tendon where an avascular zone is compressed by the greater tuberosity when the arm is abducted and relieved when adducted. Swimmers' shoulders are forced through thousands of revolutions each day, so the susceptible area tends to impinge on the coracoacromial arch, leading to the impingement syndrome, which can progress with continued stress and age.<sup>10</sup>

### Symptoms

- Stage 1: pain only after activity
- Stage 2: pain at beginning only, then after activity
- Stage 3: pain during and after activity, affects performance

### Management

- Early recognition is important.
- Discuss training program with coach.
- Consider alteration of technique.
- Application of ICE after each swim.
- Use NSAIDs.
- Avoid corticosteroid injections.
- Refer for physiotherapy for scapular stabilisation and cervicothoracic mobilisation.

## Shoulder pain in the elderly

As a rule most of the shoulder problems increase with age. Special features in the elderly are:

- polymyalgia rheumatica (increased incidence with age)
- supraspinatus tears and persistent 'tendonitis'
- other rotator cuff disorders
- stiff shoulder due to adhesive capsulitis
- osteoarthritis of AC and glenohumeral joints
- cervical dysfunction with referred pain
- the avascular humeral head

Since the rotator cuff is prone to degeneration with age, there is a high incidence of rotator cuff tears in the elderly that are mostly asymptomatic.

## The avascular humeral head

The humeral head may become avascular after major proximal humeral fractures. With experience, it is

usually possible to predict the fractures at special risk. Early humeral head replacement with a prosthesis can lead to excellent pain relief and to a return of good function. Once the head has collapsed, there is secondary capsular contracture. Prosthetic replacement of the head is then rarely associated with an adequate return of joint movement. Thus, early referral of comminuted proximal humeral fractures for an expert opinion in all age groups is good practice. Early replacement can improve the functional outcome.<sup>11</sup>

### § Rotator cuff tendonopathy<sup>6</sup>

Rotator cuff tendonopathy, also referred to as 'impingement syndrome', is the commonest cause of shoulder pain. It can be associated with inflammation (tendonitis), a tear in a tendon or impingement under the acromion. It may involve one tendon, usually the supraspinatus, or more of the rotator cuff tendons. It is most frequently encountered in young people engaged in sport involved in overhead activities and people over 50 years, in whom rotator cuff tears occur most often. The diagnosis can usually be made on the history and physical examination.

### Supraspinatus tendonopathy

Supraspinatus tendonopathy can vary in intensity from mild to extremely severe. The severe cases usually involve calcification (calcific peri-arthritis) of the tendon, which has a very rapid onset, and spread to the subacromial bursa (subacromial bursitis).

### The impingement tests<sup>5</sup>

These are effective tests for supraspinatus lesions as they force impingement of the rotator cuff and bursa under the acromion. One of these tests is the 'emptying the can' resistance test. The arm is placed in the 'emptying the can' position (90° of abduction, 30° of horizontal flexion and full internal rotation). Elevation of the arm is resisted against the therapist's downward push. This also tests the strength of supraspinatus. Impingement can also be tested in external rotation when the arm is abducted to 90° and externally rotated. Other tests include those of Speed, Neer and Hawkins.<sup>6</sup>

### Treatment<sup>12</sup>

Systematic reviews to date have a lack of sufficient information to provide conclusive evidence-based recommendations for treatment.<sup>13</sup> NSAIDs might provide some relief from pain while corticosteroid injections and physiotherapy could improve range of movement. Experienced therapists believe that peritendon and subacromial corticosteroid injections are efficacious in selected patients.

- Rest during the acute painful phase
- Analgesics and NSAIDs (up to 4 weeks)
- Peritendon or subacromial injection (if no tears on ultrasound)
- Physiotherapy—an active program including scapular stabilising exercises and rotator cuff strengthening

### Injection technique

The ideal injection is a specific injection onto the tendon rather than general infiltration into the subacromial space. As a rule the therapeutic result is quite dramatic after one or two days of initial discomfort (often severe). The tendon can be readily palpated as a tender cord anterolaterally as it emerges from beneath the acromion to attach to the greater tuberosity of the humerus. This identification is assisted by depressing the shoulder via a downward pull on the arm and then externally and internally rotating the humerus. This manoeuvre allows the examiner to locate the tendon readily.

### Method

- Identify and mark the tendon.
- Place the patient's arm behind the back, with the back of the hand touching the far waistline. This locates the arm in the desired internal rotation and forces the humeral head anteriorly.
- Insert a 23-gauge 32-mm needle under the acromion along the line of the tendon, and inject around the tendon just under the acromion (see FIG. 63.5). If the gritty resistance of the tendon is encountered, slightly withdraw the needle to ensure that it lies in the tendon sheath.
- The recommended injection is 1 mL of a soluble or long-acting corticosteroid with 5 mL of 1% lignocaine.

### Persistent supraspinatus tendonopathy

There are three factors to consider with this problem:

- 1 A very tight subacromial space. Refer for subacromial decompression by division of the thickened coracoacromial ligament. Even in younger patients this procedure (with or without acromioplasty) may be indicated for those with pain persisting beyond 12 months.
- 2 Rotator cuff tear or degeneration. In middle-aged and elderly patients, persisting tendonitis is usually due to rotator cuff tear and degeneration, an underdiagnosed condition. Excellent clinical and functional results can be achieved if surgery is performed when the tear is small.

**FIGURE 63.5** Injection placement for supraspinatus tendonopathy

- 3 Calcification of the tendon. This problem usually settles but occasionally surgical intervention is necessary.

### Typical pain profile—supraspinatus tendonopathy

Site:	the shoulder and outer border of arm; maximal over deltoid insertion
Radiation:	to elbow
Quality:	throbbing pain, can be severe
Frequency:	constant, day and night
Duration:	constant
Onset:	gradual or sudden, such as straining the shoulder (e.g. dog on leash, working under car, fall onto outstretched arm)
Offset:	nil
Aggravation:	specific movements, putting on shirt, toilet activity, lying on shoulder (unable to sleep)
Relief:	analgesics only
Associated features:	trigger point over supraspinatus origin
Examination (typical features):	<ul style="list-style-type: none"> <li>— painful resisted abduction</li> <li>— painful arc</li> <li>— painful resisted external rotation</li> <li>— positive impingement test</li> <li>— positive 'emptying the can' sign</li> </ul>
Diagnosis:	high-resolution ultrasound

## Other rotator cuff lesions

The patient may present with dominant signs of subscapularis or infraspinatus lesions, or a combination of two or three tendinous lesions, including the supraspinatus. This problem could be confused with milder adhesive capsulitis, hence the value of investigations such as ultrasound.

### Management

A subacromial space injection of 1 mL of corticosteroid and 2–3 mL of 1% local anaesthetic, using the posterior approach, generally achieves a good result for multiple affected rotator cuff tendons with or without subacromial bursitis.

### Method

With the patient sitting upright the large posterior gap between the medial acromial ridge and the humeral head is identified by palpation from behind. The needle (23 gauge, 32 or 38 mm long) is inserted into this gap just inferior to the acromion. The solution should flow into this space without resistance.

## Rotator cuff tears

Asymptomatic rotator cuff tears are common, being present in 4% of people <40 years old and in more than 50% of those over 60 years, but a significant number will become symptomatic over time.<sup>14</sup> Explain to the patient that 'the rotator cuff is worn not torn' rather like the frayed heel of a sock that may have a split in it.

Diagnostic tip: 98% specificity for all three signs:<sup>15</sup>

- supraspinatus weakness
- weakness in external rotation
- impingement (in external or internal rotation or both)

If two of these three tests are positive in a patient over 60 there is a 98% chance of a rotator cuff tear.

### § Subacromial bursitis

Subacromial (subdeltoid) bursitis is the more severe association of rotator cuff pathology and may require hospital admission for pain control. It is the only inflammatory disorder around the shoulder joint where localised tenderness is a reliable sign.

### Management

- Strong analgesics (e.g. paracetamol and codeine)
- Large local injection of 5–8 mL of local anaesthetic into and around the bursa just

beneath the acromion, followed immediately by 1 mL of corticosteroid (long-acting) into the focus of the lesion

### § Adhesive capsulitis

Adhesive capsulitis or capsulosis is an acute inflammation affecting the glenohumeral joint, which becomes fibrotic and contracted. It can arise spontaneously or post injury and may be partial or global, which is the classic cause of the 'frozen shoulder'. Differential diagnoses include monoarticular rheumatoid arthritis, a crystal arthropathy such as gout, and septic arthritis. It is worse in diabetics. It is common and estimated to affect 2–5% of the general population and 10–20% of diabetics.<sup>14</sup>

It generally occurs in three stages:<sup>14</sup>

- 1 'freezing, frozen and thawing'—an inflammatory painful phase of 2–9 months
- 2 a fibrotic contracted phase of 4–12 months
- 3 partial or complete resolution of 5–26 months

### Treatment

For analgesia choose between paracetamol, paracetamol with codeine and NSAIDs (weigh the risk). For severe pain oral corticosteroids rapidly alleviate pain, improve function and may provide sustained benefit. A typical dose is prednisolone 30 mg (o) daily for 3 weeks, then taper dose over next 2 weeks and cease.<sup>16</sup>

This problem, which can persist for at least 18–24 months (average time to restore motion is 30 months) and is usually self-limiting, can be treated with an intra-articular injection of corticosteroid but it is often unsuccessful. The modern treatment is arthrographic hydrodilatation of the glenohumeral joint with a large quantity of sterile solution (to stretch the capsule) ± corticosteroid. This procedure should be performed slowly to produce an audible 'pop' as fluid distends into the subacromial and subcoracoid bursae. Another important treatment is severing adhesions under arthroscopic control. The rule is: if very stiff use arthroscopy; if more mobile use a distension procedure. Active exercises are important to restore function. Fifty per cent of people with adhesive capsulitis do not regain full normal movement if untreated.

Current evidence from systemic reviews indicates that both hydrodistension and intra-articular injections are likely to be beneficial.<sup>12,17</sup>

Exercise in the acute phase can exacerbate pain but a gentle program is useful when it settles. If stiffness persists, manipulation under anaesthesia and/or arthroscopic debridement of adhesions may be helpful.

### Typical pain profile—adhesive capsulitis

Usually affects people in their 40s, 50s and 60s.

Site:	around the shoulder and outer border of arm
Radiation:	to elbow
Quality:	deep throbbing pain
Frequency:	constant, day and night (severe cases)
Duration:	constant
Onset:	spontaneous, usually gradual, wakes the patient from sleep
Offset:	nil
Aggravation:	activity, dressing, combing hair, heat
Relief:	analgesics only (partial relief)
Associated features:	stiffness of arm, may be frozen
Examination (typical features):	<ul style="list-style-type: none"> <li>— 'frozen' shoulder (some cases)</li> <li>— various active and passive movements painful and restricted, especially extension</li> <li>— resisted movements pain-free (patient compensates with scapulo-humeral movements)</li> </ul>
Diagnosis:	high-resolution ultrasound

### § Bicipital tendonopathy

Bicipital tendonopathy is a lesion such as fraying or tearing of the long head of the biceps, which causes pain in front of the shoulder. Important signs include pain on resisted flexion of the elbow joint and on resisted supination with the elbow flexed to 90° and forearm pronated (Yergason test). A painful arc may be present when the intrascapular part is affected. Hence it is often confused with one of the rotator cuff lesions. Sometimes it is possible to elicit local tenderness by palpation along the course of the tendon in the bicipital groove. This is best done when the arm is externally rotated. Most active shoulder movements, especially external rotation, bring on the pain.

Bicipital tendonopathy usually follows chronic repetitive strains in young to middle-aged adults (e.g. home decorating, weight training, tennis, swimming freestyle, cricket bowling and baseball pitching). Two complications are complete rupture and subluxation of the tendon out of its groove.

One treatment to consider is a corticosteroid and local anaesthetic injection at the site of maximal tenderness in the bicipital groove (see FIG. 63.6). As a rule it is best to refer a significant lesion.

**FIGURE 63.6** Injection placement for bicipital tendonopathy

Quality:	a deep, intense ache
Frequency:	daily
Duration:	constant but easier in afternoon and evening
Onset:	wakes with pain at greatest intensity
Offset:	nil
Aggravating factors:	staying in bed, inactivity
Relieving factors:	activity (slight relief)
Associated features:	severe morning stiffness 'in muscles'; malaise; $\pm$ weight loss, depression
Diagnosis:	greatly elevated ESR (can be normal)
Treatment:	corticosteroids give dramatic relief but long-term management can be problematic; regular review and support is essential (refer <a href="#">CHAPTER 32</a> )

## § Rupture of the biceps tendon

Rupture of the long head of biceps usually occurs in the older person. It may be spontaneous or occur after lifting or falling on the outstretched hand. The patient usually feels a tearing or snapping sensation in the shoulder. The shoulder may be painful and difficult to move. The upper arm looks bruised and a lump due to rolled-up belly of biceps is obvious on flexion of the elbow. Active treatment is not usually indicated but surgical intervention is appropriate for young, active people, especially those in power sports.

## § Polymyalgia rheumatica

It is very important not to misdiagnose polymyalgia rheumatica in the older person (over 50 years) presenting with bilateral pain and stiffness in the shoulder girdle. It may or may not be associated with hip girdle pain. Polymyalgia rheumatica sometimes follows an influenza-like illness. The patients seem to complain bitterly about their pain and seem flat and miserable. In the presence of a normal physical examination they are sometimes misdiagnosed as 'rheumatics' or 'fibrositis'.

### Typical pain profile—polymyalgia rheumatica

Site:	shoulders and upper arms (see <a href="#">FIG. 63.7</a> )
Radiation:	towards lower neck

**FIGURE 63.7** Polymyalgia rheumatica: typical area of pain around the shoulder girdle

## § Posterior dislocation of the shoulder

This is a rare form of shoulder instability, which is often misdiagnosed. On first inspection there may not be an obvious abnormality of the shoulder contour. Consider this condition if there is a history of electric shock or a tonic-clonic convulsion. The major clinical sign is painful restriction of external rotation, which is usually completely blocked. Routine shoulder X-rays following trauma should always include the 'axillary shoot-through' view and then the diagnosis becomes obvious. Early diagnosis and management can prevent a poor outcome and perhaps litigation.<sup>9,18</sup>

## § Recurrent subluxation

Recurrent anterior or inferior subluxations, or both, are probably more common than recurrent dislocations, yet frequently are not diagnosed. Patients who complain of attacks of sudden weakness and even a 'dead arm feeling' lasting for a few minutes with overhead activities of the arm should be investigated for this condition.

The disorder is usually apparent on careful stress testing of the shoulder. Air-contrast CT arthrography is considered the best investigation. Surgery is usually curative while conservative treatment often fails for younger patients.

## Glenoid labrum injuries<sup>4,7</sup>

The glenoid labrum is the ring of fibrous tissue attached to the rim of the glenoid and provides volume to the cavity and stability to the glenohumeral joint. Injuries to the labrum are divided into superior labrum anterior to posterior (SLAP) or non-SLAP lesions and further into stable and unstable lesions.

Non-SLAP lesions include degenerative, flap and vertical labral tears as well as unstable lesions such as the classic Bankart lesion, where the labrum and capsule is detached from the rim (see CHAPTER 135).

## § Shoulder instability<sup>5,16</sup>

Recurrent shoulder instability can be divided into three main types.

- 1 Those with a tendency to generalised laxity of multiple joints including the shoulder and which tend to dislocate with minor injuries. Surgery is less effective and treatment is based on improving muscular stability with physiotherapy rehabilitation.
- 2 Those following trauma, which includes avulsion of the anterior labrum (Bankart lesion). Physiotherapy tends to be less effective and the patients often require surgical repair.
- 3 Those with chronic rotator cuff tendonopathy/impingement who develop subtle instability. Refer first to a sports physician or physiotherapist for assessment and management, preferably conservative initially.

The 'apprehension' test is useful to confirm the diagnosis of traumatic anterior instability. In this test the patient lies supine while the arm is externally rotated with the elbow flexed to 90°. The test is more

reliable when the patient expresses apprehension that the shoulder will 'come out', rather than pain.

## § Osteoarthritis of the glenohumeral joint

This is usually secondary to local trauma, long-standing rotator cuff lesions and multiple surgical interventions. Shoulder movements are stiff and usually restricted in all directions. Plain X-rays show typical osteoarthritic changes. Treatment includes basic analgesics and short courses of NSAIDs plus exercises to improve mobility. Patients usually manage to cope with osteoarthritis of the shoulder, but for severe pain and stiffness arthroplasty or joint replacement should be considered.

## § Acromioclavicular osteoarthritis

This condition is usually traumatic or degenerative and is relatively common in builders and sportspeople, especially rowers, and the elderly. A key test for AC joint pain is the Paxinos sign, which is positive when pain is elicited on compression of the joint by placing one hand on the back of the acromion and one on the clavicle. It is treated with rest and support and analgesics. Intra-articular injections of corticosteroids can be used for resistant or severe cases. If these measures are ineffectual, pain may be relieved by excision of the lateral end of the clavicle.

## When to refer

- Persisting night pain with shoulder joint stiffness
- Persisting supraspinatus tendonopathy; consider possibility of rotator cuff tear or degeneration, especially in the elderly
- Persisting restriction of movement, such as restricted cross-body flexion (indicates capsular constriction)
- Persisting supraspinatus tendonopathy or other rotator cuff problem, because decompression of the subacromial space with division of the coracoacromial ligament ± acromioplasty gives excellent results
- Confirmed or suspected posterior dislocation of the shoulder—the most commonly missed major joint dislocation
- Confirmed or suspected recurrent subluxation or avascular humeral head
- Children with shoulder joint instability
- Swimmer's shoulder refractory to changes in technique and training schedule

- Severe osteoarthritis of the glenohumeral joint (which usually follows major trauma) for consideration of prosthetic replacement
- Severe osteoarthritis of the AC or glenohumeral joint

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Exercises for your shoulder
- Polymyalgia rheumatica
- Shoulder: frozen shoulder
- Shoulder: tendonitis

## Practice tips

- Consider dysfunction of the cervical spine, especially C4–5 and C5–6 levels, as a cause of shoulder pain.
- Tendonitis and bursitis are very refractory to treatment and tend to last for several months. One well-placed injection of local anaesthetic and corticosteroid may give rapid and lasting relief.
- Test for supraspinatus disorders (including swimmer's shoulder) with the impingement tests, including the 'emptying the can' test.
- Modern ultrasound is the investigation of choice for painful disorders of the rotator cuff, especially to investigate tears in tendons.
- An elderly person presenting with bilateral shoulder girdle pain has polymyalgia rheumatica until proved otherwise. Relief from corticosteroids is dramatic. Although bilateral, it may start as unilateral discomfort.
- Dysfunction of the cervical spine can coexist with dysfunction of the shoulder joints.
- Correlation between clinical symptoms and the degree of tendon injury or failure is not reliable.<sup>18</sup>

Orthopaedic surgeon to students 1965

Pain in the arm and hand is a common problem in general practice, tending to affect the middle aged and elderly in particular.

## Overview of causes of a painful arm and hand

Like pain in the shoulder, pain originating from the cervical spine and shoulder disorders can extend down the arm. While pain from disorders of the shoulder joint (because of its C5 innervation) does not usually extend below the elbow, radiculopathies originating in the cervical spine can transmit to distal parts of the arm (see FIG. 64.4, later in this chapter).

Important causes are illustrated in FIGURE 64.1. Myocardial ischaemia must be considered, especially for pain experienced down the inner left arm.

Soft tissue disorders of the elbow are extremely common, especially tennis elbow. Two types of tennis elbow are identifiable: 'backhand' tennis elbow, or lateral epicondylitis, and 'forehand' tennis elbow, or medial epicondylitis, which is known also as golfer's or pitcher's elbow.

Other significant elbow disorders include inflammatory disorders of the elbow joint, such as rheumatoid arthritis, osteoarthritis and olecranon bursitis, which may follow recurrent trauma, gout, rheumatoid arthritis or infection.

Another important group of disorders are the various regional pain syndromes around the wrists, including the common de Quervain tenosynovitis (affecting the tendons of extensor pollicis brevis and abductor pollicis longus) and to a lesser extent the extensor tendons to the fingers. Pain from these overuse syndromes can be referred in a retrograde manner into the forearm.

A fascinating and poorly understood syndrome is that related to dysfunction of the upper four vertebral segments of the thoracic spine, which can cause referred pain in the arm that does not correspond to the dermatomes. This syndrome is often confused with the more common regional pain disorders such as tenosynovitis and tennis elbow.

FIGURE 64.1 Important causes of arm pain (excluding trauma and arthritis)

The various causes of the painful arm can be considered with the diagnostic strategy model (see TABLE 64.1).

## A diagnostic approach

### Probability diagnosis

The commonest causes of arm pain are referred pain and radiculopathies caused by disorders of the cervical spine, the tennis elbows (lateral and, to a lesser extent,

**Table 64.1** Pain in the arm and hand: diagnostic strategy model

Q.	Probability diagnosis
A.	Dysfunction of the cervical spine (lower) Disorders of the shoulder Medial or lateral epicondylitis Overuse tendonitis of the wrist Carpal tunnel syndrome Osteoarthritis of the thumb and DIP joints
Q.	Serious disorders not to be missed
A.	Cardiovascular: <ul style="list-style-type: none"> <li>• angina (referred)</li> <li>• myocardial infarction</li> <li>• axillary vein thrombosis</li> </ul> Neoplasia: <ul style="list-style-type: none"> <li>• Pancoast tumour</li> <li>• bone tumours (rare)</li> </ul> Severe infections: <ul style="list-style-type: none"> <li>• septic arthritis (shoulder/elbow)</li> <li>• osteomyelitis</li> <li>• infections of tendon sheath and fascial spaces of hand</li> <li>• sporotrichosis (gardener's arm)</li> </ul>
Q.	Pitfalls (often missed)
A.	Entrapment neuropathies (e.g. median nerve, ulnar nerve) Pulled elbow (children) Foreign body (e.g. elbow) Rarities: <ul style="list-style-type: none"> <li>• polymyalgia rheumatica (for arm pain)</li> <li>• reflex sympathetic dystrophy</li> <li>• thoracic outlet syndrome</li> <li>• arm claudication (left arm)</li> <li>• Kienböck disorder</li> </ul>
Q.	Seven masquerades checklist
A.	Depression Diabetes Spinal dysfunction
Q.	Is the patient trying to tell me something?
A.	Highly likely, especially with the so-called RSI syndromes.

medial epicondylitis), carpal tunnel syndrome (CTS) and regional pain syndromes caused by inflammation of the tendons around the wrist and thumb.

Disorders of the shoulder, particularly supraspinatus tendonitis, should be considered if the pain is present in the C5 dermatome distribution. Pain in the hand is commonly caused by osteoarthritis of the carpometacarpal joint of the thumb and the distal interphalangeal (DIP) joints, and also by CTS.

## Serious disorders not to be missed

Like any other presenting problem, it is vital not to overlook malignant disease or severe infection. In the case of the arm, possible malignant disease includes tumours in bones, lymphoma involving axillary glands and Pancoast tumour, which may cause severe arm pain before any signs are evident.

Neoplastic tumours of the hand are uncommon and usually benign. Benign tumours include giant cell tumour of the tendon sheath, pigmented villonodular synovitis, neurilemmoma and neurofibroma. Malignant tumours are exceptionally rare but can include synovioma and rhabdomyosarcoma.

In addition, myocardial ischaemia, especially infarction in the case of pain of sudden onset, should be considered for left arm pain.

Sepsis can involve joints, the olecranon bursa and the deeper compartments of the hand, the latter leading to serious sequelae if not rapidly diagnosed and treated.

Subclavian or axillary vein thrombosis, known as 'effort thrombosis', causes swelling in the arm with pain high in the axilla. It is seen in people working constantly above their head, such as painters and basketballers. It is an emergency requiring antithrombotic therapy.

## Pitfalls

Such conditions may include entrapment syndromes for peripheral nerves. If in doubt the patient should be referred for electromyography. Variations of peripheral nerve entrapments include the pronator syndrome (compression of the median nerve by the pronator teres or a fibrous band near the origin of the deep flexor muscles) and ulnar nerve entrapment at the elbow in the cubital fossa and, rarely, in the Guyon canal in the wrist.

Lesions of the nerve roots comprising the brachial plexus can also cause arm pain, especially in the C5 and C6 distribution. These can be detected by the brachial plexus tension tests.

## Rarer causes of arm pain

These include polymyalgia rheumatica, although the pain typically involves the shoulder girdle, regional pain syndrome (Sudeck atrophy) and the thoracic outlet syndromes.

The thoracic outlet syndromes include problems arising from compression or intermittent obstruction of the neurovascular bundle supplying the upper extremity, for example, cervical rib syndrome, costoclavicular syndrome, scalenus

anterior and medius syndrome, 'effort thrombosis' of axillary and subclavian veins and the subclavian steal syndrome.

The commonest cause of the thoracic outlet syndrome is sagging musculature related to ageing, obesity, and heavy breasts and arms, aptly described by Swift and Nichols as 'the droopy shoulder syndrome'.<sup>1</sup>

Cervical ribs are relatively common and may or may not contribute to the thoracic outlet syndrome. Often the cause is a functional change in the thoracic outlet due to the 'droopy shoulder syndrome' with no significant anatomical fault.<sup>2</sup>

Arm claudication is also rare. It can occur with arterial obstruction due to occlusion of the proximal left subclavian artery or the innominate artery. Exercise of the arm may be associated with central nervous system symptoms as well as claudication.

## Seven masquerades checklist

Of the seven primary masquerades, spinal dysfunction and depression are those most likely to be associated with arm pain. Nerve root pain arising from entrapment in intervertebral foramina of the cervical spine or from a disc prolapse frequently leads to pain and/or paraesthesia in the arm.

Although diabetic neuropathy primarily manifests in the lower limbs it may be associated with neuropathies in the hands, including erythromelalgia (redness and burning related to heat). Hypothyroidism may cause a CTS.

## Psychogenic considerations

The hand can be regarded as a highly emotive 'organ' that is frequently used to give outward expression to inner feelings. These can range from grossly disturbed psychiatric behaviour, manifested as a hysterical conversion disorder by a non-functioning hand, to occupational neuroses such as repetition strain injury (RSI) and malingering.<sup>3</sup> Experienced occupational physicians and surgeons<sup>3</sup> find the hand and arm a source of functional disability most often as a result of industrial injury. Of great concern are the various so-called RSI disorders, which in some people may be a means of work avoidance or a 'ticket' for compensation or both.

## The clinical approach

### History

The painful arm represents a real diagnostic challenge, so the history is very relevant.

It is common for arm pain to cause sleep disturbances and three causes are cervical disorders, CTS and the thoracic outlet syndrome. The working rule is:

- thoracic outlet syndrome—patients cannot fall asleep
- CTS—patients wake in the middle of the night
- cervical spondylosis—wakes the patient with pain and stiffness that persists well into the day<sup>4</sup>

The history should include an analysis of the pain and a history of trauma, particularly unaccustomed activity. In children evidence should be obtained about the nature of any injury, especially pulling the child up by the arms or a fall on an outstretched hand, which can cause potentially serious fractures around the elbow.

## Examination

As part of the physical examination of the painful arm it may be necessary to examine a variety of joints, including the cervical spine (CHAPTER 62), shoulder (CHAPTER 63), elbow, wrist and the various joints of the hand. The arms should be inspected as a whole and it is very important to have both arms free of clothing and compare both sides.

### Elbow joint

*Inspection* (from anterior, lateral and posterior aspects). Hold elbow in an anatomical position to measure the carrying angle of forearm—elbow fully extended, forearm supinated (palm facing forwards) normal 5–15° (greater in females). Note any swellings:

- olecranon bursitis (bursa over olecranon)
- nodules:
  - RA (subcutaneous border ulna)
  - gout
  - SLE (rare) and rheumatic fever (very rare)
  - granulomas (e.g. sarcoidosis)

*Palpation*. Perform with patient supine and elbow held in approximately 70° flexion. Palpate bony landmarks and soft tissue. Note especially any tenderness over lateral epicondyle (tennis elbow) and medial epicondyle (golfer's elbow).

*Movement* (test active and passive). Hinge joint:

- extension—flexion (0° to 150°):
  - the arc for daily living is 30–130°
  - limitation of extension is an early sign of synovitis
- pronation—supination (rotation):
  - occurs at radiohumeral joint
  - test in two positions: 90° flexion (held to side of body) + at full extension

- supination 85° plus
- pronation 75° plus

#### Resisted movements

- Painful resisted flexion at wrist = medial epicondylitis
- Painful resisted extension at wrist = lateral epicondylitis

### Wrist joint

Follow the usual rules: look, feel, move, test function, measure, look elsewhere and X-ray. Note swellings or deformities, including the 'anatomical snuff box' and distal end of radius. Feel for heat, tenderness and swelling, especially over the radial aspect of the wrist.

*Movements.* With elbow fixed at 90° and held into the waist:

- 1 compare dorsiflexion and palmar flexion on both sides (normal range extension 70–80°; flexion 80–90°)
- 2 compare ulnar deviation (normal to 45°) and radial deviation (20°)
- 3 compare pronation and supination (normal to 90° for both)

### Neurological examination

Test sensation, motor power and reflexes where indicated.

Summary of tests for motor power:

- C5—test resisted movement deltoid
- C6—test resisted movement biceps
- C7—test resisted movement triceps
- C8—test resisted EPL and FDL
- T1—test resisted interossei

Sensory patterns are presented in **FIGURE 62.4** (**CHAPTER 62**).

### Investigations

Pain in the arm and hand can be difficult to diagnose but the rule to follow is: 'If in doubt, X-ray and compare both sides'. This applies particularly to elbow injuries in children. The presence of a foreign body in the hand or arm also requires consideration.

Investigations to consider include:

- blood film and WCC
- ESR
- ECG
- imaging
  - plain X-rays e.g. cervical spinal
  - ultrasound
  - arthrograms (shoulder, elbow, wrist)

- CT scanning
- technetium bone scan
- nerve conduction studies
- electromyography

*Note:* Modern sophisticated ultrasound examination is becoming a vital diagnostic modality for soft tissue disorders such as tendonopathy.

### Arm pain in children

The main concerns with children are the effects of trauma, especially around the elbow. Considerable awareness of potential problems and skilful management are required with children's elbow fractures. Foreign bodies in the arm also have to be considered.

#### § Pulled elbow

This typically occurs in children under 8 years of age, usually at 2–5 years, when an adult applies sudden traction to the child's extended and pronated arm (see **FIG. 64.2a**): the head of the radius can be pulled distally through the annular radioulnar ligament (see **FIG. 64.2b**).<sup>5</sup>

### Symptoms and signs

- The crying child refuses to use the arm.
- The arm is limp by the side or supported in the child's lap.
- The elbow is flexed slightly (any flexion will be strenuously resisted).
- The forearm is pronated or held in mid-position.
- The arm is tender around the elbow (without bruising or deformity).

*Note:* An X-ray is not usually necessary.

### Treatment

#### Method

- 1 Gain the child's confidence.
- 2 The child stands facing the doctor with the parent holding the non-affected arm.
- 3 Place one hand around the child's elbow to give support, pressing the thumb over the head of the radius.
- 4 With the other hand, firmly and smoothly flex the elbow and suddenly and firmly twist the forearm into full supination (see **FIG. 64.2c**). A faint click (which will be painful) will be heard. After a few minutes the child will settle and resume full pain-free movement. Warn parents that recurrences are possible up to 6 years.

**FIGURE 64.2** Pulled elbow: (a) mechanism of injury, (b) annular ligament displaced over head of radius, (c) reduction by supination

### Alternative method

An easier method for the child is to very gently alternate pronation and supination through a small arc as you flex the elbow.

*Note:* Spontaneous resolution can occur eventually. Place the arm in a sling if necessary. If you cannot get the child's cooperation, send them home in a 'high' sling.

Fractures and avulsion injuries around the elbow joint, which are a major problem in children, are discussed in more detail in [CHAPTER 135](#).<sup>6</sup>

## Arm pain in the elderly

Elderly patients are more likely to be affected by problems such as referred pain, radiculopathy or myelopathy from cervical spondylosis, tumours, polymyalgia rheumatica, entrapment neuropathies such as CTS and ulnar nerve entrapment. The latter can be related to trauma, such as Colles fractures. In addition the elderly are more prone to suffer from the thoracic outlet syndrome as previously described under 'Pitfalls'. Osteoarthritis of the hand and tenosynovitis, such as trigger thumb or finger, are more common with advancing age.

### TENNIS ELBOW

Tennis elbow is caused by overuse or overload of the muscles of the forearm, especially in the middle aged. Two types are identifiable: 'backhand' tennis elbow, or lateral epicondylitis, and 'forehand' tennis elbow, or medial epicondylitis, which is also known as golfer's or pitcher's elbow. 'Backhand' tennis elbow, which will be termed lateral tennis elbow, is the common classic variety. It is an overload injury caused by excessive strain on the extensor muscles of the forearm resulting from wrist extension. Both conditions are generally self-limiting, but symptoms can persist for up to 2 years, or even much longer.

### § Lateral tennis elbow (lateral epicondylitis)

The patient who presents with this common and refractory problem is usually middle aged and only about one in 20 plays tennis. A typical clinical profile is presented in [TABLE 64.2](#).

### Signs

On examination the elbow looks normal, and flexion and extension are painless.

There are three important positive physical signs:

- 1 localised tenderness to palpation over the anterior aspect of the lateral epicondyle
- 2 pain on passive stretching at the wrist with the elbow held in extension and the forearm prone (see [FIG. 64.3](#))
- 3 pain on resisted extension of the wrist with the elbow held in extension and the forearm prone (see [FIG. 64.4](#))

### Management

Although there are myriad treatments, the cornerstones of therapy are rest from the offending activity and exercises to strengthen the extensors of the wrist. The application of ice may help relieve discomfort of acute pain. Three systematic reviews have found little evidence for efficacy of any one specific intervention but short-term use of NSAIDs and progressive strengthening and stretching exercises were better than placebo.<sup>7</sup> A trial of oral NSAIDs or topical NSAID applied tds may be worthwhile.<sup>8</sup>

### Exercises

Stretching and strengthening exercises for the forearm muscles represent the best management for tennis elbow. Three options are presented.

**Table 64.2** Lateral tennis elbow: typical clinical profile

<b>Age</b>	40–60 years
<b>Occupation</b>	Carpenter, bricklayer, housewife, gardener, dentist, violinist
<b>Sport</b>	Tennis, squash
<b>Symptoms</b>	Pain at outer elbow, referred down back of forearm Rest pain and night pain (severe cases) Pain in the elbow during gripping hand movements (e.g. turning on taps, turning door handles, picking up objects with grasping action, carrying buckets, pouring tea, shaking hands)
<b>Signs</b>	No visible swelling Localised tenderness over lateral epicondyle, anteriorly Pain on passive stretching wrist Pain on resisted extension wrist and third finger Normal elbow movement
<b>Course</b>	6 to 24 months
<b>Management</b>	Basic: <ul style="list-style-type: none"> <li>• rest from offending activity</li> <li>• RICE* and oral NSAIDs if acute</li> <li>• exercises—stretching and strengthening</li> </ul> Additional (if refractory): <ul style="list-style-type: none"> <li>• corticosteroid/LA injection (max. two)</li> <li>• manipulation</li> <li>• surgery</li> </ul>

\* RICE: rest, ice, compression, elevation

**FIGURE 64.3** Lateral tennis elbow test: reproducing pain on passive stretching at the wrist

- 1 *The wringing exercise.* Chronic tennis elbow can be cured by a simple wringing exercise using a small hand towel.<sup>9</sup>

*Method*

- Roll up the hand towel.

**FIGURE 64.4** Lateral tennis elbow test: reproducing pain on resisted extension of the wrist

- With the arm extended, grasp the towel with the affected side placed in neutral.
- Then exert maximum wringing pressure: first flexing the wrist for 10 seconds, then extending the wrist for 10 seconds.

This is an isometric 'hold' contraction.

This exercise should be performed only twice a day, initially for 10 seconds in each direction.

After each week increase the time by 5 seconds in each twisting direction until 60 seconds is reached (week 11). This level is maintained indefinitely.

*Note:* Despite severe initial pain, the patient must persist, using as much force as possible. Review at 6 weeks to check progress and method.

- 2 *'Weights' exercise.* The muscles are strengthened by the use of hand-held weights or dumbbells. A suitable starting weight is 0.5 kg, building up gradually (increasing by 0.5 kg) to 5 kg, depending on the patient.

*Method*

- To perform this exercise the patient sits in a chair beside a table.
  - The arm is rested on the table so that the wrist extends over the edge.
  - The weight is grasped with the palm facing downwards (see FIG. 64.5).
  - The weight is slowly raised and lowered by flexing and extending the wrist.
  - The flexion/extension wrist movement is repeated 10 times, with a rest for 1 minute, and the program is repeated twice.
- 3 *The pronating exercise.*<sup>10</sup> A suitable stretching exercise is to rhythmically rotate the hand and wrist inwards with the elbow extended and the forearm pronated (see FIG. 64.6). Another proven exercise program is that outlined by Nirschl<sup>11</sup> and this can be provided by referral to a physiotherapist familiar with the program.

### Injection therapy

The injection of 1 mL of a long-acting corticosteroid and 1 mL of local anaesthetic should be reserved for

**FIGURE 64.5** Lateral tennis elbow: the dumbbell exercise with the palm facing down

**FIGURE 64.6** Tennis elbow stretching exercise: the hand and wrist are rhythmically rotated inwards until the painful point is reduced

those severe cases when pain restricts simple daily activities, and not used initially for those patients with only intermittent pain.

A Netherlands study showed that corticosteroid injections are the best short-term treatment for tennis elbow. Over the longer term, physiotherapy offers better results than injection but is on a par with a wait and see approach.<sup>12</sup>

### Surgery

Severe and refractory cases can be referred for surgery but this is rarely indicated and there is no evidence to date on its efficacy. The usual procedure is the stripping of the common extensor origin combined with debridement of any granulation tissue.<sup>3</sup> Other treatments include glyceryl trinitrate patches and autologous blood injections.

## § Medial tennis elbow (medial epicondylitis)

In 'forehand' tennis elbow, or golfer's elbow, the lesion is the common flexor tendon at the medial epicondyle. The pain is felt on the inner side of the elbow and does not radiate far. The main signs are localised tenderness to palpation and pain on resisted flexion of the wrist.

In tennis players it is caused by stroking the ball with a bent forearm action or using a lot of top spin, rather than stroking the ball with the arm extended.

The treatment is similar to that for lateral epicondylitis except that in a dumbbell exercise program that palm must face upwards.

### After-care and prevention (lateral and medial epicondylitis)

Tennis should be resumed gradually. Players recovering from tennis elbow should start quietly with a warm-up period and obtain advice on style, including smooth stroke play. During a game they should avoid elbow bending and 'wristy' shots. A change to a good-quality racket (wooden or graphite frame) with a medium-sized head and suitable grip size may be appropriate.<sup>11</sup> The patient should be advised not to use a tightly strung, heavy racket or heavy tennis balls. It may be worthwhile to advise the use of a non-stretch band or brace situated about 7.5 cm below the elbow.

## § Olecranon bursitis

Olecranon bursitis presents as a swelling localised to the bursa (which has a synovial membrane) over the olecranon process. The condition may be caused by trauma, arthritic conditions (rheumatoid arthritis and gout) or infection.

Traumatic bursitis may be caused by a direct injury to the elbow or by chronic friction and pressure as occurs in miners (beat elbow), truck drivers or carpet layers. Acute olecranon bursitis with redness and warmth can occur in rheumatoid arthritis, gout, pseudogout, haemorrhage and infection (sepsis).<sup>13</sup> Septic bursitis must be considered where the problem is acute or subacute in onset, and hence aspiration of the bursa contents with appropriate laboratory examination is necessary (smear, Gram stain, culture and crystal examination). Treatment depends on the cause.

### Simple aspiration/injection technique

Chronic recurrent traumatic olecranon bursitis with a synovial effusion may require surgery but most

cases can resolve with partial aspiration of the fluid and then injection of corticosteroid through the same needle. Sepsis must be ruled out.

### § Overuse syndromes of forearm muscles<sup>8</sup>

Pain is often experienced in the belly of a muscle, such as the flexors and extensors, following unaccustomed use of the wrists and elbows. There is pain on contraction and stretching of the muscles and tenderness on palpation. This problem can be limiting for a significant period. Early treatment includes relative rest, ice packs, analgesics (paracetamol) and gradual return to activity. Referral for physiotherapy to supervise rehabilitation is important.

### § Carpal tunnel syndrome

Patients with CTS complain of 'pins and needles' affecting the pulps of the thumb, and index, middle and half of the ring finger (see FIG. 64.7). They usually notice these symptoms after, rather than during, rapid use of the hands. They may also complain of pain, which may even radiate proximally as far as the shoulder, from the volar aspect of the wrist. Causes or associations of CTS are presented in TABLE 64.3.

**Table 64.3** Carpal tunnel syndrome: causes or associations

Idiopathic
Acromegaly
Amyloidosis
Consider cervical nerve root pressure
Diabetes mellitus
Fibrosis
Granulomatous disorders (TB, etc.)
Hypothyroidism
Multiple myeloma
Occupational: repetitive work with flexed wrists
Paget disease
Pregnancy
Premenstrual oedema
Rheumatoid arthritis
Tophaceous gout
Trauma

**FIGURE 64.7** Carpal tunnel syndrome (median nerve compression syndrome)

### The pathognomonic symptom

Patients complain of awakening from their sleep at night with 'pins and needles' affecting the fingers. They get out of bed, shake their hands, the 'pins and needles' subside and they return to sleep. In severe cases, the patient may awaken two or three times a night and go through the same routine.

### Work-related CTS

CTS is seen in many work situations requiring rapid finger and wrist motion under load, such as

meat workers and process workers. A type of flexor tenosynovitis develops and thus nerve compression in the tight tunnel. It is advisable to arrange confirmatory investigations by nerve conduction studies and electromyography for this work-induced overuse disorder. This testing is also indicated where the diagnosis is uncertain or if the condition persists and numbness or weakness develops.

### Diagnosis (simple clinical tests)

In the physical examination a couple of simple tests can assist with confirming the diagnosis. These are the Tinel test and Phalen test. However, they are 'soft' signs with a relatively low sensitivity and specificity.<sup>14</sup>

#### Tinel test

- Hold the wrist in a neutral or flexed position and tap over the median nerve at the flexor surface of the wrist. This should be over the retinaculum just lateral to the palmaris longus tendon (if present) and the tendons of flexor digitorum superficialis (see FIG. 64.8).
- A positive Tinel sign produces a tingling sensation (usually without pain) in the distribution of the median nerve.

FIGURE 64.8 Carpal tunnel syndrome: Tinel sign

#### Phalen test

- The patient approximates the dorsum of both hands, one to the other, with wrists maximally flexed and fingers pointing downwards.
- This position is held for 60 seconds.
- A positive test reproduces tingling and numbness along the distribution of the median nerve.

#### Two point discrimination

The test that has the highest specificity of all basic clinical tests is two point discrimination, but it has low sensitivity for CTS.<sup>14</sup>

#### Treatment

The treatment is determined by the severity. For mild cases simple rest and splinting (particularly at night) is sufficient. Carpal tunnel injection with 1 mL of corticosteroid is frequently of diagnostic as well as therapeutic value (see FIG. 64.9). Ultrasound therapy has been used with some success. Surgical release (flexor retinaculotomy) is necessary for patients with sensory or motor deficits and those with recalcitrant CTS.

Systematic evidence-based reviews indicate the benefit of short-term oral corticosteroids<sup>7</sup> and

FIGURE 64.9 Injection technique for carpal tunnel syndrome: between the palmaris longus and ulnar artery

local corticosteroid injection (short-term). NSAIDs, diuretics and wrist splinting are unlikely to be beneficial.

In reference to surgery, one review found similar clinical outcomes between open carpal tunnel release and endoscopic release but the latter had more complications.<sup>7</sup>

### § Trigger finger/thumb (flexor tenosynovitis)

In the fingers the common work-induced condition is stenosing flexor tenosynovitis, also known as trigger thumb and finger. Trigger finger or thumb has a reported lifetime risk of 2.6% in the population and is more common in the fifth and sixth decades of life.<sup>15</sup> It is associated with type 1 diabetes, rheumatoid arthritis, gout, hypothyroidism and amyloidosis. It is caused by the same mechanism as de Quervain stenosing tenosynovitis. In middle age these tendons, which are rapidly and constantly being flexed and extended, can undergo attrition wear and tear, and fibrillate and fragment; this causes swelling, oedema and painful inflammation and the formation of a nodule on the tendon that triggers back and forth across the thick, sharp edge of the 'pulley' (of the fibrous tunnel in the finger) (see FIG. 64.10).

These patients may present with a finger locked in the palm of the hand; the finger can only be

extended passively (manually) with the other hand. It is easily diagnosed by triggering. If the pulp of the finger is placed over the 'pulley' crepitus can be felt and tenderness elicited. The thumb and fourth (ring) finger are commonly affected, at the level of the metacarpal head.

### Treatment

Although surgery is simple and effective, treatment by injection is often very successful. The injection is made under the tendon sheath and not into the tendon or its nodular swelling. The approach can be proximal, distal or lateral to the nodule. Controlled trials report a success rate of up to 70%.<sup>15</sup>

### Method

- The patient sits facing the doctor with the palm of the affected hand facing upwards.
- Draw 1 mL of long-acting corticosteroid solution into a syringe and attach a 25 gauge needle for the injection.
- Insert the needle at an angle distal to the nodule and direct it proximally within the tendon sheath (see FIG. 64.11). This requires tension on the skin with free fingers.
- By palpating the tendon sheath, you can (usually) feel when the fluid has entered the tendon sheath.
- Inject 0.5–1 mL of the solution, withdraw the needle and ask the patient to exercise the fingers for 1 minute.

FIGURE 64.10 Trigger thumb

FIGURE 64.11 Injection site for trigger finger

## Postinjection

Improvement usually occurs after 48 hours and may be permanent. The injection can be repeated after 3 weeks if the triggering is not completely relieved. If triggering recurs, surgery is indicated. This involves division of the thickened tendon sheath only.

## § Dupuytren contracture

This contracture, which causes discomfort and dysfunction rather than pain, is fibrous hyperplasia of palmar fascia leading to nodular formation and contracture over the fourth and fifth fingers in particular (see FIG. 64.12). It occurs in about 10% of males over 65 years. The cause is unknown but there is an AD genetic predisposition. It is associated with smoking, alcoholism, liver cirrhosis, COPD, diabetes and heavy manual labour. If the palmar nodule is growing rapidly, injection of corticosteroids or collagenase (e.g. Xiafelx) into the cord or nodule may be beneficial. Surgical intervention is indicated for a significant flexion deformity.

FIGURE 64.12 Dupuytren contracture showing flexion contractures of the fourth and fifth digits and a palmar cord

## § De Quervain tenosynovitis (washerwoman's sprain)

At the wrist, a not uncommon, work-induced condition is de Quervain stenosing tenosynovitis of the first dorsal extensor compartment tendons (extensor pollicis brevis and abductor pollicis longus), which pass along the radial border of the wrist to the base of the thumb. It is usually seen when the patient

is required to engage in rapid, repetitious movements of the thumb and the wrist, especially for the first time, and thus is common in assembly line workers, such as staple gun operators.

## Clinical features

- Typical age 40–50 years
- Pain at and proximal to wrist on radial border
- Pain during pinch grasping
- Pain on thumb and wrist movement
- Dull ache or severe pain (acute flare-up)
- Can be disabling with inability to use hand (e.g. writing)

## Triad of diagnostic signs

- Tenderness to palpation over and just proximal to radial styloid
- Firm tender localised swelling in area of radial styloid (may be mistaken for exostosis)
- Positive Finkelstein sign (the pathognomonic test)

## Finkelstein test

- The patient folds the thumb into the palm with the fingers of the involved hand folded over the thumb, thus making a fist.
- Move (adduct) the wrist in an ulnar direction (towards the little finger) to stretch the involved tendons as you stabilise the forearm with the other hand (see FIG. 64.13).
- A positive test is indicated by reproduction of or increased pain.

FIGURE 64.13 Finkelstein test

## Treatment

- Rest and avoid the causative stresses and strains on the thumb abductors.
- Use a custom-made splint that involves the thumb and immobilises the wrist.
- Consider trial of oral NSAIDs for 14–21 days.

- Local long-acting corticosteroid injection can relieve and may even cure the problem but care should be taken to inject the suspension within the tendon sheath rather than into the tendon.
- Surgical release is required for chronic cases.

### Method of tendon sheath injection

- Identify and mark the most tender site of the tendon and the line of the tendon. Identify and avoid the radial artery.
- Thoroughly cleanse the skin with an antiseptic such as povidone-iodine 10% solution.
- Insert the tip of the needle (23 gauge) about 1 cm distal to the point of maximal tenderness (see FIG. 64.14).
- Advance the needle almost parallel to the skin along the line of the tendon.
- Inject about 0.5 mL of the corticosteroid suspension within the tendon sheath. If the needle is in the sheath very little resistance to the plunger should be felt, and the injection causes the tendon sheath to billow out.

FIGURE 64.14 Tendon sheath injection

### Tendonopathy

After excluding CTS, trigger thumb/finger, de Quervain tenosynovitis, rheumatoid and related disease, tendonitis is uncommon in the hand.<sup>16</sup> Tendonitis may occur in other extensor compartments of the wrist and hand with unusual repetitive stressful actions, such as power drills jamming, and in conveyor quality control where an object is picked up with the forearm prone, supinating to examine it and pronating to replace it.

Treatment is rest from the provoking activity, splintage and tendon sheath injection with long-acting corticosteroid in a manner similar to that described for de Quervain tenosynovitis.

### Intersection syndrome<sup>17</sup>

Intersection syndrome is caused by a bursitis that develops at the site where the extensor pollicis brevis and abductor pollicis longus tendons cross over the extensor carpi radialis tendons (see FIG. 64.15). The bursitis is due to friction at the crossing point or due to tenosynovitis of the extensor tendons. On palpation tenderness is found dorsally on the radial side with swelling and crepitus. Treatment is based on relative rest, a trial of NSAIDs and an injection of local anaesthetic and corticosteroid into the bursa.

FIGURE 64.15 Intersection syndrome: pain is present over the intersection of tendons

### Post-traumatic chronic wrist pain<sup>10</sup>

Patients often present with persistent wrist pain following trauma, such as a fracture, sprain to the wrist or even a seemingly mild strain, such as falling down with the wrist flexed into the hand. An undiagnosed fracture, ischaemic necrosis or unstable ligamentous injury including a triangular fibrocartilage tear should be investigated by radiology or referral where appropriate. Look for a scapholunate ligament tear (which causes wrist instability) with tenderness 2 cm distal to the tubercle on the radial side of the lunate. For persistent tenderness an injection of corticosteroid and local anaesthetic into the tender site is advisable.<sup>8</sup> Imaging including MRI can be helpful but if in doubt about the diagnosis refer to a hand and wrist surgeon.

### Ischaemic necrosis

Ischaemic necrosis, particularly of the scaphoid, can occur following failure to recognise a fracture. Tenderness in the 'anatomical snuff box' following trauma should be treated as a scaphoid until repeated X-rays prove negative. In children, chronic pain in the region of the lunate suggests avascular necrosis—Kienböck disease, presenting with dorsal wrist pain (see later in this chapter).

## § Ganglia<sup>15</sup>

About 60–70% of these common soft tissue tumours occur on the dorsal aspect of the wrist. The vast majority arise from the dorsal scapholunate ligament. Pain can result from compression on an adjacent nerve or joint space. If the diagnosis is uncertain an ultrasound scan (or even an MRI) may pinpoint the tumour. See CHAPTER 126 for treatment.

## NEUROVASCULAR DISORDERS OF THE HAND

Painful vascular disorders, which are more likely to occur in women in cold weather, include Raynaud phenomenon, erythromelalgia, chilblains and acute blue fingers syndrome. Acrocyanosis is not a painful condition.

## § Raynaud phenomenon

The basic feature of Raynaud phenomenon, which is a vasospastic disorder, is sequential discolouration of the digits from pallor to cyanosis to rubor upon exposure to cold and other factors (a useful mnemonic is WBR, namely white → blue → red) (see FIG. 64.16). The rubor is a reactive hyperaemia when fingers become red and tender. Associated symptoms are pain, tingling and numbness. It is possible to get loss of tissue pulp at the ends of the fingers and subsequent necrotic ulcers. The benign form is the

FIGURE 64.16 Raynaud phenomenon: symptoms and colour changes of fingers with cold

commonest, but may indicate an evolving connective tissue disorder. It is highly significant if it extends to the MCP joints (see CHAPTER 32).

## Causes

### Primary

- Raynaud syndrome (idiopathic)

### Secondary

- Occupational trauma (vibrating machinery)
- Connective tissue disorders (e.g. rheumatoid arthritis, SLE, systemic sclerosis, CREST, polyarteritis nodosa)
- Arterial disease (e.g. Buerger disease)
- Haematological disorders (e.g. polycythaemia, cold agglutinin disease, leukaemia)
- Drugs (e.g. beta blockers, sympathomimetic drugs with receptor activity, ergotamine, nasal decongestants)

## Aggravating factors

- Smoking
- Cold, wet weather
- Stress or emotional upset

## Differential diagnoses

- Chilblains—itchy, patchy discolouration without pallor
- Diffusely cold mottled hands—recover quickly on warming

## Investigations

Exclude underlying causes with appropriate tests.

## Treatment<sup>15</sup>

- In an attack it is best to warm the extremities gradually.
- Total body protection from cold—wear layered clothing to prevent heat loss.
- Use an electric blanket at night, as required.
- Use mittens, fleece-lined gloves and thick woollen socks.
- Gloves or mittens should be worn when handling cold surfaces and objects, such as frozen food.
- Avoid smoking.
- Consider sympathectomy.

## Vasodilators (during cold weather)<sup>15</sup>

topical glyceryl trinitrate 2% ointment—applied to the base of the affected fingers two to four times daily or applied over the radial artery or dorsum of the hand  
or

amlodipine 5–20 mg (o) once daily  
 or  
 nifedipine SR 30–60 mg (o) once daily  
 or  
 diltiazem SR 180–240 mg (o) once daily

### § Erythromelalgia (erythermalgia)

This condition is characterised by erythema (redness), a burning sensation and swelling of the hands (and feet) after exposure to heat and exercise. It may be primary or secondary to a disease such as diabetes, haematological disorders<sup>13</sup> (e.g. polycythaemia rubra vera) and connective tissue disease. Treatment of primary erythromelalgia includes trials of aspirin, phenoxybenzamine (Dibenyline), methysergide or sympathectomy.

### § Acute blue fingers syndrome in women

This unusual syndrome involves the sudden onset of pain and cyanosis of the ventral aspect of the digit initially, and then the entire digit. It lasts for two or three days and the attacks recur one or more times per year. No abnormalities are found on physical or on laboratory examination.

The cause is probably spontaneous rupture of a vein at the base of the finger.

### § Chilblains (perniosis)

#### Precautions

- Think Raynaud phenomenon
- Protect from trauma and secondary infection
- Do not rub or massage injured tissues
- Do not apply heat or ice

#### Treatment

##### Physical treatment

- Elevate affected part
- Warm gradually to room temperature

##### Drug treatment

- Apply glyceryl trinitrate vasodilator spray or ointment or patch (use plastic gloves and wash hands for ointment)

##### Other treatment

- Drink rum at night
- Nifedipine SR 30 mg daily

### § Regional pain syndrome

The hand can be affected by the complex regional pain syndrome, previously called reflex sympathetic dystrophy (RSD, also in this case Sudeck atrophy). The patient presents with severe pain, swelling and disability of the hand. It may occur spontaneously or, more usually, it follows trauma that may even be trivial. It can occur after a Colles fracture, especially with prolonged immobilisation.

#### Clinical features

- Throbbing, burning pain, worse at night
- Paraesthesia
- Initial: red, swollen hand; warm, dry skin
- Later: cold, cyanosed and mottled, moist skin; shiny and stiff fingers
- Wasting of small muscles
- X-rays—patchy decalcification of bone (diagnostic)

The problem eventually settles but may take years. Patients need considerable support, encouragement, basic pain relief, mobility in preference to rest and perhaps referral to a pain clinic.

### § Kienböck disorder

Kienböck disease is avascular necrosis of the carpal lunate bone (see FIG. 64.17), which may fragment and collapse, eventually leading to osteoarthritis of the wrist.

It presents usually in young adults over the age of 15 as insidious, progressive wrist pain and stiffness that limits grip strength and hand function. Males are affected more often than females and the right hand more than the left, indicating the relationship to trauma.

## ARTHRITIC CONDITIONS OF THE WRIST AND HAND

Arthritis of the hand is an inappropriate diagnosis and specificity is required to highlight the various joints that are the targets of the specific arthritides, which include osteoarthritis, rheumatoid arthritis, spondyloarthropathies, gout, haemochromatosis, and connective tissue disorders. Typical target areas in the hand are shown in FIGURE 64.17.

### § Osteoarthritis

Osteoarthritis commonly involves the interphalangeal joints of the fingers (especially the DIP joints)<sup>18</sup> and the carpometacarpal (CMC) joint of the thumb.

**FIGURE 64.17** Typical sites of arthritic conditions and osteochondritis in the hand

Degenerative changes produce bony swellings around the margins of the joints—Heberden nodes of the DIP joints and less commonly Bouchard nodes of the PIP joints. A patchy distribution occurs in metacarpophalangeal, intercarpal and wrist joints, usually related to trauma.

### Osteoarthritis of the thumb

This is very common, especially in women. Pain is felt at the base of the thumb, and tenderness on palpation of the CMC joint is typical. Functional limitation is progressive, with weakness of the pinch grip and limited thumb excursion. Surgical correction may be required.

## Rheumatoid arthritis

In rheumatoid arthritis the DIP joints are often spared (only about 30% involved) but the metacarpophalangeal and proximal interphalangeal joints and wrist joints are generally affected symmetrically and bilaterally. Rheumatoid arthritis tends to affect the metacarpophalangeal joints of the fourth finger less commonly.

## Gout

Gout may involve normal joints of the hand but is encountered more frequently in osteoarthritic joints of the hand (especially DIP joints) in elderly people taking diuretics. This clinical feature is known as nodular gout.

## Seronegative arthropathies

A similar appearance to rheumatoid arthritis occurs except that with psoriatic arthritis the terminal joints are often involved with swelling, giving the appearance of 'sausage digits'. (Refer [CHAPTERS 35](#) and [38](#).)

## INFECTIONS OF THE HAND

Although not encountered as frequently as in the past, serious suppurative infections of the deep fascial spaces of the hand and tendon sheath can still occur, especially with penetrating injuries and web space infection.

Infections of the hand include:

- infected wounds with superficial cellulitis or lymphangitis (*Streptococcus pyogenes*)
- subcutaneous tissues—nail bed (paronychia), pulp (whitlow e.g. herpes simplex)
- erysiploid—this is a specific infection in one finger of fishermen or meat handlers, caused by *Erysipelothrix insidiosa*. There is a purplish erythema that gradually extends over days. It is rapidly cured by penicillin
- tendon sheath infection (suppurative tenosynovitis)—this is a dangerous and painful infection that can cause synovial adhesions with severe residual finger stiffness. The affected finger is hot and swollen and looks like a sausage
- 'aquarium' or 'swimming pool' granuloma—non-painful infection of the tendon sheath due to *Mycobacterium marinum* following a minor cut of the finger; refer to infectious disease physician
- deep palmar fascial space infection—infection from an infected tendon sheath or web space

may spread to one of the two deep palmar spaces: the medial (midpalmar space) or lateral (thenar) space

- sporotrichosis (gardener's arm)—a chronic fungal infection from contaminated spikes of wood or rose thorns presenting as hard non-tender nodules in the skin of the hand and extending along the lymphatics of the arm. The diagnosis is confirmed by biopsy. Treat with itraconazole

### Management of serious infection

- Early appropriate antibiotic treatment for infection and early surgical referral where necessary.
- Antibiotics (adult doses)<sup>19</sup>  
*Streptococcus pyogenes* (mild to moderate cellulitis, lymphangitis)  
 procaine penicillin 1.5 g IM daily, 3 to 7 days  
 or  
 phenoxymethylpenicillin 500 mg (o) 6 hourly for 10 days  
 If severe to cover both *S. pyogenes* and *Staphylococcus aureus* infection (suspected or proved)  
 flucloxacillin/dicloxacillin 2 g IV 6 hourly until improved, then oral for 10 days.

### § 'Cracked' hands and fingers

- Wear protective work gloves: cotton-lined PVC gloves.
- Use soap substitutes (e.g. Cetaphil lotion, Dove). apply 2–5% salicylic acid and 10% liq picis carb in white soft paraffin ointment.  
 or  
 corticosteroid ointment: class II–III

### When to refer

- Disabling osteoarthritis of carpometacarpal joint for possible surgical repair
- Myelopathy (motor weakness) and persistent radiculopathy (nerve root pain and sensory changes) in the arm
- Unresolving nerve entrapment problems such as median and ulnar nerves
- Elbow injuries in children with proven or possible supracondylar fracture or avulsion epicondylar fractures
- Evidence or suspicion of suppurative infection of the tendon sheaths or deep palmar fascial spaces
- Septic arthritis and osteomyelitis

- Regional pain syndrome
- Other conditions not responding to conservative measures

### Practice tips

- With elbow injuries in children, X-ray both elbows and compare one side with the other; this helps to determine whether there is displacement of fragments or a disturbance in the normal anatomy of the elbow.
- Tendonopathy and other enthesal problems of the arm are common and tend to take 1–2 years to resolve spontaneously, yet they resolve rapidly with rest, an exercise program or corticosteroid injections. Surgical relief is effective for refractory cases.
- The so-called thoracic outlet syndrome is probably most often caused by 'the droopy shoulder syndrome' rather than by a cervical rib.
- Consider corticosteroid injections for CTS and stenosing tenosynovitis (de Quervain and trigger finger or thumb). They are very effective and often curative.
- The site of arthritis in the hand provides a reasonable guide as to the cause.
- Always keep regional pain syndrome in mind for persistent burning pain in the hand following injury—trivial or severe.

*Which of your hips has the most profound sciatica?*

William Shakespeare (1564–1616), *Measure for Measure*

Pain in the hip, buttock, groin and upper thigh tends to be interrelated. Patients often present complaining of pain in the 'hip' but point to the buttock or lower back as the site of their pain. Most pain in the buttock has a lumbosacral origin. Pain originating from disorders of the lumbosacral spine (commonly) and the knee (uncommonly) can be referred to the hip region, while pain from the hip joint (L3 innervation) may be referred commonly to the thigh and the knee. Disorders of the abdomen, retroperitoneal region and pelvis may cause hip and groin pain, sometimes mediated by irritation of the psoas muscle.

## Key facts and checkpoints

- Hip troubles have a significant age relationship (see FIG. 65.1).
- Children can suffer from a variety of serious disorders of the hip—such as developmental dysplasia of the hip (DDH), Perthes disease, Perthes disease, transient synovitis, SCFE, tuberculosis, septic arthritis, slipped capital femoral epiphysis (SCFE) and inflammatory arthritis—all of which demand early recognition and management.

- SCFE typically presents in the obese adolescent (10–15 years) with knee pain and a slight limp.
- Every newborn infant should be tested for DDH, which can usually be treated successfully when diagnosed early.
- Limp has an inseparable relationship with painful hip and buttock conditions, especially those of the hip.
- The spine is the most likely cause of pain in the buttock in adults.
- Disorders of the hip joint commonly refer pain to the knee and thigh.
- If a woman, especially one with many children, presents with bilateral buttock or hip pain, consider dysfunction of the sacroiliac joints (SIJs) as the cause.
- If a middle-aged or elderly woman presents with hip pain, always consider the underdiagnosed conditions of trochanteric bursitis or gluteus medius tendonitis (greater trochanteric pain syndrome).

FIGURE 65.1 Typical ages of presentation of hip disorders

**Table 65.1** Hip and buttock pain: diagnostic strategy model

- Q. Probability diagnosis
- A. Traumatic muscular strains  
Referred pain from spine  
Osteoarthritis of hip  
Greater trochanteric pain syndrome
- 
- Q. Serious disorders not to be missed
- A. Cardiovascular:
- buttock claudication
- Neoplasia:
- metastatic cancer
  - osteoid osteoma
- Septic infections:
- septic arthritis
  - osteomyelitis
  - tuberculosis
  - pelvic and abdominal infections: pelvic abscess, pelvic inflammatory disease, prostatitis
  - synovial chondromatosis
- Childhood disorders:
- DDH
  - Perthes disease
  - slipped femoral epiphysis
  - transient synovitis (irritable hip)
  - juvenile chronic arthritis
- 
- Q. Pitfalls (often missed)
- A. Polymyalgia rheumatica
- Fractures:
- stress fractures femoral neck
  - subcapital fractures
  - sacrum
  - pubic rami
- Avascular necrosis femoral head
- Femoro-acetabular impingement
- Torn acetabular labrum
- Sacroiliac joint disorders
- Inguinal or femoral hernia
- Bursitis or tendonitis:
- greater trochanteric pain syndrome
  - ischial bursitis
  - iliopsoas bursitis
- Osteitis pubis
- Neurogenic claudication
- Chilblains
- Rarities:*
- haemarthrosis (e.g. haemophilia)
  - Paget disease
  - nerve entrapments: sciatica 'hip pocket nerve', obturator, lateral cutaneous nerve thigh

Q. Seven masquerades checklist

- A. Depression  
Spinal dysfunction

Q. Is the patient trying to tell me something?

- A. Non-organic pain may be present. Patient with arthritis may be fearful of being crippled.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in **TABLE 65.1**.

### Probability diagnosis

The commonest cause of hip and buttock pain presenting in general practice is referred pain from the lumbosacral spine and the sacroiliac joints.<sup>1</sup> The pain is invariably referred to the outer buttock and posterior hip area (see **FIG. 65.2**). The origin of the pain can be the facet joints of the lumbar spine, intervertebral disc disruption or, less commonly, the SIJs. Much of this pain is inappropriately referred to as 'lumbago', 'fibrositis' and 'rheumatism'.

Trauma and overuse injuries from sporting activities are also common causes of muscular and ligamentous strains<sup>2</sup> around the buttock, hip and groin.

The hip joint is a common target of osteoarthritis. This usually presents after 50 years of age but can present earlier if the hip has been affected by another condition.

**FIGURE 65.2** Referral patterns of pain from the lumbosacral spine and the sacroiliac joints

## Serious disorders not to be missed

The major triad of serious disorders—cardiovascular, neoplasia and severe infections—are applicable to this area albeit limited in extent.

### Aortoiliac occlusion

Ischaemic muscle pain, including buttock claudication secondary to aortoiliac arterial occlusion, is sometimes confused with musculoskeletal pain. An audible bruit over the vessels following exercise is one clue to diagnosis.

### Neoplasia

Primary tumours including myeloma, lymphoma and sarcoma, can arise rarely in the upper femur and pelvis (especially the ileum). However, these areas are relatively common targets for metastases, especially from the prostate, breast and lung.

### Infection

Some very important, at times ‘occult’, infections can develop in and around the hip joint.

Osteomyelitis is prone to develop in the metaphysis of the upper end of the femur and must be considered in the child with intense pain, a severe limp and fever. Tuberculosis may also present in children (usually under 10 years) with a presentation similar to Perthes disease.

Transient synovitis or ‘irritable hip’ is the most common cause of hip pain and limp in childhood.

Inflammation of the side wall of the pelvis as in a deep pelvic abscess (e.g. from appendicitis), pelvic inflammatory disease (PID) including pyosalpinx, or an ischiorectal abscess, can cause deep hip and groin pain and a limp. This pain may be related to irritation of the obturator nerve.

Retroperitoneal haematoma can cause referred pain and femoral nerve palsy.

Childhood disorders that must not be missed include:

- DDH and acetabular dysplasia
- Perthes disease
- SCFE
- stress fractures of the femoral neck

Inflammatory disorders of the hip joint that should be kept in mind include:

- rheumatoid arthritis
- juvenile chronic arthritis (JCA)
- rheumatic fever (a flitting polyarthritis)
- spondyloarthropathy

## ‘Red flag’ pointers to potentially serious hip conditions

- Swelling, redness, very limited joint motion
- Pain, fever, systemic features (in absence of trauma)
- Neurological changes (e.g. loss of power)
- Rapid joint swelling after trauma
- Constant localised pain unaffected by movement

## Pitfalls

There are many pitfalls associated with hip and buttock pain and these include the various childhood problems. Fractures can be a pitfall, especially subcapital fractures.

SIJ disorders are often missed, whether it be the inflammation of sacroiliitis or mechanical dysfunction of the joint.

Inflammatory conditions around the hip girdle are common and so are often misdiagnosed. These include the common gluteus medius tendonitis and trochanteric bursitis (greater trochanteric pain syndrome).

Polymyalgia rheumatica commonly causes shoulder girdle pain in the elderly but pain around the hip girdle can accompany this important problem.

Chilblains around the upper thighs occur in cold climates and are often known as ‘jodhpur’ chilblains because they tend to occur during horse riding in very cold weather.

Nerve entrapment syndromes require consideration. Meralgia paraesthetica is a nerve entrapment causing pain and paraesthesia over the lateral aspect of the hip (see FIG. 66.3, CHAPTER 66).

An interesting modern phenomenon is the so-called ‘hip pocket nerve’ syndrome. If a man presents with ‘sciatica’, especially confined to the buttock and upper posterior thigh (without local back pain), consider the possibility of pressure on the sciatic nerve from a wallet in the hip pocket. This problem is occasionally encountered in people sitting for long periods in cars (e.g. taxi drivers). It appears to be related to the increased presence of plastic credit cards in wallets (see FIG. 65.3).

Paget disease can involve the upper end of the femur and the pelvis. Increased pain may indicate a fracture or malignant change causing osteosarcoma.

## General pitfalls

- Failure to test the hips of neonates carefully and follow up developmental dysplasia of the hip.
- Misdiagnosis of arthritis and other disorders of the hip joint because of referred pain.

- Overlooking an SCFE or a stress fracture of the femoral neck in teenage boys, especially athletes. If an X-ray shows that the epiphysis is fusing or has fused, arrange a technetium bone scan.

**FIGURE 65.3** 'Hip pocket nerve' syndrome: location and relations of sciatic nerve in the buttock

## Seven masquerades checklist

The one outstanding masquerade is spinal dysfunction, which is the most likely cause of pain in the buttock. Many dermatomes meet at the buttock and theoretically pain in the buttock can result from any lesion situated in a tissue derived from L1, L2, L3, S2, S3 and S4.<sup>1</sup> Symptoms from L3 can spread from the outer buttock to the front of the thigh and down the leg, over the medial aspect of the knee to the calf. Such a distribution is common to an L3 nerve root lesion and arthritis of the hip.

Furthermore, dysfunction of the facet joints and sacroiliac joints can refer pain to the buttock. The relatively common L1 lesion due to dysfunction at the T12–L1 spinal level can lead to referred pain over the outer upper quadrant of the buttock and also to the groin (see FIG. 65.2).

## Psychogenic considerations

Cyriax<sup>1</sup> claims that the hip shares with the back and the shoulder 'an enhanced liability to fixation' for psychological reasons. This problem is often related to work compensation factors and overpowering stresses at home. A common finding in psychoneurotic patients complaining of buttock and thigh pain is 90° limitation of flexion at the hip joint. The importance of testing passive movements of the hip joint is obvious,

for often such limitation of flexion is combined with a full range of rotation. In arthritis of the hip joint internal rotation is invariably affected first.

Such patients often walk into the office with a marked limp and leaning on a thick stick. It requires great skill to evaluate and manage them tactfully and successfully.

On the other hand, patients with genuine osteoarthritis fear being crippled and ending in a wheelchair. They require considerable education and reassurance.

## The clinical approach

### History

Pain associated with hip joint pathology is usually described as a deep aching pain, aggravated by movement<sup>2</sup> and felt in the groin and anteromedial aspect of the upper thigh, sometimes exclusively around the knee (see FIG. 66.1 in CHAPTER 66). A limp is a frequent association.

An obstetric history in a woman may be relevant for sacroiliac pain.

### Key questions

- Can you tell me how the pain started?
- Could you describe the pain?
- Point to where the pain is exactly.
- Does the pain come on after walking for a while and stop as soon as you rest?
- Is there any stiffness, especially first thing in the morning?
- Do you have any difficulty climbing stairs?
- Do you get any backache?
- Do your movements feel free?
- Do you have a limp?
- Do you have a similar ache around the shoulders?
- Have you had an injury such as a fall?
- Have you lost any weight recently?
- Do you have night pain?
- Do you have trouble with shoes and socks?
- How far can you walk?
- Is it painful to lie on the affected side at night?
- Did you have a hip problem as a child?
- Does the pain respond to any treatments?

### Examination

Follow the traditional methods of examination of any joint: lo ok, feel, move, measure, test function, lo ok else where and X-ray. The patient should strip down to the underpants to allow maximum exposure.

## Inspection

Ask the patient to point exactly to the area of greatest discomfort. Careful observation of the patient, especially walking, provides useful diagnostic information. Note any antalgic (painful) gait—if walking with a limp, the leg adducted and foot somewhat externally rotated, osteoarthritis of the hip joint is the likely diagnosis.

If called to a patient who has suffered an injury such as a fall or vehicle accident, note the position of the leg. If shortened and externally rotated (see FIG. 65.4a), a fractured neck of femur is the provisional diagnosis; if internally rotated, suspect a posterior dislocation of the hip (see FIG. 65.4b). With anterior dislocation of the hip, the hip is externally rotated.

Get the patient to lie supine on the couch with the anterior superior iliac spines (ASISs) of the pelvis placed squarely and note the shape and position of the limbs. Look for muscle wasting.

**FIGURE 65.4** (a) General configuration of the legs for a fractured neck of femur, (b) general configuration for a posterior dislocated hip

## Palpation

Feel one to two finger breadths below the midpoint of the inguinal ligament for joint tenderness. Check for trochanteric bursitis, gluteus medius tendonitis and other soft tissue problems over the most lateral bony aspect of the upper thigh.

## Movements

- Passive movements with *patient supine* (normal range is indicated):
  - flexion with patient's knees flexed (compare both sides): 0–125°

- external rotation (knee and hip extended in adults): 0–45°
- internal rotation (knee and hip extended in adults): 0–45°
- abduction (stand on same side—steady pelvis): 0–45°
- adduction (should see the patella of the opposite leg): 0–30°

In children it is most important to measure rotation and abduction/adduction with the knee and hip flexed to detect early Perthes disease or SCFE.

### • Patient prone:

- extension (one hand held over SIJ): 0–20°

*Note:* Osteoarthritis of the hip typically affects internal rotation (IR), extension and abduction first.

## Measurements

- True leg length (ASIS to medial malleolus)
- Apparent leg length (umbilicus to medial malleolus)

*Note:*

- Unequal true leg length = hip disease on shorter side
- Unequal apparent leg length = tilting of pelvis

Feel the height of the greater trochanter relative to the ASIS to determine if shortening is in the hip or below.

## Test function including gait and special tests

Gait:

- Antalgic gait—shortened stance phase of affected leg, as patient doesn't want to stand on it, indicates pain with weight-bearing
- Coxalgic gait—upper torso shifts towards painful side due to pain in the hip
- Trendelenburg gait (the gluteus medius lurch)—similar to coxalgic but pelvis tilts
- Trendelenburg test—tests hip abductors (gluteus medius): the non-weight-bearing hemipelvis drops if abnormal
- Thomas test—tests for fixed flexion deformity
- Squeeze test for osteitis pubis (see CHAPTER 136)
- Femoroacetabular impingement<sup>3</sup> (FAI)—get the patient to hold the hip in 90° of flexion and maximal internal rotation. Then bring the leg into adduction (FADIR test). Reproduction of pain is a positive test and indicates intra-articular hip pathology such as labral tears and a CAM or Ganz (bone outgrowth) lesion. The FABERE test

(see later in chapter) also tests for this pathology. FAI causes anterior groin and trochanteric regional pain.

### Look elsewhere

Examine the lumbosacral spine, SIJs, groin and knee. Consider hernias and possibility of PID. Feel pulses and test for femoral bruits.

### Investigations

These can be selected from:

- serological tests: RA factor, FBE, ESR, C-reactive protein
- radiological:
  - plain AP X-ray of pelvis showing both hip joints
  - lateral X-ray ('frog' lateral best in children)
  - X-ray of lumbosacral spine and SIJs
  - CT scan: hip joint, pelvis, lumbosacral spine
  - MRI scan: stress fracture, early avascular necrosis, early osteomyelitis, labral tears of hip joint, metastases, soft tissue tumours
  - isotope bone scan; useful for whole body bony metastases
- needle aspiration of joint: if septic arthritis suspected

### Role of ultrasound

Ultrasound diagnosis is now sensitive in children in detecting fluid in the hip joint, and can diagnose septic arthritis and also localise the site of an osteomyelitic abscess around a swollen joint. It can accurately assess the neonatal hip joint and confirm the position of the femoral head in children <6 months. Ultrasound is used less since increased availability of MRI.

## Hip pain in children

Hip disorders have an important place in childhood and may present with a limp when the child is walking. These important disorders include:

- DDH
- congenital subluxation of hip and acetabular dysplasia
- transient synovitis
- Perthes disease
- septic arthritis/osteomyelitis
- SCFE
- pathological fractures through bone cyst

The important features of hip pain in children are summarised in **TABLE 65.2**.

### § Developmental dysplasia of the hip

In DDH, previously known as congenital dislocation of the hip, the underdeveloped femoral head dislocates posteriorly and superiorly. DDH is described as transiently unstable or as a mild subluxation (1 in 80 hips at birth, which stabilises in a few days) and frankly dislocated (1 in 800 hips).<sup>4</sup> Risk factors include family history, breech delivery, oligohydramnios and caesarean section.

### Clinical features

- Females:males = 6:1
- Asymmetry in 40%
- Bilateral in one-third
- Tight adductors and short leg evident
- Diagnosed early by Ortolani and Barlow tests (abnormal thud or clunk on abduction); test usually negative after 2 months

**Table 65.2** Comparison of important causes of hip pain in children

	DDH	Transient synovitis	Perthes	SCFE	Septic arthritis
<b>Age (years)</b>	0–4	4–8	4–8	10–15	Any
<b>Limp</b>	+	+	+	+	Won't walk
<b>Pain</b>	–	+	+	+	++ +
<b>Limited movement</b>	Abduction	All, especially abduction and IR	Abduction and IR	All, especially IR	All
<b>Plain X-ray</b>	No diagnostic value in neonatal period (use ultrasound). US up to 6 months then plain X-ray	Normal	Subchondral fracture Dense head Pebble stone epiphysis	AP may be normal Frog lateral view shows slip	Normal Use ultrasound

- Ultrasound excellent (especially up to 3–4 months) and more sensitive than clinical examination
- X-ray difficult to interpret up to 3 months, then helpful

*Note:*

- 1 When diagnosed and treated from birth it is possible to produce a normal joint after a few months in an abduction splint.
- 2 Every baby should be examined for DDH during the first day of life and before discharge from hospital and at the 6-week check.<sup>4</sup> The Ortolani and Barlow tests remain important means of detecting an unstable or dislocated hip, but ultrasound is becoming more important and is recommended for high-risk babies (e.g. breech, family history of DDH).

### Screening examination

Carry out the examination on a large firm bench with the baby stripped. Relaxation is essential; give the baby a bottle if necessary. Be gentle and have warm hands.

With the legs extended any asymmetry of the legs or skin creases is noted.

### Ortolani test (IN test: gentle clunk into acetabulum)

- Hold the leg in the hand with knee flexed—thumb over groin (lesser trochanter) and middle finger over greater trochanter—see **FIGURE 65.5**. Steady the pelvis with the other hand.
- Flex hips to about 90°, gently abduct to 45° (note any clunk or jerk as hip reduces).

### Barlow test (OUT test: gentle clunk out of acetabulum)

- As one hand stabilises the pelvis, grasp the knee of the relevant leg, then flex the hip to 90°, abduct 10–20°.
- With gentle but firm backward pressure, rock the femur backwards and forwards on the pelvis by pressing forward with the middle finger and backwards with the thumb. Note any jerk or clunk as hip ‘goes out’ of the acetabulum. If the femoral head displaces, there is dislocation.

Plain X-ray has little or no place in the diagnosis of DDH in the neonatal period.<sup>5</sup> Ultrasound imaging is recommended. Early referral for treatment is essential. If not detected early the femoral head stays

**FIGURE 65.5** Examination of the infant for DDH: demonstrating Ortolani sign on left side

out of the acetabulum and after the age of 1 year the child may present with delay in walking or a limp. The diagnosis is then detected by X-ray.

### Treatment (guidelines)

- DDH must be referred to a specialist<sup>4</sup>
- 0–6 months—Pavlik harness or abduction splint
- 3–18 months—reduction (closed or open) and cast (pelvic spica)
- >18 months—open reduction and possible osteotomy

*Note:* Despite early treatment some cases progress to acetabular dysplasia (underdevelopment of the ‘roof’ of the hip joint) and to premature osteoarthritis. Thus a follow-up X-ray of the pelvis during teenage years should be considered for anyone with a history of DDH.

### § Perthes disease

Perthes disease results in the femoral head becoming partly or totally avascular (i.e. avascular necrosis).

### Clinical features

- Males:females = 4:1
- Usual age 4–8 years (rarely 2–18 years)
- Sometimes bilateral
- Presents as a limp and aching (hip or groin pain)
- May be knee pain
- ‘Irritable’ hip early
- Limited movement in abduction and IR

*X-ray.* Joint space appears increased and femoral head too lateral: typical changes of sclerosis, deformity and collapse of the femoral capital epiphysis may be delayed.

## Management

- Refer urgently (provide crutches)
- Aim is to keep femoral head from becoming flat
- Choice of treatment depends on severity of the condition and age of the patient

If untreated, the femoral head usually becomes flat over some months, leading to eventual osteoarthritis. Some untreated cases of Perthes disease heal and have a normal X-ray.

## § Transient synovitis

This common condition is also known as 'irritable hip' or observation hip<sup>6</sup> and is the consequence of a self-limiting synovial inflammation.

## Clinical features

- Child aged 3–8 years (usually 6 years)
- Sudden onset of hip pain and a limp
- Child can usually walk but with pain (some may not)
- May be history of trauma or recent URTI or viral illness
- Painful limitation of movements, especially abduction and rotation
- Blood tests and X-rays normal (may be soft tissue swelling); ESR may be mildly elevated
- Ultrasound shows fluid in the joint

*Differential diagnosis.* This includes septic arthritis, JCA, Perthes disease.

*Outcome.* It settles to normal within 7 days, without sequelae.

*Treatment.* Refer early. Treatment is bed rest or the use of crutches and analgesics. Follow-up X-ray is needed in 4 to 6 months to exclude Perthes disease. Aspiration under general anaesthetic may be needed to exclude septic arthritis.

## § Slipped capital femoral epiphysis

One problem of the displaced capital epiphysis of the femoral head (SCFE) is when some patients develop avascular necrosis despite expert treatment. Diagnosis of the condition before major slipping is important. This necessitates early consultation with the teenager experiencing hip or knee discomfort and then accurate interpretation of X-rays.

## Clinical features

- Adolescent 10–15 years, often obese
- Most common in the oversized and undersexed (e.g. the heavy prepubertal boy)
- Bilateral in 20%

- Limp and irritability of hip on movement
- Anterior hip (groin) pain
- Knee pain
- Hip rotating into external rotation on flexion and often lies in external rotation (ER)
- Most movements restricted, especially IR

Any adolescent with a limp or knee pain should have X-rays (AP and frog view) of both hips (see FIG. 65.6). Otherwise, this important condition will be overlooked. SCFE is graded I to IV.

FIGURE 65.6 Appearance of a slipped capital femoral epiphysis; note that, in the normal state, a line drawn along the superior surface of the femoral neck passes through the femoral head, but passes above it with SCFE

## Management

- Cease weight-bearing and refer urgently to an orthopaedic surgeon. Also refer if the clinical signs indicate SCFE but the X-rays look normal.
- If acute slip, gentle reduction via traction is better than manipulation in preventing later avascular necrosis.
- Once reduced, pinning is performed.

## § Septic arthritis

Septic arthritis of the hip should be suspected in all children with acutely painful or irritable hip problems. These patients may not be obviously sick on presentation, particularly in infants <2 years. A negative needle aspiration does not exclude septic arthritis. If sepsis is suspected it is better to proceed to an arthrotomy if clinically indicated.

The irritable hip syndrome should be diagnosed only after negative investigations, including plain films and ultrasound, full blood examination, ESR and bone scan. Needle aspiration has to be considered but irritable hip is often diagnosed without it, by observing in hospital in traction. If a deterioration or elevated temperature develops, needle aspiration with or without arthrotomy is indicated.

## § Avulsion bony injuries

Forceful contraction of muscles originating around the pelvis can lead to avulsion at their origin in those with skeletal immaturity. This causes acute pain and muscular dysfunction:

- anterior superior iliac spine (sartorius)
- anterior inferior iliac spine (long head rectus femoris)
- ischial tuberosity (hamstrings)
- lesser trochanter (psoas)

Management includes X-ray and referral. As a rule, surgical reattachment is not required.

## The little athlete

The most common problem in the little athlete is pain or discomfort in the region of the iliac crest or anterior or superior iliac spines, usually associated with traction apophysitis or with acute avulsion fractures.<sup>7</sup> There is localised tenderness with pain on stretching and athletes should rest until they can compete without discomfort.

If there are persistent signs, pain in the knee, hip irritability or restricted range of motion, X-rays should be ordered to exclude serious problems such as SCFE or Perthes disease.

## Hip and buttock pain in the elderly

The following conditions are highly significant in the elderly:

- osteoarthritis of the hip
- aortoiliac arterial occlusion → vascular claudication
- spinal dysfunction with nerve root or referred pain
- degenerative spondylosis of lumbosacral spine → neurogenic claudication
- polymyalgia rheumatica
- trochanteric bursitis
- fractured neck of femur
- secondary tumours

## § Subcapital fractures

The impacted subcapital fractured femoral neck can often permit weight-bearing by an elderly patient. No obvious deformity of the leg is present. Radiographs are therefore essential for the investigation of all painful hips in the elderly. Patients often give a story of two falls—the first<sup>8</sup> very painful, the second with the hip just ‘giving way’ as the femoral head fell off.

The displaced subcapital fracture has at least a 40% incidence of avascular necrosis and usually requires prosthetic replacement in patients over 70 years. MRI scan is the investigation of choice if the X-rays are normal. Intertrochanteric fractures are also common (see CHAPTER 135).

## § Avascular necrosis

The age of onset is usually 20–50 (average 38 years). Consider this with hip pain and deep groin pain especially with IR in those at risk: corticosteroid use, SLE, sickle cell disease, past hip fracture or dislocation, pregnancy, alcoholic liver disease. Investigate with imaging (as above) and refer.

## § Osteoarthritis of the hip

Osteoarthritis of the hip is the most common form of hip disorder. It can be caused by primary osteoarthritis, which is related to an intrinsic disorder of articular cartilage, or to secondary osteoarthritis. Predisposing factors to the latter include previous trauma, DDH, septic arthritis, acetabular dysplasia, SCFE and past inflammatory arthritis.

### Clinical features

- Equal sex incidence
- Usually after 50 years, increases with age
- May be bilateral: starts in one, other follows
- Insidious onset
- At first, pain worse with activity, relieved by rest, and then nocturnal pain and pain after resting
- Stiffness, especially after rising
- Characteristic deformity
- Stiffness, deformity and limp may dominate (pain mild)
- Pain usually in groin—may be referred to medial aspect of thigh, buttock or knee

### Examination

- Antalgic gait
- Usually gluteal and quadriceps wasting
- First hip movements lost are IR and extension
- Fixed flexion deformity
- Hip held in flexion and ER (at first)
- Eventually all movements affected
- Order of movement loss is IR, extension, abduction, adduction, flexion, ER

### Treatment

- Careful explanation: patients fear osteoarthritis of hip

- Weight loss if overweight
- Relative rest
- Use crutches for acute pain
- Analgesics and NSAIDs (judicious use)
- Aids and supports (e.g. walking stick)
- Physiotherapy
- Physical therapy, including isometric exercises
- Hydrotherapy—very useful

### Surgery

This is an excellent option for those with severe pain or disability unresponsive to conservative measures. Total hip replacement is the treatment of choice in older patients but a femoral osteotomy<sup>9</sup> may be considered in younger patients in selected cases. In selected patients in their 30s and 40s with severe disease, total hip replacement is being performed successfully. A type of total hip replacement called hip resurfacing is becoming more popular in certain situations in patients under 60 years of age; >90% achieve a good result. Most replacements last 15–20 years.

### § Groin pain

All conditions involving the hip joint, especially osteoarthritis, can present with groin pain (see CHAPTER 136). Consider an unrecognised fracture neck of femur, psoas abscess, Paget disease, osteitis pubis and hernias. Also consider hip labral or chondral lesions. Hip labral injuries present with inguinal pain or upper anterior thigh pain, and require investigation and referral.

### § Osteitis pubis

See CHAPTER 136.

### § Hip labral tears<sup>10</sup>

Acetabular labral tears are becoming better recognised in motor accident victims, dancers and athletes, especially with the use of MRI and hip arthroscopy. Patients may complain of sharp impingement pain in the hip and/or groin and of painful clicking, catching or locking. The impingement test should be performed (see earlier in chapter). X-rays will exclude bony hip pathology while MRI is the radiological investigation of choice. According to Paoloni, examination after hip joint anaesthetic injection is the gold standard for diagnosing hip pathology.<sup>11</sup> Refer for possible surgical treatment through hip arthroscopy.

### § Sacroiliac pain

Pain arising from SIJ disorders is normally experienced as a dull ache in the buttock but can be referred to the groin or posterior aspect of the thigh. It may mimic pain from the lumbosacral spine or the hip joint. The pain may be unilateral or bilateral. It is worse in loading situations e.g. walking, running, getting in and out of cars.

There are no accompanying neurological symptoms such as paraesthesia or numbness but it is common for more severe cases to cause a heavy aching feeling in the upper thigh.

### Causes of SIJ disorders

- Inflammatory (the spondyloarthropathies)
- Infections (e.g. TB, *Staphylococcus aureus*—rare)
- Osteitis condensans ilii
- Degenerative changes
- Mechanical disorders
- Post-traumatic, after sacroiliac disruption or fracture
- Childbirth—in postnatal period

### Examination

The SIJs are difficult to palpate and examine but there are several tests that provoke them.

*Direct pressure.* With the patient lying prone a rhythmic springing force is applied directly to the upper and lower sacrum respectively.

*Winged compression test.* With the patient lying supine and with arms crossed, 'separate' the iliac crests with a downwards and outwards pressure. This compresses the SIJs.

*Lateral compression test.* With hands placed on the iliac crests, thumbs on the ASISs and heels of hand on the rim of the pelvis, compress the pelvis. This distracts the SIJs.

*Patrick or FABERE test.* This method can provoke the hip as well as the SIJ. The patient lies supine on the table and the foot of the involved side and extremity is placed on the opposite knee (the hip joint is now flexed, externally rotated and abducted). The knee and opposite ASIS are pressed downwards simultaneously (see FIG. 65.7). If low back or buttock pain is reproduced the cause is likely to be a disorder of the SIJ.

*Unequal sacral 'rise' test.* Squat behind the standing patient and place hands on top of the iliac crests and thumbs on the posterior superior iliac spines (PSIS). Ask the patient to bend slowly forwards and touch the floor. If one side moves higher relative to the other a

**FIGURE 65.7** The Patrick (FABERE) test for right-sided hip or sacroiliac joint lesion, illustrating directions of pressure from the examiner

problem may exist in the SIJs (e.g. a hypomobile lesion in the painful side if that side's PSIS moves higher).

### Mechanical disorders of the SIJ

These problems are more common than appreciated and can be caused by hypomobile or hypermobile problems.

Hypomobile SIJ disorders are usually encountered in young people after some traumatic event, especially women following childbirth (notably multiple or difficult childbirth), or after a heavy fall onto the buttocks, as well as in those with structural problems (e.g. shortened leg). Pain tends to follow rotational stresses of the SIJ (e.g. tennis, dancing). Excellent results are obtained by passive mobilisation or manipulation, such as the non-specific rotation technique with the patient lying supine, as described in *Practice Tips* by the author.<sup>12</sup>

Hypermobile SIJ disorders are sometimes seen in athletes with instability of the symphysis pubis, in women after childbirth and in those with a history of severe trauma to the pelvis (e.g. MVAs, horse riders with foot caught in the stirrups after a fall). The patient presents typically with severe aching pain in the lower back, buttocks or upper thigh. Such problems are difficult to treat and manual therapy usually exacerbates the symptoms. Treatment consists of relative rest, analgesics and a sacroiliac supportive belt.

### Greater trochanteric pain syndrome<sup>13</sup>

Pain around the lateral aspect of the hip is a common disorder, and is usually seen as lateral hip pain radiating down the lateral aspect of the thigh in older people engaged in walking exercises, tennis and similar activities. It is analogous in a way to the shoulder girdle, where supraspinatus tendonitis and subacromial bursitis are common wear-and-tear injuries.

The cause is tendonopathy of the gluteus medius tendon (considered to be the main pathology), where it inserts into the lateral surface of the greater trochanter of the femur and/or gluteus minimus tendon with or without inflammation of the trochanteric bursa. The degenerative tendon may tear, rupture or become detached. The pain of this condition tends to occur at night, especially after activity such as long walks and gardening. X-rays are usually normal but ultrasound may demonstrate the pathology.

### Clinical features

- Female >45–50 years
- Pain on outside hip referred to as far as foot
- Pain on lying on hip at night
- Pain climbing stairs, getting in and out of car
- Limp

### Treatment

A trial of NSAIDs (weigh the risks) is worthwhile and physiotherapy involving hip-strengthening exercises is first-line treatment. Injection therapy, ideally under ultrasound, is also worthwhile.

### Method of injection without ultrasound

- Determine the points of maximal tenderness over the trochanteric region and mark them. (For tendonitis, this point is immediately above the superior aspect of the greater trochanter—see **FIG. 65.8**).
- Inject aliquots of a mixture of 1 mL of long-acting corticosteroid with 5–7 mL of local anaesthetic into the tender area, which usually occupies an area similar to that of a standard marble.

The injection may be very effective. Follow-up management includes sleeping with a small pillow under the involved buttock, sleeping on a sheepskin

**FIGURE 65.8** Injection technique for gluteus medius tendonitis (into area of maximal tenderness)

rug and stretching the gluteal muscles with knee-chest exercises. Advise the patients to walk with the feet turned out—the ‘Charlie Chaplin gait’. One or two (maximum) repeat injections over 6 or 12 months may be required. Surgical intervention such as iliotibial band release  $\pm$  bursectomy may be necessary. Local application of ice and massage therapy may provide relief.

65

### § Fascia lata syndrome

Pain in the lateral thigh can be caused by inflammation of the fascia lata. It is often due to overuse or weak musculature around the hip. Treatment is relative rest and physiotherapy.

### § Ischial bursitis

Tailor’s bottom or ‘weaver’s bottom’, which is occasionally seen, is a bursa overlying the ischial tuberosity. Irritation of the sciatic nerve may coexist and the patient may appear to have sciatica.

#### Clinical features

- Severe pain when sitting, especially on a hard chair
- Tenderness at or just above the ischial tuberosity

#### Treatment

- Infiltration into the tender spot of a mixture of 4 mL of 1% lignocaine and 1 mL of LA corticosteroid (avoid the sciatic nerve)
- Foam rubber cushion with two holes cut out for the ischial prominences

### § Snapping or clicking hip (coxa saltans)

Some patients complain of a clunking, clicking or snapping hip, either palpable and/or audible. This represents an annoying problem that may cause pain in the groin or thigh. It is more common in females with a wide pelvis.

#### Causes

- A taut iliotibial band (tendon or tensor fascia femoris) slipping backwards and forwards over the prominence of the greater trochanter *or*
- The iliopsoas tendon snapping across the iliopectineal eminence at the anterior brim of the pelvis
- The gluteus maximus sliding across the greater trochanter
- Joint laxity

#### Treatment

The basics of treatment are:

- explanation and reassurance
- exercises to stretch the iliotibial band<sup>14</sup>

Occasionally surgery is necessary to lengthen the iliotibial band.

#### Exercises

- The patient lies on the ‘normal’ side and flexes the affected hip, with the leg straight and a weight around the ankle (see FIG. 65.9), to a degree that produces a stretching sensation along the lateral aspect of the thigh.
- This iliotibial stretch should be performed for 1–2 minutes, twice daily.

**FIGURE 65.9** One treatment for the clicking hip

## When to refer

- Clinical evidence or suspicion of severe childhood disorders: DDH, Perthes disease, septic arthritis, SCFE or osteomyelitis
- Undiagnosed pain, especially night pain
- Any fractures or suspicion of fractures such as impacted subcapital fracture or stress fracture of the femoral neck
- Patients with true claudication in buttock, whether it is vascular from aortoiliac occlusion or neurogenic from spinal canal stenosis
- Patients with disabling osteoarthritis of the hip not responding to conservative measures; excellent results are obtained from surgery to the hip
- Any mass or lump

## Practice tips

- Training on a plastic DDH model should be essential for all neonatal practitioners in order to master the manoeuvres for examining the neonatal hip.
- True hip pain is usually felt in the groin, thigh and medial aspect of the knee.
- The name of the FABERE test is an acronym for **F**lexion, **A**bduction, **E**xternal **R**otation and **E**xtension of the hip.
- Night pain adds up to inflammation, bursitis or tumour.
- The hip joint can be the target of infections such as *Staphylococcus aureus* or tuberculosis or inflammatory disorders such as rheumatoid and the spondyloarthropathies, but these are rare numerically compared with osteoarthritis.

Pain in the leg has many causes, varying from a simple cramp to an arterial occlusion. Overuse of the legs in the athlete can lead to a multiplicity of painful leg syndromes, ranging from simple sprains of soft tissue to compartment syndromes. A major cause of leg pain lies in the source of the nervous network to the lower limb, namely the lumbar and sacral nerve roots of the spine. It is important to recognise radicular pain, especially from L5 and S1 nerve roots, and also the patterns of referred pain, such as from apophyseal (facet) joints and sacroiliac joints (SIJs).

### Key facts and checkpoints

- Always consider the lumbosacral spine, the SIJs and hip joints as important causes of leg pain.
- Hip joint disorders may refer pain around the knee only (without hip pain).
- Nerve root lesions may cause pain in the lower leg and foot only (without back pain).
- Nerve entrapment is suggested by a radiating burning pain, prominent at night and worse at rest.
- Older people may present with claudication in the leg from spinal canal stenosis or arterial obstruction or both.
- Think of the hip pocket wallet as a cause of sciatica from the buttocks down.
- Acute arterial occlusion to the lower limb requires relief within 4 hours (absolute limit of 6 hours).
- The commonest site of acute occlusion is the common femoral artery.
- Varicose veins can cause aching pain in the leg.

### A diagnostic approach

A summary of the diagnostic strategy model is presented in TABLE 66.1.

**Table 66.1** Pain in the leg: diagnostic strategy model

Q. Probability diagnosis	
A. Muscle cramps	
	Nerve root 'sciatica'
	Osteoarthritis (hip, knee)
	Exercise-related pain (e.g. Achilles tendonitis), muscular injury (e.g. hamstring)
Q. Serious disorders not to be missed	
A. Vascular:	
	• peripheral vascular disease
	• arterial occlusion (embolism)
	• thrombosis popliteal aneurysm
	• deep venous thrombosis
	• iliofemoral thrombophlebitis
	Neoplasia:
	• primary (e.g. myeloma)
	• metastases (e.g. breast to femur)
	Infection:
	• osteomyelitis
	• septic arthritis
	• erysipelas
	• lymphangitis
	• gas gangrene
Q. Pitfalls (often missed)	
A. Osteoarthritis hip	
	Osgood–Schlatter disorder
	Spinal canal stenosis → neurogenic claudication
	Herpes zoster (early)
	Greater trochanteric pain syndrome
	Nerve entrapment e.g. meralgia paraesthetica
	'Hip pocket nerve': from wallet pressure
	Iatrogenic: injection into nerve
	Sacroiliac disorders
	Sympathetic dystrophy (causalgia)
	Peripheral neuropathy
	Rarities:
	• osteoid osteoma
	• polymyalgia rheumatica (isolated)
	• Paget disease
	• popliteal artery entrapment
	• tabes dorsalis
	• Ruptured Baker cyst

Q. Seven masquerades checklist

- A. Depression  
Diabetes  
Drugs (indirect)  
Anaemia (indirect)  
Spinal dysfunction

Q. Is the patient trying to tell me something?

- A. Quite possible. Common with work-related injuries.

## Probability diagnosis

Many of the causes, such as foot problems, ankle injuries and muscle tears (e.g. hamstrings and quadriceps), are obvious and common. There is a wide range of disorders related to overuse syndromes in athletes.

A very common cause of acute severe leg pain is cramp in the calf musculature, the significance of which escapes some patients as judged by middle-of-the-night calls.

One of the commonest causes is nerve root pain, invariably single, especially affecting the L5 and S1 nerve roots. Tests of their function and of the lumbosacral spine for evidence of disc disruption or other spinal dysfunction will be necessary. Should multiple nerve roots be involved, other causes, such as compression from a tumour, should be considered. Remember that a spontaneous retroperitoneal haemorrhage in a patient on anticoagulant therapy can cause nerve root pain and present as intense acute leg pain. The nerve root sensory distribution is presented in [FIGURE 66.1](#).

Other important causes of referred thigh pain include ischiogluteal bursitis (weaver's bottom) and gluteus medius tendonitis or trochanteric bursitis.

## Serious disorders not to be missed

### Neoplasia

Malignant disease, although uncommon, should be considered, especially if the patient has a history of one of the primary tumours, such as breast, lung or kidney. Such tumours can metastasise to the femur. Consider also osteogenic sarcoma and multiple myeloma, which are usually seen in the upper half of the femur. The possibility of an osteoid osteoma should be considered with pain in a bone relieved by aspirin.

### Infections

Severe infections are not so common, but septic arthritis and osteomyelitis warrant consideration.

Superficial infections such as erysipelas and lymphangitis occur occasionally.

### Vascular problems

Acute severe ischaemia can be due to thrombosis or embolism of the arteries of the lower limb. Such occlusions cause severe pain in the limb and associated signs of severe ischaemia, especially of the lower leg and foot.

Chronic ischaemia due to arterial occlusion can manifest as intermittent claudication or rest pain in the foot due to small vessel disease.<sup>1</sup>

Various pain syndromes are presented in [FIGURE 66.2](#). It is important to differentiate vascular claudication from neurogenic claudication (see [TABLE 66.2](#)).

**FIGURE 66.1** Dermatomes of the lower limb, representing approximate cutaneous distribution of the nerve roots

FIGURE 66.2 Arterial occlusion and related symptoms according to the level of obstruction

### Venous disorders

The role of uncomplicated varicose veins as a cause of leg pain is controversial. Nevertheless, varicose veins can certainly cause a dull aching 'heaviness' and cramping, and can lead to painful ulceration.

Superficial thrombophlebitis is usually obvious, but it is vital not to overlook deep venous thrombosis. These more serious conditions of the veins can cause pain in the thigh or calf.

### Pitfalls

There are many traps and pitfalls in the painful leg. Herpes zoster at the pre-eruption phase is an old trap and more so when the patient develops only a few vesicles in obscure parts of the limbs.

In future we can expect to encounter more cases of spinal canal stenosis (secondary to the degenerative changes) in the elderly. The early diagnosis can be difficult, and buttock pain on walking has to be distinguished from vascular claudication due to a high arterial obstruction.

The many disorders of the SIJ and hip region can be traps, especially the poorly diagnosed yet common

gluteus medius tendonitis. Another more recent phenomenon is the 'hip pocket nerve syndrome', where a heavy wallet crammed with credit cards can cause pressure on the sciatic nerve.

One of the biggest traps, however, is when hip disorders, particularly osteoarthritis, present as leg pain, especially on the medial aspect of the knee.

Nerve entrapments (see FIG. 66.3) are an interesting cause of leg pain, although not as common as in the upper limb. Some entrapments to consider include:

- lateral cutaneous nerve of thigh, known as meralgia paraesthetica
- common peroneal nerve
- posterior tibial nerve at ankle (the 'tarsal tunnel' syndrome)
- obturator nerve, in obturator canal
- femoral nerve (in inguinal region or pelvis)

Then there are the rare causes. One overlooked problem is complex regional pain syndrome I (sympathetic dystrophy), which may follow even minor trauma to the limb. This 'causalgia' syndrome manifests as burning or aching pain with vasomotor

**Table 66.2** Comparison of the clinical features of neurogenic and vascular claudication

	Neurogenic claudication	Vascular claudication
<b>Cause</b>	Spinal canal stenosis	Aortoiliac arterial occlusive disease
<b>Age</b>	Over 50 Long history of backache	Over 50
<b>Pain site and radiation</b>	Proximal location, Initially lumbar, buttocks and legs Radiates distally	Distal location Buttocks, thighs and calves (especially) Radiates proximally
<b>Type of pain</b>	Weakness, burning, numbing or tingling (not cramping)	Cramping, aching, squeezing
<b>Onset</b>	Walking (uphill and downhill) Distance walked varies Prolonged standing	Walking a set distance each time, especially uphill
<b>Relief</b>	Lying down Flexing spine (e.g. squat position) May take 20–30 minutes	Standing still—fast relief Slow walking decreases severity
<b>Associations</b>	Bowel and bladder symptoms	Impotence Rarely, paraesthesia or weakness
<b>Physical examination</b>		
Peripheral pulses	Present	Present (usually)
Lumbar extension	Aggravates	Reduced or absent in some, especially after exercise No change
Neurological	Saddle distribution Ankle jerk may be reduced after exercise	<i>Note:</i> abdominal bruits after exercise
<b>Diagnosis confirmation</b>	Radiological studies	Duplex ultrasound Ankle brachial index Arteriography

instability in the limbs. The essential feature is the disparity between the intensity of the pain and the severity of the inciting injury.

### General pitfalls

- Overlooking beta blockers and anaemia as a precipitating factor for vascular claudication
- Overlooking hip disorders as a cause of knee pain
- Mistaking occlusive arterial disease for sciatica
- Confusing nerve root syndromes with entrapment syndromes

### Seven masquerades checklist

The outstanding cause of leg pain in this group is spinal dysfunction. Apart from nerve root pressure due to a disc disruption or meralgia paraesthetica, pain can be referred from the apophyseal (facet) joints. Such pain can be referred as far as the mid-calf (see FIG. 66.4).

The other checklist conditions—depression, diabetes, drugs and anaemia—can be associated with pain in the leg. Depression can reinforce any painful complex.

Diabetes can cause discomfort through a peripheral neuropathy that can initially cause localised pain before anaesthesia predominates. Drugs such as beta blockers, and anaemia, can precipitate or aggravate intermittent claudication in a patient with a compromised circulation.

### Psychogenic considerations

Pain in the lower leg can be a frequent complaint (maybe a magnified one) of the patient with non-organic pain, such as the malingerer, the conversion reaction patient (hysteria) and the depressed. Sometimes regional pain syndrome (reflex or post-traumatic) is incorrectly diagnosed as functional.

**FIGURE 66.3** Distribution of pain in the leg from entrapment of specific nerves; the sites of entrapments are indicated by an X

66

## The clinical approach

Careful attention to basic detail in the history and examination can point the way of the clinical diagnosis.

### History

In the history it is important to consider several distinctive aspects, outlined by the following questions.

- Is the pain of acute or chronic onset?
- If acute, did it follow trauma or activity?
  - If not, consider a vascular cause: vein or artery; occlusion or rupture.
- Is the pain 'mechanical' (related to movement)?
  - If it is unaltered by movement of the leg or a change in posture, it must arise from a soft tissue lesion, not from bone or joints.

**FIGURE 66.4** Possible referred pain patterns from dysfunction of an apophyseal joint, illustrating pain radiation patterns from stimulation by injection of the right L4–5 apophyseal joint

Source: Reproduced with permission from C Kenna and J Murtagh. *Back Pain and Spinal Manipulation*. Sydney: Butterworths, 1989

- Is the pain postural?
  - Analyse the postural elements that make it better or worse.
  - If worse on sitting, consider a spinal cause (discogenic) or ischial bursitis.
  - If worse on standing, consider a spinal cause (instability) or a local problem related to weight-bearing (varicose veins).
  - If worse lying down, consider vascular origin, such as small vessel peripheral vascular disease. If worse lying on one side, consider greater trochanteric pain syndrome.
  - Pain unaffected by posture is activity-related.
- Is the pain related to walking?
  - *No*: Determine the offending activity (e.g. joint movement with arthritis).
  - *Yes*: If immediate onset, consider local cause at site of pain (e.g. stress fracture). If delayed onset, consider vascular claudication or neurogenic claudication.

- Is the site of pain the same as the site of trauma?
  - If not, the pain in the leg is referred. Important considerations include lesions in the spine, abdomen or hip and entrapment neuropathy.
- Is the pain arising from the bone?
  - If so, the patient will point to the specific site and indicate a 'deep' bone pain (consider tumour, fracture or, rarely, infection) compared with the more superficial muscular or fascial pain.
- Is the pain arising from the joint?
  - If so, the clinical examination will determine whether it arises from the joint or juxtaposed tissue.
- radiology:
  - leg X-rays, especially knee, hip
  - plain X-ray of lumbosacral spine
  - CT scan of lumbosacral spine
  - ultrasound or MRI of greater trochanteric area
  - MRI scan of lumbosacral spine
  - bone scan
- electromyography
- vascular:
  - arteriography
  - duplex ultrasound scan
  - ankle brachial index
  - venous pool radionuclide scan
  - contrast venography
  - air plethysmograph (varicose veins)
  - D-dimer test

## Examination

The first step is to watch the patient walk and assess the nature of any limp.

Note the posture of the back and examine the lumbar spine. Have both legs well exposed for the inspection.

Inspect the patient's stance and note any asymmetry and other abnormalities, such as swellings, bruising, discolouration, or ulcers and rashes. Note the size and symmetry of the legs and the venous pattern. Look for evidence of ischaemic changes, especially of the foot.

Palpate for local causes of pain and if no cause is evident examine the spine, blood vessels (arteries and veins) and bone. Areas to palpate specifically are the ischial tuberosity, trochanteric area, hamstrings and tendon insertions. Palpate the superficial lymph nodes. Note the temperature of the feet and legs. Perform a vascular examination, including the peripheral pulses and the state of the veins if appropriate.

If evidence of peripheral vascular disease (PVD), remember to auscultate the abdomen and adductor hiatus, and the iliac, femoral and popliteal vessels.

A neurological examination may be appropriate, particularly to test nerve root lesions or entrapment neuropathies.

Examination of the joints, especially the hip and SIJs, is very important.

## Investigations

A checklist of investigations that may be necessary to make the diagnosis is as follows:

- FBE and ESR

## Leg pain in children

Aches and pains in the legs are a common complaint in children. The most common cause is soreness and muscular strains due to trauma or unaccustomed exercise. One cause of bilateral leg pain in children is leukaemia. Consider osteomyelitis (refer [CHAPTER 69](#)).

It is important to consider child abuse, especially if bruising is noted on the back of the legs.

## 'Growing pains'

So-called 'growing pains', or idiopathic leg pain, is thought to be responsible for up to 20% of leg pain in children.<sup>2</sup> Such a diagnosis is vague and often made when a specific cause is excluded. It is usually not due to 'growth' but related to excessive exercise or trauma from sport and recreation, and probably emotional factors.

The pains are typically intermittent and symmetrical and deep in the legs, usually in the anterior thighs or calves. Although they may occur at any time of the day or night, typically they occur at night, usually when the child has settled in bed. The pains usually last for 30 to 60 minutes and tend to respond to attention such as massage with an analgesic balm or simple analgesics (refer to [CHAPTER 91](#)).

## Serious problems

It is important to exclude fractures (hence the value of X-rays if in doubt), malignancy (such as osteogenic sarcoma, Ewing tumour or infiltration from leukaemia or lymphoma), osteoid osteoma, osteomyelitis, scurvy and beriberi (rare disorders in

developed countries) and congenital disorders such as sickle-cell anaemia, Gaucher disease and Ehlers–Danlos syndrome.

## Leg pain in the elderly

The older the patient, the more likely it is that arterial disease with intermittent claudication and neurogenic claudication due to spinal canal stenosis will develop. Other important problems of the elderly include degenerative joint disease, such as osteoarthritis of the hips and knees, muscle cramps, herpes zoster, Paget disease, polymyalgia rheumatica (affecting the upper thighs) and sciatica.

## SPINAL CAUSES OF LEG PAIN

Problems originating from the spine are an important, yet at times complex, cause of pain in the leg.

Important causes are:

- nerve root (radicular) pain from direct pressure
- referred pain from:
  - disc pressure on tissues in front of the spinal cord
  - apophyseal joints
  - SIJs
- spinal canal stenosis causing claudication

Various pain patterns are presented in FIGURES 66.3 and 66.4.

### § Nerve root pain

Nerve root pain from a prolapsed disc is a common cause of leg pain. A knowledge of the dermatomes of the lower limb (see FIG. 66.1) provides a pointer to the involved nerve root, which is usually L5 or S1 or both. The L5 root is invariably caused by an L4–5 disc prolapse and the S1 root by an L5–S1 disc prolapse. The nerve root syndromes are summarised in TABLE 66.3.

A summary of the physical examination findings for the most commonly involved nerve roots is presented in TABLE 66.3.

### § Sciatica

See CHAPTER 38. Sciatica is defined as pain in the distribution of the sciatic nerve or its branches (L4, L5, S1, S2, S3) that is caused by nerve pressure or irritation. Most problems are due to entrapment neuropathy of a nerve root, in either the spinal canal (as outlined above) or the intervertebral foramen.

It should be noted that back pain may be absent and peripheral symptoms only will be present.

## Treatment

### Acute sciatica

A protracted course can be anticipated, in the order of 12 weeks (see CHAPTER 38). The patient should be reassured that spontaneous recovery can be expected. A trial of conservative treatment would be recommended thus:

- back care education
- relative bed rest if very painful only (2 days is optimal)—a firm base is ideal
- return to activities of daily living ASAP
- analgesics (avoid narcotic analgesics if possible)
- NSAIDs (2 weeks is recommended)
- basic exercise program, including swimming
- traction can help, even intermittent manual

Referral to a therapist of your choice (e.g. physiotherapist) might be advisable. Conventional spinal manipulation is usually contraindicated for radicular sciatica. If the patient is not responding or the circumstances demand more active treatment, an epidural anaesthetic injection is appropriate. Surgical intervention may be necessary.

### Chronic sciatica

If a trial of NSAIDs, rest and physiotherapy has not brought significant relief, an epidural anaesthetic (lumbar or caudal) using half-strength local anaesthetic (e.g. 0.25% bupivacaine HCl) and a depot corticosteroid (e.g. triamcinolone) is advisable. The lumbar route under image intensification is preferred.

## REFERRED PAIN

Referred pain in the leg can arise from disorders of the SIJs or from spondylogenic disorders. It is typically dull, heavy and diffuse. The patient uses the hand to describe its distribution compared with the use of fingers to point to radicular pain.

### § Spondylogenic pain

Non-radicular or spondylogenic pain is that which originates from any of the components of the vertebrae (spondyles), including joints, the intervertebral disc, ligaments and muscle attachments. An important example is distal referred pain from disorders of the apophyseal joints, where the pain can be referred to any part of the limb as far as the calf and ankle but most commonly to the gluteal region and proximal thigh (see FIG. 66.4).

Another source of referred pain is that caused by compression of a bulging disc against the posterior

**Table 66.3** Comparison of neurological findings of the neurological levels L3, L4, L5 and S1

Nerve root	Pain distribution (see FIG. 67.1)	Sensory loss	Motor function	Reflex
<b>L3</b>	Front of thigh, inner aspect of thigh, knee and leg	Anterior aspect of thigh 	Extension of knee 	Knee jerk 
<b>L4</b>	Anterior thigh to front of knee	Lower outer aspect of thigh and knee, inner great toe 	Flexion, adduction of knee, inversion of foot 	Knee jerk 
<b>L5</b>	Lateral aspect of leg, dorsum of foot and great toe	Dorsum of foot, great toe, 2nd, 3rd and 4th toes, anterolateral aspect of lower leg 	Dorsiflexion of great toe 	Tibialis posterior (clinically impractical) 
<b>S1</b>	Buttock to back of thigh and leg, central calf, lateral aspect of ankle and sole of foot	Lateral aspect of ankle, foot (4th and 5th toes) 	Plantar flexion of ankle and toes, eversion of foot 	Ankle jerk 

longitudinal ligament and dura. The pain is typically dull, deep and poorly localised. The dura has no specific dermatomal localisation, and so the pain is usually experienced in the low back, sacroiliac area and buttocks. Less commonly it can be referred to the coccyx, groin and both legs to the calves. It is not referred to the ankle or the foot.

### § Sacroiliac dysfunction

This causes typically a dull ache in the buttock but it can be referred to the iliac fossa, groin or posterior aspects of the thighs (see CHAPTER 65). It rarely radiates to or below the knee. It may be caused by inflammation (sacroiliitis) or mechanical dysfunction. The latter must be considered in a postpartum woman presenting with severe aching pain present in both buttocks and thighs.

## NERVE ENTRAPMENT SYNDROMES

Entrapment neuropathy can result from direct axonal compression or can be secondary to vascular problems, but the main common factor is a nerve passing through a narrow rigid compartment where movement or stretching of that nerve occurs under pressure.

### Clinical features

- Pain at rest (often worse at night)
- Variable effect with activity
- Sharp, burning pain
- Radiating and retrograde pain
- Clearly demarcated distribution of pain
- Paraesthesia may be present
- Tenderness over nerve
- May be positive Tinel sign

### § Meralgia paraesthetica

This is the commonest lower limb entrapment and is due to the lateral femoral cutaneous nerve of the thigh being trapped under the lateral end of the inguinal ligament, 1 cm medial to the ASIS.<sup>3</sup>

The nerve is a sensory nerve from L2 and L3. It occurs mostly in middle-aged people, due mainly to thickening of the fibrous tunnel beneath the inguinal ligament, and is associated with obesity, pregnancy, ascites or local trauma such as belts, trusses and corsets. Its entrapment causes a burning pain with associated numbness and tingling (see FIG. 66.3).

The distribution of pain is confined to a localised area of the lateral thigh and does not cross the midline of the thigh.

### Differential diagnosis

- L2 or L3 nerve root pain (L2 causes buttock pain also)
- Femoral neuropathy (extends medial to midline)

### Treatment

- Injection of corticosteroid medial to the ASIS, under the inguinal ligament
- Surgical release (neurolysis) if refractory
- Treat the cause (e.g. weight reduction, constricting belt, corset)

*Note:* Meralgia paraesthetica often resolves spontaneously.

### § Peroneal nerve entrapment

The common peroneal (lateral popliteal) nerve can be entrapped where it winds around the neck of the fibula or as it divides and passes through the origin of the peroneus longus muscle 2.5 cm below the neck of the fibula. It is usually injured, however, by trauma or pressure at the neck of the fibula.

### Symptoms and signs

- Pain in the lateral shin area and dorsum of the foot
- Sensory symptoms in the same area
- Weakness of eversion and dorsiflexion of the foot (described by patients as 'a weak ankle')

### Differential diagnosis

- L5 nerve root (similar symptoms)

### Treatment

- Shoe wedging or other orthotics to maintain eversion
- Neurolysis is the most effective treatment

### § Tarsal tunnel syndrome

This is an entrapment neuropathy of the posterior tibial nerve in the tarsal tunnel beneath the flexor retinaculum on the medial side of the ankle. The condition is due to dislocation or fracture around the ankle or tenosynovitis of tendons in the tunnel from injury, rheumatoid arthritis, and other inflammations.

### Symptoms and signs

- A burning or tingling pain in the toes and sole of the foot, occasionally the heel

- Retrograde radiation to calf, perhaps as high as the buttock
- Numbness is a late symptom
- Discomfort often in bed at night and worse after standing
- Removal of shoe may give relief
- Sensory nerve loss variable, may be no loss
- Tinel test (finger or reflex hammer tap over nerve below and behind medial malleolus) may be positive
- Tourniquet applied above ankle may reproduce symptoms

The diagnosis is confirmed by electrodiagnosis.

### Treatment

- Relief of abnormal foot posture with orthotics
- Corticosteroid injection into tunnel
- Decompression surgery if other measures fail

## VASCULAR CAUSES OF LEG PAIN

### § Occlusive arterial disease

Risk factors for peripheral vascular disease (for development and deterioration):

- smoking
- diabetes mellitus
- hypertension
- hypercholesterolaemia
- family history
- atrial fibrillation (embolism)

Aggravating factors:

- beta-blocking drugs
- anaemia

### § Acute lower limb ischaemia

Sudden occlusion is a dramatic event that requires immediate diagnosis and management to save the limb.

#### Causes

- Embolism—peripheral arteries
- Thrombosis: major artery, popliteal aneurysm
- Traumatic contusion (e.g. postarterial puncture)

The symptoms and signs of acute embolism and thrombosis are similar, although thrombosis of an area of atherosclerosis is often preceded by symptoms of chronic disease (e.g. claudication). The commonest site of acute occlusion is the common femoral artery (see FIG. 66.5).

FIGURE 66.5 Common sites of acute arterial occlusion

### Signs and symptoms—the 6 Ps

- Pain
- Pallor
- Paraesthesia or numbness
- Pulselessness
- Paralysis
- 'Perishing' cold

The pain is usually sudden and severe and any improvement may be misleading. Sensory changes initially affect light touch, not pinprick. Paralysis (paresis or weakness) and muscle compartment pain or tenderness is a most important and ominous sign.

Other signs include mottling of the legs, collapsed superficial veins, and no capillary return. If the foot becomes dusky purple and fails to blanch on pressure, irreversible necrosis has occurred.

*Note:* Look for evidence of atrial fibrillation.

## Examination of arterial circulation

This applies to chronic ischaemia and also to acute ischaemia.

### Skin and trophic changes

Note colour changes, hair distribution and wasting. Note the temperature of the legs and feet with the backs of your fingers.

### Palpation of pulses

It is important to assess four pulses carefully (see FIG. 66.6). Note that the popliteal and posterior tibial pulses are difficult to feel, especially in obese subjects.

**Femoral artery.** Palpate deeply just below the inguinal ligament, midway between the ASIS and the symphysis pubis. If absent or diminished, palpate over abdomen for aortic aneurysm.

**Popliteal artery.** Flex the leg to relax the hamstrings. Place fingertips of both hands to meet in the midline. Press them deeply into the popliteal fossa to compress artery against the upper end of the tibia (i.e. just below the level of the knee crease). Check for a popliteal aneurysm (very prominent popliteal pulsation).

FIGURE 66.6 Sites of palpation of peripheral pulses in the leg

**Posterior tibial artery.** Palpate, with curved fingers, just behind and below the tip of the medial malleolus of the ankle.

**Dorsalis pedis artery.** Feel at the proximal end of the first metatarsal space just lateral to the extensor tendon of the big toe.

### Oedema

Look for evidence of oedema: pitting oedema is tested by pressing firmly with your thumb for at least 5 seconds over the dorsum of each foot, behind each medial malleolus and over the shins.

### Postural colour changes (Buerger test)

Raise both legs to about 60° for about 1 minute, when maximal pallor of the feet will develop. Then get the patient to sit up on the couch and hang both legs down.<sup>4</sup>

Note, comparing both feet, the time required for return of pinkness to the skin (normally less than 10 seconds) and filling of the veins of the feet and ankles (normally about 15 seconds). Look for any unusual rubor (dusky redness) that takes a minute or more in the dependent foot. A positive Buerger test is pallor on elevation and rubor on dependency and indicates severe chronic ischaemia.

### Auscultation for bruits after exercise

Listen over abdomen and femoral area for bruits.

*Note:* Neurological examination (motor, sensory, reflexes) is normal unless there is associated diabetic peripheral neuropathy.

### Treatment

Golden rules. Occlusion is usually reversible if treated within 4 hours (i.e. limb salvage). It is often irreversible if treated after 6 hours (i.e. limb amputation).

- Intravenous heparin (immediately) 5000 U
- Emergency embolectomy (ideally within 4 hours):
  - under general or local anaesthesia
  - through an arteriotomy site in the common femoral artery
  - embolus extracted with Fogarty balloon or catheter
- or
- Stenting of vessels (a good modern option)—discuss this with an interventional cardiovascular physician
- Arterial bypass if acute thrombosis in chronically diseased artery
- In selected cases thrombolysis with streptokinase or urokinase appropriate

- Amputation (early) if irreversible ischaemic changes
- Lifetime anticoagulation with warfarin will be required

*Note:* An acutely ischaemic limb is rarely life threatening in the short term. Thus, even in the extremely aged, demented or infirm, a simple embolectomy not only is worthwhile but also is usually the most expedient treatment option.

## § Chronic lower limb ischaemia

Chronic ischaemia caused by gradual arterial occlusion can manifest as intermittent claudication, rest pain in the foot, or overt tissue loss—ulceration, gangrene (see FIG. 66.7).

**FIGURE 66.7** Gangrene of the lateral aspect of the foot following attempted amputation of an ischaemic toe. A below-knee amputation was eventually required.

Intermittent claudication is a pain or tightness in the muscle on exercise (Latin *claudicare*, to limp), relieved by rest. Rest pain is a constant severe burning-type pain or discomfort in the forefoot at rest, typically occurring at night when the blood flow slows down.

The main features are compared in TABLE 66.4.

### Intermittent claudication

The level of obstruction determines which muscle belly is affected (see FIGS 66.2 and 66.6).

### Proximal obstruction (e.g. aortoiliac)

- Pain in the buttock, thigh and calf, especially when walking up hills and stairs
- Persistent fatigue over whole lower limb
- Impotence is possible (Leriche syndrome)

**Table 66.4** Comparison between intermittent claudication and ischaemic rest pain

	Intermittent claudication	Ischaemic rest pain
<b>Quality of pain</b>	Tightness/cramping	Constant ache
<b>Timing of pain (typical)</b>	Daytime; walking, other exercise	Night-time; rest
<b>Tissue affected</b>	Muscle	Skin
<b>Site</b>	Calf > thigh > buttock	Forefoot, toes, heels
<b>Aggravation</b>	Walking, exercise	Recumbent, walking
<b>Relief</b>	Rest	Hanging foot out of bed; dependency
<b>Associations</b>	Beta blockers Anaemia	Night cramps Swelling of feet

## Obstruction in the thigh

- Superficial femoral (the commonest) causes pain in the calf (e.g. 200–500 m), depending on collateral circulation
- profunda femoris → claudication at about 100 m
- multiple segment involvement → claudication at 40–50 m

## Causes

- Atherosclerosis (mainly men over 50, smokers)
- Embolisation (with recovery)
- Buerger disease: affects small arteries, causes rest pain and cyanosis (claudication uncommon)
- Popliteal entrapment syndrome (<40 years of age)

*Note:* The presence of rest pain implies an immediate threat to limb viability.

## Investigations

- FBE: exclude polycythaemia and thrombocytosis
- Colour Doppler ultrasound: measure resting ankle systolic BP; determine ankle/brachial index; normal value 0.9–1.1
- Angiography: the gold standard, reserved for proposed intervention
- Digital subtraction angiography (developing)

## Management of occlusive vascular disease

### Prevention (for those at risk)

- Smoking is *the* risk factor and must be stopped.
- Other risk factors, especially hyperlipidaemia, must be attended to and weight reduction to ideal weight is important.
- Exercise is excellent, especially walking.

### Diagnostic plan

- Check if patient is taking beta blockers.
- General tests: blood examination, random blood sugar, urine examination, ECG.
- Measure blood flow by duplex ultrasound examination or ankle brachial index.
- Arteriography should be performed *only* if surgery is contemplated.

### Treatment

- General measures (if applicable): control obesity, diabetes, hypertension, hyperlipidaemia, cardiac failure.
- Achieve ideal weight.
- There must be absolutely no smoking.
- Exercise: daily graduated exercise to the level of pain. About 50% will improve with walking; so advise as much walking as possible.
- Try to keep legs warm and dry.
- Maintain optimal foot care (podiatry).
- Drug therapy: aspirin 150 mg daily.

*Note:*

- Vasodilators and sympathectomy are of little value.
- About one-third progress, while the rest regress or don't change.<sup>5</sup>

### When to refer to a vascular surgeon

- 'Unstable' claudication of recent onset; deteriorating
- Severe claudication—unable to maintain lifestyle
- Rest pain
- 'Tissue loss' in feet (e.g. heel crack, ulcers on or between toes, dry gangrenous patches, infection)

**Surgery.** Reconstructive vascular surgery is indicated for progressive obstruction, intolerable claudication and obstruction above the inguinal ligament:

- endarterectomy—for localised iliac stenosis

- bypass graft (iliac or femoral artery to popliteal or anterior or posterior tibial arteries)

**Percutaneous transluminal dilation.** This angioplasty is performed with a special intra-arterial balloon catheter for localised limited occlusions. An alternative to the balloon is laser angioplasty.

## VENOUS DISORDERS

### § Varicose veins

Varicose veins are dilated, tortuous and elongated superficial veins in the lower extremity.

The veins are dilated because of incompetence of the valves in the superficial veins or in the communicating or perforating veins between the deep and superficial systems (see FIG. 66.8). The cause is a congenital weakness in the valve and the supporting vein wall but there are several predisposing factors (TABLE 66.5), the most important being family history, female sex (5:1), pregnancy and multiparity. Previous DVT can also damage valves, especially calf perforators, and cause varicose veins.

FIGURE 66.8 The common sites of varicose veins

**Table 66.5** Risk factors for varicose veins

Female sex  
Family history  
Pregnancy  
Multiparity  
Age  
Occupation  
Diet (low fibre)

Dilated superficial veins, which can mimic varicose veins, may be caused by extrinsic compression of the veins by a pelvic or intra-abdominal tumour (e.g. ovarian cancer, retroperitoneal fibrosis). Uncommonly, but importantly, superficial veins dilate as they become collaterals following previous DVT, especially if the ilio-femoral segment is involved.

### Symptoms

Varicose veins may be symptomless, the main complaint being their unsightly appearance. Symptoms include swelling, fatigue, heaviness in the limb, an aching discomfort and itching.

### Varicose veins and pain

They may be painless even if large and tortuous. Pain is a feature where there are incompetent perforating veins running from the posterior tibial vein to the surface through the soleus muscle.

Severe cases lead to the lower leg venous hypertension syndrome<sup>6</sup> characterised by pain that is worse after standing, cramps in the leg at night, irritation and pigmentation of the skin, swelling of the ankles and loss of skin features such as hair.

A careful history will usually determine if the aching is truly due to varicose veins and not to transient or cyclical oedema, which is a common condition in women.<sup>7</sup>

The complications of varicose veins are summarised in **TABLE 66.6**.

**Table 66.6** Complications of varicose veins

Superficial thrombophlebitis  
Skin 'eczema' (10%)  
Skin ulceration (20%)  
Bleeding  
Calcification  
Marjolin ulcer (squamous cell carcinoma)

### Examination

The following tests will help determine the site or sites of the incompetent valves.

*Venous groin cough impulse.* This helps determine long saphenous vein incompetence. Place the fingers over the line of the vein immediately below the fossa ovalis (4 cm below and 4 cm lateral to the pubic tubercle).<sup>8</sup> Ask the patient to cough—an impulse or thrill will be felt expanding and travelling down the long saphenous vein. A marked dilated long saphenous vein in the fossa ovalis (saphena varix) will confirm incompetence. It disappears when the patient lies down.

*Trendelenburg test.* In this test for long saphenous vein competence the patient lies down and the leg is elevated to 45° to empty the veins (see **FIG. 66.9a**). Apply a tourniquet with sufficient pressure to prevent reflux over the upper thigh just below the fossa ovalis. (Alternatively, this opening can be occluded by firm finger pressure, as originally described by Trendelenburg.)

The patient then stands. The long saphenous system will remain collapsed if there are no incompetent veins below the level of the fossa ovalis. When the pressure is released the vein will fill rapidly if the valve at the saphenofemoral junction is incompetent (see **FIG. 66.9b**). This is a positive Trendelenburg test.

*Note:* A doubly positive Trendelenburg test is when the veins fill rapidly before the pressure is released and then with a 'rush' when released. This indicates coexisting incompetent perforators and long saphenous vein.

*Short saphenous vein incompetence test.* A similar test to the Trendelenburg test is performed with the pressure (tourniquet or finger) being applied over the short saphenous vein just below the popliteal fossa (see **FIG. 66.10**).

*Incompetent perforating vein test.* Accurate clinical tests to identify incompetence in the three common sites of perforating veins on the medial aspect of the leg, posterior to the medial border of the tibia, are difficult to perform. The general appearance of the leg and palpation of the sites give some indication of incompetence here.

*Note:* Venous duplex ultrasound studies will accurately localise sites of incompetence and determine the state of the functionally important deep venous system.

### Prevention

- Maintain ideal weight.
- Eat a high-fibre diet.
- Rest and wear supportive stockings if at risk (pregnancy, a standing occupation).

FIGURE 66.9 (a) Trendelenburg test: the leg is elevated to 45° to empty the veins and a tourniquet applied

FIGURE 66.10 Testing for competence of the short saphenous vein

FIGURE 66.9 (b) Trendelenburg test: test for competence of long saphenous venous system (medial aspect of knee)

### Treatment

- Keep off legs as much as possible.
- Sit with legs on a footstool.
- Use supportive stockings or tights (apply in morning before standing out of bed).
- Avoid scratching itching skin over veins.

### Compression sclerotherapy

- Use a small volume of sclerosant (e.g. sodium tetradecyl sulphate—Fibro-vein 3%).
- It is ideal for smaller, isolated veins, particularly below the knee joint.

### Surgical ligation and stripping

- This is the best treatment when a clear association exists between symptoms and obvious varicose veins (i.e. long saphenous vein incompetence).
- Remove obvious varicosities and ligate perforators.

*Note:* Surgery for varicose veins may not relieve heavy, aching legs.

## § Superficial thrombophlebitis

### Clinical features

- Usually occurs in superficial varicose veins
- Presents as a tender, reddened subcutaneous cord in leg
- Usually localised oedema
- No generalised swelling of the limb or ankle
- Requires symptomatic treatment only (see below) unless there is extension above the level of the knee when there is a risk of pulmonary embolism
- Venous duplex scan is diagnostic and also determines:
  - extent of superficial thrombosis, and
  - if coexisting, unsuspected DVT is present

### Treatment

The objective is to prevent propagation of the thrombus by uniform pressure over the vein.

- Cover whole tender cord with a thin foam pad.
- Apply a firm elastic bandage (preferable to crepe) from foot to thigh (well above cord).
- Leave pad and bandage on for 7–10 days.
- Bed rest with leg elevated if severe, otherwise keep active.
- If complication of IV infusion: prescribe a NSAID (e.g. diclofenac 75 mg bd or diclofenac 1% gel topically tds).<sup>9</sup>
- If spontaneous: LMWH (e.g. dalteparin 5000 units SC daily for 4 weeks).<sup>9</sup>
- The traditional glycerin and ichthyol dressings are still useful.
- Consider association between thrombophlebitis and deep-seated carcinoma.
- If the problem is above the knee, ligation of the vein at the saphenofemoral junction is indicated.

## § Deep venous thrombosis

Refer to CHAPTER 133.

## § Iliofemoral thrombophlebitis (phlegmasia dolens)<sup>10</sup>

This rare but life-threatening condition is when an extensive clot obstructs the iliofemoral veins so completely that subcutaneous oedema and blanching occurs. This initially causes a painful ‘milky white leg’, previously termed phlegmasia alba dolens (used to be seen in late pregnancy or early puerperium). It may deteriorate and become cyanotic—phlegmasia

cerulea dolens—representing incipient venous infarction. Massive iliofemoral occlusion is an emergency as such patients may develop ‘shock’, gangrene and pulmonary embolus.

## OTHER PAINFUL CONDITIONS

## § Cellulitis and erysipelas

The causative organisms are *Streptococcus pyogenes* (commonest) and *Staphylococcus aureus*. Others include *Haemophilus influenzae*, *Aeromonas* and fungal infection (especially in the immunocompromised). Predisposing factors include cuts, abrasions, ulcers, insect bites, foreign matter, IV drug use, and skin disorders such as eczema and tinea pedis of toe webs. Look for evidence of diabetes.

- Rest in bed.
- Elevate limb (in and out of bed).
- Use aspirin or paracetamol for pain and fever.
- Wound cleansing and dressing with non-sticking saline dressings.

### *Streptococcus pyogenes* (the common cause)<sup>11</sup>

- If *S. pyogenes* confirmed: phenoxymethylpenicillin 500 mg(o) 6 hourly for 10 days
- If organism doubtful: flu/dicloxacillin 500 mg (o) 6 hourly for 7–10 days
- If penicillin hypersensitive/allergic: cephalexin 500 mg (o) 6 hourly or (if severe) cephalazolin 2 g IV 6 hourly

### *Staphylococcus aureus*<sup>12</sup>

- Severe, may be life-threatening: flucloxacillin/dicloxacillin 2 g IV 6 hourly for 7–10 days
- Less severe: flucloxacillin/dicloxacillin 500 mg (o) 6 hourly for 7–10 days or cephalexin 500 mg (o) 6 hourly

## § Furuncle (boil) of groin

A painful furuncle caused by *S. aureus* in the hairy area of the groin is common. The aim is to treat conservatively.

- Localised:
  - local antiseptics

- hot compresses
- drain when 'ripe'
- Deep/extensive:
  - dicloxacillin 500 mg (o) 6 hourly for 5–7 days
  - drain when 'ripe', not before

### § Pain in the calf

Calf pain is usually not serious except if swelling is present. Some of the uncommon causes have serious implications and necessitate careful assessment.

Common causes: cramp, muscle stiffness, muscle injury e.g. gastrocnemius tear, claudication (PVD).

Not to be missed: deep venous thrombosis, cellulitis, thrombophlebitis.

Other: ruptured Baker cyst, referred pain (back, knees), Achilles tendon rupture.

### § Nocturnal muscle cramps

*Note:* Treat cause (if known)—tetanus, drugs, sodium depletion, hypothyroidism, hypocalcaemia, pregnancy.

#### Physical measures

- Muscle stretching and relaxation exercises: calf stretching for 3 minutes before retiring,<sup>11</sup> then rest in chair with the feet out horizontal to the floor with cushion under tendoachilles for 10 minutes.
- Massage and apply heat to affected muscles.
- Try to keep bedclothes off feet and lower part of legs—a doubled-up pillow at the foot of the bed can be used.

#### Medication for idiopathic cramps

- Tonic water before retiring may help.
- Drug treatment:  
Consider:  
biperiden 2–4 mg nocte  
magnesium co tablets (e.g. Crampeze)

Quinine sulphate is effective but with a 1–3% incidence of haematological abnormalities, especially thrombocytopenia, it is no longer recommended in Australia. It is very toxic to children. More severe idiopathic cramps may respond to magnesium.<sup>13</sup>

### § Roller injuries to legs

A patient who has been injured by a wheel passing over a limb, especially a leg, can present a difficult problem. A freely spinning wheel is not so dangerous,

but serious injuries occur when a non-spinning (braked) wheel passes over a limb and these are compounded by the wheel then reversing over it. This leads to a 'degloving' injury due to shearing stress. The limb may look satisfactory initially, but skin necrosis may follow.

- Admit to hospital for observation.
- Fasciotomy with open drainage may be an option for a compartment syndrome.
- Surgical decompression with removal of necrotic fat is often essential.
- Rehydrate the patient and monitor renal function.

### When to refer

- The sudden onset of pain, pallor, pulselessness, paralysis, paraesthesia and coldness in the leg
- Worsening intermittent claudication
- Rest pain in foot
- Presence of popliteal aneurysm
- Superficial thrombophlebitis above knee
- Evidence of DVT
- Suspicion of gas gangrene in leg
- Worsening hip pain
- Evidence of disease in bone (e.g. neoplasia, infection, Paget disease)
- Severe sciatica with neurological deficit (e.g. floppy foot, absent reflexes)

### Practice tips

- Always X-ray the legs (including hips) of a patient complaining of unusual deep leg pain, especially a child.
- Pain that does not fluctuate in intensity with movement, activity or posture has an inflammatory or neoplastic cause.
- Hip disorders such as osteoarthritis and slipped femoral epiphysis can present as pain in the knee (usually medial aspect).
- Consider retroperitoneal haemorrhage as a cause of acute severe nerve root pain, especially in people on anticoagulant therapy.
- Avoidance of amputation with acute lower limb ischaemia depends on early recognition (surgery within 4 hours—too late if over 6 hours).

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education*  
6th edition:

- Calf muscle injury
- Cramp
- Deep vein thrombosis
- Sciatica

*The human knee is a joint and not a source of entertainment.*

The knee, which is a gliding hinge joint, is the largest synovial joint in the body. Its small area of contact of the bone ends at any one time makes it dependent on ligaments for its stability. Although this allows a much increased range of movement it does increase the susceptibility to injury, particularly from sporting activities. Finding the cause of a knee problem is one of the really difficult and challenging features of practice. It is useful to remember that peripheral pain receptors respond to a variety of stimuli. These include inflammation due either to inflammatory disorders or chemical irritation such as crystal synovitis, traction pain (e.g. trapped meniscus stretching the capsule), tension on the synovium capsule (e.g. effusion or haemarthrosis), and impact loading of the subchondral bone.

### Key facts and checkpoints

- Disorders of the knee account for about one presentation per 50 patients per year.<sup>1</sup>
- The commoner presenting symptoms in order of frequency are pain, stiffness, swelling, clicking and locking.<sup>1</sup>
- The age of presentation of a painful knee has varied significance as many conditions are age-related.
- Excessive strains across the knee, such as a valgus-producing force, are more likely to cause ligament injuries, while twisting injuries tend to cause meniscal tears.
- A ruptured anterior cruciate ligament (ACL) is a commonly missed injury of the knee.<sup>2</sup> It should be suspected with a history of either a valgus strain or a sudden pivoting of the knee, often associated with a cracking or popping sensation. It is often associated with the rapid onset of haemarthrosis or inability to walk or weight-bear.
- A rapid onset of painful knee swelling (minutes to 1–4 hours) after injury indicates blood in the joint—*haemarthrosis*.
- Swelling over 1–2 days after injury indicates synovial fluid—*traumatic synovitis*.

Percy Hammond, 1912, review of a play

- Any collateral ligament repair should be undertaken early but, if associated with ACL injuries, early surgery may result in knee stiffness. Thus, surgery is often delayed. With isolated ACL ruptures, early reconstruction is appropriate in the high-performance athlete; otherwise, delayed reconstruction is appropriate if there is clinical instability.<sup>3</sup>
- Acute spontaneous inflammation of the knee may be part of a systemic condition such as rheumatoid arthritis, rheumatic fever, gout, pseudogout (chondrocalcinosis), a spondyloarthropathy (psoriasis, ankylosing spondylitis, reactive arthritis, bowel inflammation), Lyme disease and sarcoidosis.
- Consider Osgood–Schlatter disorder (OSD) in the prepubertal child (especially a boy aged 10–14) presenting with knee pain.
- Disorders of the lumbosacral spine (especially L3 to S1 nerve root problems) and of the hip joint (L3 innervation) refer pain to the region of the knee joint.
- If infection or haemorrhage is suspected the joint should be aspirated.
- The condition known as anterior knee pain is the commonest type of knee pain and accounts for at least 11% of sports-related musculoskeletal problems. The prime cause of this is patellofemoral dysfunction pain. It is a benign condition with a good prognosis.

## The knee and referred pain—key knowledge

### Pain from the knee joint

Disorders of the knee joint give rise to pain felt accurately at the knee, often at some particular part of the joint, and invariably in the anterior aspect, very seldom in the posterior part of the knee. An impacted loose body complicating osteoarthritis and a radial tear of the lateral meniscus<sup>4</sup> are the exceptional disorders liable to refer pain proximally and distally in the limb, but the problems obviously originate from the knee.

## Pain referred to the knee

Referred pain to the knee or the surrounding region is a time-honoured trap in medicine. The two classic problems are disorders of the hip joint and lumbosacral spine.

- The hip joint is mainly innervated by L3, hence pain is referred from the groin down the front and medial aspects of the thigh to the knee (see FIG. 67.1). Sometimes the pain can be experienced on the anteromedial aspect of the knee only. It is not uncommon for children with a slipped upper femoral epiphysis to present with a limp and knee pain.
- Knee pain can be referred from the lumbosacral spine. Patients with disc lesions may notice that sitting, coughing or straining hurts the knee, whereas walking does not.

L3 nerve root pressure from an L2–3 disc prolapse (uncommon) and L4 nerve root pain will cause anteromedial knee pain; L5 reference from an L4–5 disc prolapse can cause anterolateral knee pain, while S1 reference from an L5–S1 prolapse can cause pain at the back of the knee (see FIG. 67.1).

FIGURE 67.1 Possible area of referred pain from disorders of the hip joint

## A diagnostic approach

A summary of the diagnostic strategy model is presented in TABLE 67.1.

**Table 67.1** The painful knee: diagnostic strategy model

Q.	Probability diagnosis
A.	Ligament strains and sprains ± traumatic synovitis Osteoarthritis Patellofemoral syndrome Prepatellar bursitis
Q.	Serious disorders not to be missed
A.	Acute cruciate ligament tear Vascular disorders: <ul style="list-style-type: none"> <li>• deep venous thrombosis</li> <li>• superficial thrombophlebitis</li> </ul> Neoplasia: <ul style="list-style-type: none"> <li>• primary in bone</li> <li>• metastases</li> </ul> Severe infections: <ul style="list-style-type: none"> <li>• septic arthritis</li> <li>• tuberculosis</li> </ul> Rheumatoid arthritis Juvenile chronic arthritis Rheumatic fever
Q.	Pitfalls (often missed)
A.	Referred pain: back or hip Foreign bodies Intra-articular loose bodies Osteochondritis dissecans Osteonecrosis Synovial chondromatosis Osgood–Schlatter disorder Meniscal tears Fractures around knee Pseudogout (chondrocalcinosis) Gout → patellar bursitis Ruptured popliteal cyst Rarities: <ul style="list-style-type: none"> <li>• sarcoidosis</li> <li>• Paget disease</li> <li>• spondyloarthropathy</li> </ul>
Q.	Seven masquerades checklist
A.	Depression Diabetes Drugs (indirect) Spinal dysfunction
Q.	Is the patient trying to tell me something?
A.	Psychogenic factors relevant, especially with possible injury compensation.

## Probability diagnosis

A UK study<sup>1</sup> highlighted the fact that the commonest causes of knee pain are simple ligamentous strains and bruises due to overstress of the knee or other minor trauma. Traumatic synovitis may accompany some of these injuries. Some of these so-called strains may include a variety of recently described syndromes, such as the synovial plica syndrome, patellar tendonopathy and infrapatellar fat-pad inflammation (see FIG. 67.2).

FIGURE 67.2 Lateral view of knee showing typical sites of various causes of knee pain

Low-grade trauma of repeated overuse, such as frequent kneeling, may cause prepatellar bursitis known variously as 'housemaid's knee' or 'carpet layer's knee'. Infrapatellar bursitis is referred to as 'clergyman's knee'.

Osteoarthritis of the knee, especially in the elderly, is a very common problem. It may arise spontaneously or be secondary to previous trauma with associated internal derangement and instability.

The most common overuse problem of the knee is the patellofemoral joint pain syndrome (often previously referred to as chondromalacia patellae).

## Serious disorders not to be missed

Neoplasia in the bones around the knee is relatively uncommon but still needs consideration. The commonest neoplasias are secondaries from the breast, lung, kidney, thyroid and prostate. Uncommon examples include osteoid osteoma, osteosarcoma and Ewing tumour (more likely in younger people). Septic arthritis and infected bursitis are prone to occur in the knee joint, especially following contaminated lacerations and abrasions. Septic arthritis from blood-borne infection can be of the primary type in children, where the infection is either staphylococcal or due to *Haemophilus influenzae*, or gonococcal arthritis in adults. Rheumatic fever should be kept in mind with a fleeting polyarthritis that involves the knees and then affects other joints.

Inflammatory disorders such as spondyloarthropathies, sarcoidosis, chondrocalcinosis (a crystal arthropathy due to calcium pyrophosphate dihydrate in the elderly), gout and juvenile chronic arthritis have to be considered in the differential diagnosis.

### Red flag pointers for knee pain

- Acute swelling with or without trauma
- Acute or acute on chronic erythema
- Systemic features (e.g. fever) in absence of trauma
- Unexplained chronic, persistent pain

## Pitfalls

There are myriad pitfalls in knee joint disorders, often arising from ignorance, because there are myriad problems that are difficult to diagnose. Fortunately, many of these problems can be diagnosed by X-ray. A particular trap is a foreign body, such as a broken needle acquired by kneeling on carpet.

The presence of a spontaneous effusion demands careful attention because it could represent a rheumatic disorder or conditions such as osteochondritis dissecans (more common in the young) or osteonecrosis of the femoral condyle (a necrotic problem in the elderly) and perhaps a subsequent loose body in the joint.

A ruptured Baker cyst will cause severe pain behind the knee and can be confused with deep venous thrombosis. It is important to bear in mind complications of varicose veins, which can cause pain or discomfort around the knee joint.

## General pitfalls

- Overlooking referred pain from the hip or low back as a cause of knee pain
- Failing to realise that meniscal tears can develop due to degeneration of the menisci with only minimal trauma
- Failing to X-ray the knee joint and order special views to detect specific problems, such as a fractured patella or osteochondritis dissecans

## Ottawa knee rules for X-ray of an injured knee

- Patient aged 55 years or more
- Isolated tenderness of the patella
- Tenderness at the head of the fibula
- Inability to flex to 90°
- Immediate inability to weight-bear and in the emergency room (four steps: unable to transfer weight twice onto each lower limb regardless of limping).

Furthermore, a knee X-ray may be indicated following blunt trauma or a fall-type injury if the patient is:

- <12 years or >50 years
- unable to take four weight-bearing steps in front of the clinician<sup>5</sup>

## Seven masquerades checklist

Of these, spinal dysfunction is the prime association. Diabetes may cause pain through a complicating neuropathy and drugs such as diuretics may cause gout in the elderly.

## Psychogenic considerations

Patients, young and old, may complain of knee pain, imaginary or exaggerated, to gain attention, especially if compensation for an injury is involved. This requires discreet clinical acumen to help patients work through the problem.

## The clinical approach

### History

The history is the key to diagnosis. If any injury is involved careful description of the nature of the injury is necessary. This includes past history. A special problem relates to the elderly who can sustain knee injuries after a 'drop attack', but attention can easily be diverted away from the knee with preoccupation with the cerebral pattern.

It is relevant to define whether the pain is acute or chronic, dull or sharp, and continuous or recurring. Determine its severity and position and keep in mind age-related causes.

## Key questions

### Related to an injury

- Can you explain in detail how the injury happened?
- Did you land awkwardly after a leap in the air?
- Did you get a direct blow? From what direction?
- Did your leg twist during the injury?
- Did you feel a 'pop' or hear a 'snap'?
- Did your knee feel wobbly or unsteady?
- Did the knee feel as if the bones separated momentarily?
- How soon after the injury did the pain develop?
- How soon after the injury did you notice swelling?
- Have you had previous injury or surgery to the knee?
- Were you able to walk after the injury or did you have to be carried off the ground or court?
- Does this involve work care compensation?

### No history of injury

- Does the pain come on after walking, jogging or other activity?
- How much kneeling do you do? Scrubbing floors, cleaning carpets?
- Could there be needles or pins in the carpet?
- Does your knee lock or catch?
- Does swelling develop in the knee?
- Does it 'grate' when it moves?
- Does the pain come on at rest and is there morning stiffness?
- Do you feel pain when you walk on steps or stairs?

## Significance of symptoms

### Swelling after injury

The sudden onset of painful swelling (usually within 60 minutes) is typical of haemarthrosis (see FIGS 67.3 and 67.4). Bleeding occurs from vascular structures such as torn ligaments, torn synovium or fractured bones, while injuries localised to avascular structures such as menisci do not usually bleed. About 75% of cases are due to ACL tears.<sup>6</sup> If a minor injury causes acute haemarthrosis suspect a bleeding diathesis or anticoagulant usage. The causes of haemarthrosis are listed in TABLE 67.2.

**FIGURE 67.3** Haemarthrosis in a sportsman presenting with an acutely painful swollen knee

**FIGURE 67.4** Haemarthrosis: Surgical release of intra-articular blood under pressure in the knee shown in Figure 67.3

**Table 67.2** Causes of haemarthrosis

Torn cruciate ligaments, esp. ACL
Capsular tears with collateral ligament tears
Peripheral meniscal tears
Dislocation or subluxation of patella
Osteochondral fractures
Bleeding disorders (e.g. haemophilia), anticoagulants

Swelling of an intermediate rate of onset, stiffness and pain in the order of hours (e.g. 6–24 hours) is typical of an effusion of synovial fluid. Causes include meniscal tears and milder ligamentous injuries. Swelling gradually developing over days and confined to the anterior knee is typical of bursitis such as ‘housemaid’s knee’.

### Recurrent or chronic swelling

This indicates intra-articular pathology and includes:

- patellofemoral pain syndrome
- osteochondritis dissecans
- degenerative joint disease including degenerative meniscus tears
- arthritides

### Locking

Locking usually means a sudden inability to extend the knee fully (occurs at 10–45°, average 30°) but ability to flex fully.<sup>7</sup>

### Causes

True locking:

- torn meniscus (bucket handle)
- loose body (e.g. bony fragment from osteochondritis dissecans)
- torn ACL (remnant)
- flap of articular cartilage
- avulsed anterior tibial spine
- dislocated patella
- synovial osteochondromatosis

Pseudo-locking:

- patellofemoral disorders
- first or second degree medial ligament tear
- strain of ACL
- gross effusion
- pain and spasm of hamstrings

### Catching

‘Catching’ of the knee implies that the patient feels that something is ‘getting in the way of joint movement’ but not locking. Causes include any of the conditions that cause locking, but a subluxing patella and loose bodies in particular must be considered.

### Causes of loose bodies

- Osteochondritis dissecans (usually lateral side of medial femoral condyle)
- Retropatellar fragment (e.g. from dislocation of patella)
- Dislodged osteophyte
- Osteochondral fracture—post injury
- Synovial chondromatosis

## Clicking

Clicking may be due to an abnormality such as patellofemoral maltracking or subluxation, a loose intra-articular body or a torn meniscus, but can occur in normal joints when people climb stairs or squat.

## Anterior knee pain<sup>8</sup>

Common causes include:

- patellofemoral syndrome
- osteoarthritis of the knee
- patellar tendonopathy
- osteonecrosis

## Lateral knee pain

Consider:

- osteoarthritis of lateral compartment of knee
- lesions of the lateral meniscus
- patellofemoral syndrome

## Medial knee pain

Consider:

- osteoarthritis of medial compartment of knee
- lesions of the medial meniscus
- patellofemoral syndrome

## Examination

The provisional diagnosis may be evident from a combination of the history and simple inspection of the joint but the process of testing palpation, movements (active and passive) and specific structures of the knee joint helps to pinpoint the disorder.

## Inspection

Inspect the knee with the patient walking, standing erect and lying supine. Get the patient to squat to help localise the precise point of pain. Get the patient to sit on the couch with legs hanging over the side and note any abnormality of the patella. Note any deformities, swelling or muscle wasting.

The common knee deformities are genu valgum 'knock knees' (see FIG. 67.5a), genu recurvatum 'back knee' (see FIG. 67.5b) and genu varum 'bowed legs' (see FIG. 67.5c).

A useful way of remembering the terminology is to recall that the 'l' in valgus stands for 'l' in lateral.<sup>8</sup> In the normal knee the tibia has a slight valgus angulation in reference to the femur, the angulation being more pronounced in women.

FIGURE 67.5 Knee deformities: (a) genu valgum ('knock knees'): tibia deviates laterally from knee, (b) genu recurvatum ('back knee'), (c) genu varum ('bowed legs')

## Palpation

Palpate the knee generally, concentrating on the patella, patella tendon, joint lines, tibial tubercle, bursae and popliteal fossa.

Palpate for presence of any fluid, warmth, swelling, synovial thickening, crepitus, clicking and tenderness. Feel for a popliteal (Baker) cyst in the popliteal fossa. Draw the fingers upwards over the suprapatellar pouch: synovial thickening, a hallmark of chronic arthritis, is most marked just above the patella—it feels warm, boggy, rubbery and has no fluid thrill.

Flex the knees to 45° and check for a pseudocyst, especially of the lateral meniscus (see FIG. 67.6).

FIGURE 67.6 Pseudocyst of the lateral meniscus: flex the knees to 45° to force lump (if present) to appear

## Fluid effusion

The bulge sign: compress the medial side of the joint and evacuate any fluid. The test is positive when the lateral side of the joint is then stroked and the fluid is displaced across the joint, creating a visible bulge or filling of the medial depression (see FIG. 67.7).

The test will be negative if the effusion is gross and tense, in which case the *patellar tap test* (see FIG. 67.8) is used by sharply tapping the lower pole

**FIGURE 67.7** The bulge sign with a knee effusion: fluid bulges into the medial compartment

**FIGURE 67.8** The patellar tap test

of the patella against the femur with the index finger. A positive tap is when the patella can be felt to tap against the femur and then float free.

### Movements

**Extension:** normal is 0–5°. The loss of extension is best measured by lifting the heel off the couch with the knee held down. In the normal knee the heel will lift 2.5–4 cm off the couch, that is, into hyperextension.

**Flexion** (supine or prone): normal to 135°. The normal knee flexes heel to the buttock but in locking due to medial meniscus tears there may be a gap of 5 or more centimetres between the heel and buttock.

**Rotation:** normal 5–10°. Test at 90° with patient sitting over the edge of the couch; rotate the feet with the hand steadying the knee.

**Note:** Normally, no abduction, adduction or rotation of the tibia on the femur is possible with the leg fully extended.

### Ligament stability tests

**Collateral ligaments.** Adduction (varus) and abduction (valgus) stresses of the tibia on the femur are applied in full extension and then at 30° flexion with the leg over the side of the couch. With ligament strains there is localised pain when stressed. With a complete (third degree) tear the joint will open out. This end-point feel should be carefully noted: firmness indicates stability, 'mushiness' indicates damage (see FIG. 67.9).

**FIGURE 67.9** Medial and lateral ligament instability: (a) medial instability of knee joint; (b) lateral instability of knee joint

**Cruciate ligaments.** Stability of the ACL can be tested with the anterior drawer test. This is done with the patient supine and the knee flexed to 90°. The tibia is pulled forwards off the femur and in the presence of a cruciate ligament injury there will be increased gliding of the tibia on the femur. An aberrant positive sign can occur in the presence of posterior cruciate ligament (PCL) insufficiency, in which case the knee is actually brought back to its normal site from a dropped-back position. This gives the appearance of a positive anterior drawer sign. In that situation, a Lachman test will be negative. In the presence of medial ligament injury, the increased external rotation of the tibia against the femur may add to the positive drawer sign.

### Specific provocation tests

The simplest menisci function tests are those outlined in TABLE 67.4, later in this chapter.

- *McMurray test*. The patient lies on the couch and the flexed knee is rotated (internally and externally) in varying degrees of abduction as it is straightened into extension. A hand over the affected knee feels for 'clunking' or tenderness.
- *Apley grind/distraction test*. The patient lies prone and the knee is flexed to 90° and then rotated under a compression force. Reproduction of painful symptoms may indicate meniscal tear. Then repeat the rotation under distraction—tests ligament damage.
- *Patella apprehension test*. At 15–20° flexion, attempt to push the patella laterally and note the patient's reaction.
- *Patellar tendonopathy*. Palpate patellar tendon (refer to FIG. 67.19, later in this chapter).
- *Patellofemoral pain test*. Refer to FIGURE 67.18, later in this chapter.

Examine the lumbosacral spine and the hip joint of the affected side.

## Measurements

**Quadriceps.** For suspected quadriceps wasting, measure the circumference of the thighs at equal points above the tibial tuberosity. It is helpful to assess quadriceps function by feeling the tone.

Static Q angle (see FIG. 67.10).

If the Q angle is >15° in men and >19° in women there is a predisposition to patellofemoral pain and instability.<sup>9</sup>

FIGURE 67.10 The Q angle of the knee gives a measure of patellar alignment

## Investigations

Investigation for the diagnosis of knee pain can be selected from:

- blood tests:
  - RA factor tests; ANA; HLA-B<sub>27</sub>
  - ESR
  - blood culture (suspected septic arthritis)
- radiology<sup>9</sup>:
  - plain X-ray
  - special views: intercondylar (osteochondritis dissecans, loose bodies); tangential (or skyline view for suspected patella pathology); oblique (to define condyles and patella); weight-bearing views looking for degenerative arthritis
  - bone scan: for suspected tumour, stress fracture, osteonecrosis, osteochondritis dissecans
  - MRI: excellent for diagnosing cartilage and menisci disorders and ligament damage; the investigation of choice for internal 'derangement'
  - arthrography (generally superseded by arthroscopy) or MRI
  - ultrasound: good for assessment of patellar tendon, soft tissue mass, fluid collection, Baker cyst and bursae
- CT: useful for complex fractures of tibial plateau and patellofemoral joint special dysfunction
- special:
  - examination under anaesthesia
  - arthroscopy
  - knee aspiration: culture or crystal examination

## Fractures that may be missed on plain films<sup>10</sup>

- Patellar fracture
- Tibial plateau fracture
- Tibial spine fracture
- Epiphyseal injuries in children
- Osteochondral fracture:
  - patella
  - femoral condyle
- Stress fracture upper tibia
- Avulsion fracture (e.g. Second fracture of upper lateral tibia, with ACL tear)

## Knee pain in children

Children may present with unique conditions that are usually related to growth, including epiphyseal problems. Their tendency towards muscle tightness, especially in the growth spurt, predisposes them to overuse injuries such as patellar tendonopathy and patellofemoral pain syndrome.

### First decade

A painful knee during the first decade of life (0–10 years) in non-athletes is an uncommon presenting symptom, but suppurative infection and juvenile chronic arthritis have to be considered.

Genu valgum or varum is a common presentation but usually not a source of discomfort for the child. However, genu valgum, which is often seen around 4–6 years, may predispose to abnormal biomechanical stresses, which contribute to overuse-type injuries if the child is involved in sport.

### Second decade

Pain in the knee presents most frequently in this decade and is most often due to the patellofemoral syndrome,<sup>11</sup> which is related to the retropatellar and peripatellar regions and usually anterior to the knee. It occurs in the late teenage years of both sexes.

An important problem is subluxation of the patella, typically found in teenage girls. It is caused by maltracking of the patellofemoral mechanism without complete dislocation of the patella (see FIG. 67.11).

FIGURE 67.11 Lateral subluxation of the patella

On examination, the patella is usually in a high and lateral position. Surgery may be required if symptoms persist.

OSD is common in pre-pubertal adolescent boys but can occur in those aged 10–16 years.

Other conditions found typically in this age group include:

- slipped upper femoral epiphysis—usually in middle teenage years after a growth spurt
- anserinus (‘goose foot’) bursitis
- osteochondritis dissecans

Age-related causes of the painful knee are presented in TABLE 67.3.<sup>11</sup>

Table 67.3 Age-related causes of painful knee

First decade (0–10 years)
Infection
Juvenile chronic arthritis
Second decade (10–20 years)
Patellofemoral syndrome
Subluxation/dislocation of patella
Slipped femoral epiphysis (referred)
‘Hamstrung’ knee
Osteochondritis dissecans
Osgood–Schlatter disorder
Anserinus tendonopathy
Third decade (20–30 years)
Bursitis
Mechanical disorders
Fourth and fifth decades (30–50 years)
Cleavage tear of medial meniscus
Radial tear of lateral meniscus
Sixth decade and older (50 years and over)
Osteoarthritis
Osteonecrosis
Paget disease (femur, tibia or patella)
Anserinus bursitis
Chondrocalcinosis and gout
Osteoarthritis of hip (referred pain)

### The little athlete

Children competing in sporting activities, especially running and jumping, are prone to overuse injuries such as the patellofemoral pain syndrome, traumatic synovitis of the knee joint and OSD. Haemarthrosis can occur with injuries, sometimes due to a synovial tear without major joint disruption. If knee pain persists, especially in the presence of an effusion, X-rays should be performed to exclude osteochondritis of the femoral condyle.<sup>12</sup>

### The Ottawa knee rules

A knee X-ray series is only required for children with any of the findings in the Ottawa knee rules (see earlier in this chapter).

### § Osgood–Schlatter disorder

Osgood–Schlatter disorder (OSD) is a traction apophysitis resulting from repetitive traction stresses at the insertion of the patellar tendon into the tibial tubercle, which is vulnerable to repeated traction in early adolescence.

#### Clinical features

- Commonest in ages 10–14 years
- Boys:girls = 3:1
- Bilateral in about one-third of cases
- Common in sports involving running, kicking and jumping
- Localised pain in region of tibial tubercle during and after activity
- Aggravated by kneeling down and going up and downstairs
- Development of lump in area
- Localised swelling and tenderness at affected tubercle
- Pain reproduced by attempts to straighten flexed knee against resistance

X-ray to confirm diagnosis (widening of the apophysis and possible fragmentation of bone) and exclude tumour or fracture (see FIG. 67.12).

FIGURE 67.12 Features of Osgood–Schlatter disorder

#### Management

Treatment is conservative as it is a self-limiting condition (6–18 months; average 12 months).

- If acute, use ice packs and analgesics.
- The main approach is to abstain from or modify active sports.
- Localised treatments such as electrotherapy are unnecessary.
- Corticosteroid injections should be avoided.<sup>13</sup>
- Plaster cast immobilisation should also be avoided.
- Surgery may be used (rarely) if an irritating ossicle persists<sup>14</sup> after ossification.
- Gentle quadriceps stretching.
- Graded return to full activity.

#### Prevention

- Promote awareness and early recognition of OSD.
- Program of stretching exercises for quadriceps mechanism in children in sport.

### § Osteochondritis dissecans: juvenile form<sup>7</sup>

This commonly occurs in adolescent boys aged 5–15 years whereby a segment of articular cartilage of the femoral condyle (85%) undergoes necrosis and may eventually separate to form an intra-articular loose body (see FIG. 67.13).

It usually presents as pain and effusion and locking.

If the fragment has separated, surgery to reattach it can be contemplated.

FIGURE 67.13 Osteochondritis dissecans: on X-ray, sclerosis of the lateral aspect of the medial condyle

### Knee pain in the elderly

Rheumatic disorders are very common and responsible for considerable pain or discomfort, disability and loss of independence in the elderly.

Osteoarthritis is the most common cause and excellent results are now being obtained using total knee replacement in those severely affected.

The elderly are particularly prone to crystal-associated joint diseases, including monosodium urate (gout), CPPD (pseudogout) and hydroxyapatite (acute calcific periarthritis).

### § Chondrocalcinosis of knee (pseudogout)

The main target of CPPD is the knee, where it causes chondrocalcinosis. Unlike gout, chondrocalcinosis of the knee is typically a disorder of the elderly with about 50% of the population having evidence of involvement of the knee by the ninth decade.<sup>15</sup> Most cases remain asymptomatic but patients (usually aged 60 or older) can present with an acutely hot, red, swollen joint resembling septic arthritis.

Investigations include aspiration of the knee to search for CPPD crystals, and X-ray. If positive, consider an associated metabolic disorder such as haemochromatosis, hyperparathyroidism or diabetes mellitus. The treatment is similar to acute gout although colchicine is less effective. Acute episodes respond well to NSAIDs or intra-articular corticosteroid injection.

### § Osteonecrosis<sup>7,16</sup>

Spontaneous osteonecrosis of the knee (SONK) is more common after the age of 60, especially in females; it can occur in either the femoral (more commonly) or tibial condyles. The aetiology is unknown. The sudden onset of pain in the knee, with a normal joint X-ray, is diagnostic of osteonecrosis. However, the X-ray (especially later) will demonstrate an area of osteonecrosis. The pain is usually persistent, with swelling and stiffness, and worse at night. It can take three months for the necrotic area to show radiologically although a bone scan or MRI may be positive at an early stage (see FIG. 67.14). The condition may resolve in time with reduction of weight-bearing. Surgery in the form of subchondral drilling may be required for persistent pain in the early stages.

### § Osteochondritis dissecans: adult form<sup>7</sup>

The adult form occurs more often in males and may be the result of cysts of osteoarthritis fracturing into the joint. Up to 30% are bilateral. Symptoms depend on whether the osteochondral fragment becomes

FIGURE 67.14 Osteonecrosis: necrosis in the medial femoral condyle can take three months to show radiologically

separated. A loose fragment may produce locking or collapse of the knee.

### § Loose bodies<sup>7</sup>

The large knee joint is a 'haven' for intra-articular loose bodies, which may be formed from bone, cartilage or osteochondral fragments following injury ('chip' fragment), osteochondritis dissecans, osteoarthritis, synovial chondromatosis or other conditions. They may be asymptomatic but usually cause clicking or locking with swelling. Diagnosis is by X-ray and surgical removal is necessary for recurrent problems.

### The knee 'mouse'

This common complaint is usually a result of a pedunculated fibrous lump in the prepatellar bursa, often secondary to trauma, such as falls onto the knee.

## ACUTE INJURIES

### § Meniscal tears

Medial and lateral meniscal tears are usually caused by abduction and adduction forces causing the meniscus to be compressed between the tibial and femoral condyles and then subjected to a twisting force or a rotatory movement on a semi-flexed weight-bearing knee.

The medial meniscus is three times more likely to be torn than the lateral. These injuries are common in contact sports and are often associated with ligamentous injuries. Suspect these injuries when there is a history of injury with a twisting movement with the foot firmly fixed on the ground.

However, pain in the knee can present in the patient aged 30–50 years as the menisci degenerate, with resultant cleavage tears from the posterior horn of the medial meniscus and ‘parrot beak’ tears of the mid-section of the lateral meniscus. These problems cause pain because these particular deformities create tension on the joint capsule and stretch the nerve ends. X-rays are not specifically useful but an MRI scan should confirm diagnosis.

### Clinical features

- General symptoms:<sup>9</sup>
  - joint line pain (49%)
  - locking (17%)
  - swelling (14%)
  - loss of movement: restricted flexion, loss of last 5–10° extension
- Parrot beak tear of lateral meniscus:
  - pain in the lateral joint line
  - pain radiating up and down the thigh
  - pain worse with activity
  - a palpable and visible lump when the knee is examined at 45°

Arthroscopic partial meniscectomy offers relief. The peripheral meniscus is vascular and can be repaired within 6–12 weeks of injury.<sup>17</sup>

- Cleavage tear of medial meniscus:
  - pain in medial joint line
  - pain aggravated by slight twisting of the joint

- pain provoked by patient lying on the side and pulling the knees together
- pain worse with activity

Arthroscopic meniscectomy is appropriate treatment, but some do settle with a trial of physiotherapy.

### A diagnostic memoire

TABLE 67.4 is a useful aid in the diagnosis of these injuries. There is a similarity in the clinical signs between the opposite menisci, but the localisation of pain in the medial or lateral joint lines helps to differentiate between the medial and lateral menisci.

*Note:* The diagnosis of a meniscal injury is made if three or more of the five examination findings (‘signs’ in TABLE 67.4) are present.

### LIGAMENT INJURIES

Tears of varying degrees may occur in the:

- anterior cruciate ligament
- posterior cruciate ligament
- medial collateral ligament
- lateral collateral ligament

### § Anterior cruciate ligament rupture

This is a very serious and disabling injury that may result in chronic instability. Chronic instability can result in degenerative joint changes if not dealt with

**Table 67.4** Typical symptoms and signs of meniscal injuries

	Medial meniscus tear	Lateral meniscus tear
<b>Mechanism</b>		
Twisting force on a weight-loaded flexed knee	Abduction (valgus) force Internal rotation of femur on tibia	Adduction (varus) force External rotation of femur on tibia
<b>Symptoms</b>		
1 Knee pain during and after activity	Medial side of knee	Lateral side of knee
2 Locking	Yes	Yes
3 Effusion	+ or –	+ or –
<b>Signs</b>		
1 Localised tenderness over joint line (with bucket handle tear)	Medial joint line	Lateral joint line (may be cyst)
2 Pain on hyperextension of knee	Medial joint line	Lateral joint line
3 Pain on hyperflexion of knee joint	Medial joint line	Lateral joint line
4 Pain on rotation of lower leg (knee at 90°)	On external rotation	On internal rotation
5 Weakened or atrophied quadriceps	May be present	May be present

FIGURE 67.15 Sites of rupture of the anterior cruciate ligament

adequately. Early diagnosis is essential but there is a high misdiagnosis rate. Sites of ACL rupture are shown in FIGURE 67.15.

### Mechanisms

- Sudden change in direction with leg in momentum
- Internal tibial rotation on a flexed knee (commonest) (e.g. during pivoting)
- Marked valgus force (e.g. a rugby tackle)
- May be associated with collateral ligament tears and meniscus injuries. The so-called 'unhappy triad' is a ruptured ACL, medial meniscus tear and medial collateral ligament tear.

### Clinical features

- Onset of severe pain after a sporting injury, such as landing from a jump, or a forced valgus rotational strain of the knee when another player falls across the abducted leg

- Immediate effusion of blood, usually within 30 minutes
- Common sports: contact sports—rugby, football and soccer, basketball, volleyball, skiing
- Differential diagnosis is a subluxed or dislocated patella
- Subsequent history of pain and 'giving way' of the knee

### Examination

- Gross effusion
- Diffuse joint line tenderness
- Joint may be locked due to effusion, anterior cruciate tag or associated meniscal (usually medial) tear
- Ligament tests:
  - anterior drawer: negative or positive
  - pivot shift test: positive (only if instability)
  - Lachman test: lacking an end point

*Note:* It may be necessary to examine the knee under anaesthesia, with or without arthroscopy, to assess the extent of injury.

### The Lachman test

This test is emphasised because it is a sensitive and reliable test for the integrity of the ACL. It is an anterior draw test with the knee at 15–20° of flexion. At 90° of flexion, the draw may be negative but the anterior cruciate torn.

### Method—Lachman test

- 1 The examiner should be positioned on the same side of the examination couch as the knee to be tested.
- 2 The knee is held at 15–20° of flexion by placing a hand under the distal thigh and lifting the knee into 15–20° of flexion.
- 3 The patient is asked to relax, allowing the knee to 'fall back' into the steadying hand and roll slightly into external rotation.
- 4 The anterior draw is performed with the second hand grasping the proximal tibia from the medial side (see FIG. 67.16) while the thigh is held steady by the other hand. The examiner's knee can be used to steady the thigh.
- 5 The feel of the end point of the draw is carefully noted. Normally there is an obvious jar felt as the anterior cruciate tightens. In an anterior cruciate deficient knee there is excess movement and no firm end point. The amount of draw is compared with the opposite knee. Movement greater than 5 mm is usually considered abnormal.

FIGURE 67.16 The Lachman test

Functional instability due to anterior cruciate deficiency is best elicited with the pivot shift test. This is more difficult to perform than the Lachman test.

### Pivot shift test

This is an important test for anterolateral rotatory instability. It is positive when anterior cruciate injuries are sufficient to produce a functional instability.

#### Method—Pivot shift test

- 1 The tibia is held in internal rotation by grasping the ankle firmly, with the knee in full extension.
- 2 A valgus force is applied to the knee with the hand placed on the lateral aspect of the knee just below it (this maximises subluxation in the presence of an ACL tear).
- 3 The knee is then flexed from 0–90°, listening for a 'clunk' of reduction. The test is positive when there is a sudden change of rhythm during flexion which corresponds to relocation of the subluxed knee. This usually occurs between 30° and 45° of flexion.
- 4 From this flexed position the knee is extended, seeking a click into subluxation. This is called a positive jerk test.

### Management<sup>17</sup>

The management depends on the finding by the surgeon. Surgical repair is reserved for complete ligament tears. This usually involves reconstruction

of the ligament using patellar or preferably hamstring tendons. Early reconstruction is appropriate in younger patients who participate in high levels of sporting activity for whom it can be predicted that functional instability will be a problem. In less active people, a conservative approach is appropriate. The ACL may be trimmed. Cruciate reconstruction can then be undertaken if the knee becomes clinically unstable. The presence of an ACL injury with a significant medial ligament injury will necessitate reconstructive surgery but this is probably best delayed for some weeks as the subsequent incidence of knee stiffness is high.

## § Posterior cruciate ligament rupture

### Mechanisms

- Direct blow to the anterior tibia in flexed knee
- Severe hyperextension injury
- Ligament fatigue plus extra stress on knee

### Clinical features

- Posterior (popliteal) pain, radiating to calf
- Usually no or minimal swelling
- Minimal disability apart from limitation of running or jumping
- Pain running downhill
- Recurvatum
- Posterior sag or draw

### Management

- Usually managed conservatively with immobilisation and protection for 6 weeks
- Graduated weight-bearing and exercises

## § Medial collateral ligament rupture

### Mechanisms

- Direct valgus force to knee—lateral side knee (e.g. rugby tackle from side)
- External tibial rotation (e.g. two soccer players kicking ball simultaneously)

### Clinical features

These depend on the degree of tear (1st, 2nd or 3rd degree):

- pain on medial knee
- aggravated by twisting or valgus stress
- localised swelling over medial aspect
- pseudo-locking—hamstring strain
- ± effusion
- no end point on valgus stress testing (3rd degree) (see FIG. 67.9a)

*Note:* Check lateral meniscus if MCL tear. Pellegrini-Stieda syndrome—calcification in haematoma at upper (femoral) origin of MCL—may follow.

### Management

If an isolated injury, this common injury responds to conservative treatment with early limited motion bracing to prevent opening of the medial joint line. Six weeks of limited motion brace at 20–70° followed by knee rehabilitation usually returns the athlete to full sporting activity within 12 weeks.

*Note:* The same principles of diagnosis and management apply to the less common rupture of the lateral collateral ligament, which is caused by a direct varus force to the medial side of the knee. However, lateral ligament injuries tend to involve the cruciate ligament and reconstruction of both ligaments is usually necessary.<sup>16</sup>

### § Complex regional pain syndrome I

A localised complex regional pain syndrome I (also known as reflex sympathetic dystrophy) can follow a direct fall onto the knee. (See CHAPTER 12.)

### Symptoms

- Hypersensitivity
- Full extension, loss of flexion
- Possible increasing sweating
- Tenderness of the joint

### OVERUSE SYNDROMES

The knee is very prone to overuse disorders. The pain develops gradually without swelling, is aggravated by activity and relieved with rest. It can usually be traced back to a change in the sportsperson's training schedule, footwear or technique, or to related factors. It may also be related to biomechanical abnormalities ranging from hip disorders to feet disorders.

Overuse injuries include:

- patellofemoral pain syndrome ('jogger's knee', 'runner's knee')
- patellar tendonopathy ('jumper's knee')
- anserinus tendonopathy/bursitis
- semimembranous tendonopathy/bursitis
- biceps femoris tendonopathy
- quadriceps tendonopathy/rupture
- popliteus tendonopathy
- iliotibial band friction syndrome ('runner's knee')
- the hamstring knee
- synovial plica syndrome
- infrapatellar fat-pad inflammation

It is amazing how often palpation identifies localised areas of inflammation (tendonopathy or bursitis) around the knee, especially from overuse in athletes and in the obese elderly (see FIG. 67.17).

FIGURE 67.17 Typical painful areas around the knee for overuse syndromes: (a) anterior aspect, (b) medial aspect

### § Patellofemoral pain syndrome

This syndrome, also known as chondromalacia patellae or anterior knee pain syndrome and referred to as 'jogger's knee', 'runner's knee' or 'cyclist's knee', is the most common overuse injury of the knee. There is usually no specific history of trauma. It may be related to biomechanical abnormalities and abnormal position and tracking of the patella (e.g. patella alta).

It usually presents in females aged 13–15 years with faulty knee mechanisms or in people aged 50–70 years with osteoarthritis of the patellofemoral joint.<sup>18</sup>

### Clinical features

- Pain behind or adjacent to the patella or deep in knee
- Pain aggravated during activities that require flexion of knee under loading:
  - climbing stairs
  - walking down slopes or stairs
  - squatting
  - prolonged sitting
- The ‘movie theatre’ sign: using aisle seat to stretch knee
- Crepitus around patella may be present

### Signs (chondromalacia patellae)

Patellofemoral crepitation during knee flexion and extension is often palpable, and pain may be reproduced by compression of the patella onto the femur as it is pushed from side to side with the knee straight or flexed (Perkins test).

### Method for special sign

See FIGURE 67.18.

- Have the patient supine with the knee extended.
- Grasp the superior pole of the patella and displace it inferiorly.
- Maintain this position and apply patellofemoral compression.
- Ask the patient to contract the quadriceps (it is a good idea to get the patient to practise quadriceps contraction before applying the test).
- A positive sign is reproduction of the pain under the patella and hesitancy in contracting the muscle.

FIGURE 67.18 Special sign of the patellofemoral pain syndrome

### Treatment

- Give reassurance and supportive therapy.
- Reduce any aggravating activity.
- Refer to a physiotherapist.
- Correct any underlying biomechanical abnormalities such as pes planus (flat feet) by use of orthotics and correct footwear.
- Employ quadriceps (especially) and hamstring exercises.
- Consider course (trial) of NSAIDs.

### § Patellar tendonopathy ('jumper's knee')

'Jumper's knee', or patellar tendonopathy (see FIG. 67.2, earlier in this chapter), is a common disorder of athletes involved in repetitive jumping sports, such as high jumping, basketball, netball, volleyball and soccer. It probably starts as an inflammatory response around a small tear.

### Clinical features

- Gradual onset of anterior pain
- Pain localised to below knee (in patellar tendon)
- Pain eased by rest, returns with activity
- Pain with jumping

The diagnosis is often missed because of the difficulty of localising signs. The condition is best diagnosed by eliciting localised tenderness at the inferior pole of the patella with the patella tilted. There may be localised swelling.

### Method

- Lay the patient supine in a relaxed manner with the head on a pillow, arms by the side and quadriceps relaxed (a must).
- The knee should be fully extended.
- Tilt the patella by exerting pressure over its superior pole. This lifts the inferior pole.
- Now palpate the surface under the inferior pole. This allows palpation of the deeper fibres of the patellar tendon (see FIG. 67.19).
- Compare with the normal side.
- Very sharp pain is usually produced in the patient with patellar tendonopathy.

### Management

Early conservative treatment including rest from the offending stresses is effective. Referral to a physiotherapist for exercise-based rehabilitation is appropriate. This includes adequate warm-up and warm-down. Training modification includes

FIGURE 67.19 Patellar tendonopathy: method of palpation

calf, hamstring and quadriceps muscle stretching. Modified footwear and a patellar tendon strap may be helpful in some cases. The use of NSAIDs and corticosteroid injections is disappointing. Chronic cases may require surgery.

### § Anserinus tendonopathy/bursitis

Localised tenderness is found over the medial tibial condyle where the tendons of the sartorius, gracilis and semitendinosus insert into the bone. It is distal to the joint line. It is a common cause of knee pain in the middle aged or elderly, especially the overweight woman. Pain is aggravated by resisted knee flexion.

### § Semimembranous tendonopathy/bursitis

This inflamed area is sited either at the tendon insertion or in the bursa between the tendon and the medial head of the gastrocnemius. It is an uncommon problem. The bursa occurs on the medial side of the popliteal fossa between the medial head of gastrocnemius and the semimembranous tendon. It often communicates with the knee joint and, if so, treat knee joint pathology. If not, one can give an injection of depot triamcinolone or betamethasone.

### § Biceps femoris tendonopathy/bursitis

The tendon and/or the bursa that lies between the tendon insertion and the fibular collateral ligament at the head of the fibula may become inflamed due to overuse. It is usually encountered in sprinters.

### § Popliteus tendonopathy

Tenosynovitis of the popliteus tendon may cause localised pain in the posterior or the posterolateral aspect of the knee. Tenderness to palpation is elicited with the knee flexed to 90°.

### § Iliotibial band syndrome

Inflammation develops over the lateral aspect of the knee where the iliotibial band passes over the lateral femoral condyle. An inflamed bursa can occur deep to the band. The problem, which is caused by friction of the iliotibial band on the bone, is common in long-distance runners, especially when running up and down hills, and cyclists. It presents with well-localised lateral knee pain of gradual onset. Palpation reveals tenderness over the lateral condyle 1–2 cm above the joint line.

### Treatment of tendonopathy and bursitis (small area)

Generally (apart from patellar tendonopathy), the treatment is an injection of local anaesthetic and long-acting corticosteroids into and deep to the localised area of tenderness. In addition it is important to restrict the offending activity and refer for physiotherapy for stretching exercises. Attention to biomechanical factors and footwear is important.

If conservative methods fail for iliotibial tract tendonopathy, surgical excision of the affected fibres may cure the problem.

### § Prepatellar bursitis

Repetitive low-grade direct trauma, such as frequent kneeling, can cause inflammation with swelling of the bursa, which lies between the anterior surface of the patella and the skin. 'Housemaid's knee', or 'carpet layer's knee', can be difficult to treat if rest from the trauma does not allow it to subside. If persistent, drain the fluid with a 23 gauge needle and then introduce 0.5–1 mL of long-acting corticosteroid. The presence of a bursa 'mouse' and persistent bursitis usually mean that surgical intervention is required.

Acute bursitis may also be caused by acute infection, or one of the inflammatory arthropathies (e.g. gout, seronegative spondyloarthropathies).

### § Infrapatellar bursitis

'Clergyman's knee' is produced by the same mechanisms as prepatellar bursitis and can be involved with inflammatory disorders or infection. Treatment is also the same.

## § The hamstrung knee

Cross describes this condition in young active sportspeople (second decade)<sup>9</sup> as one that causes bilateral knee pain and possibly a limp. It is caused by a failure to warm up properly and stretch the hamstring muscles, which become tender and tight during the growth spurt. A 6-week program of straight leg raising and hamstring stretching will alleviate the pain completely.

## § Synovial plica syndrome

This syndrome results from a synovial fold (an embryological remnant) being caught between the patella and the femur during walking or running. It causes an acute 'catching' knee pain of the medial patellofemoral joint (see FIG. 67.2, earlier in this chapter) and sometimes a small effusion. It generally settles without treatment.

## § Infrapatellar fat-pad inflammation

Acute compression of the fat-pad, which extends across the lower patella deep to the patellar tendon and into the knee joint (see FIG. 67.2, earlier in this chapter), during a jump or other similar trauma, produces local pain and tenderness similar to the sensation of kneeling on a drawing pin.<sup>19</sup>

The pain usually settles without therapy over a period of days or weeks. There is localised tenderness and it can be confused with patellar tendonopathy.

## ARTHRITIC CONDITIONS

### § Osteoarthritis

Osteoarthritis is a very common problem of the knee joint. Symptoms usually appear in middle life or later. It is more common in women, the obese, and in those with knee deformities (e.g. genu varum) or previous trauma, especially meniscal tears. The degenerative changes may involve either the lateral or the medial tibiofemoral compartment, the patellofemoral joint or any combination of these sites.

### Clinical features

- Slowly increasing joint pain and stiffness
- Aggravated by activities such as prolonged walking, standing or squatting
- Descending stairs is usually more painful than ascending stairs (suggestive of patellofemoral osteoarthritis)
- Pain may occur after rest, especially prolonged flexion
- Minimal effusion and variable crepitus
- Restricted flexion but usually full extension
- Often quadriceps wasting and tender over medial joint line
- Diagnosis confirmed by X-ray (weight-bearing view)

### Management options

- Relative rest
- Weight loss
- Analgesics and/or judicious use of NSAIDs
- Glucosamine: a Cochrane review showed that it is both safe and modestly effective (see CHAPTER 35)
- Walking aids and other supports
- Physiotherapy (e.g. hydrotherapy, quadriceps exercises, mobilisation and stretching techniques)
- Viscosupplementation: intra-articular injection of hylans
- Intra-articular injections of corticosteroids are generally not recommended but a single injection for severe pain can be very effective
- Surgery is indicated for severe pain and stiffness and includes arthroscopic debridement and wash out, osteotomy, arthrodesis and total joint replacement (see FIG. 67.20) or hemiarthroplasty, especially for the medial compartment with focal arthritis and varus deformity

FIGURE 67.20 Total joint replacement of knee

## § Rheumatoid arthritis

The knee is frequently affected by rheumatoid arthritis (RA) although it rarely presents as monoarticular knee pain. RA shows the typical features of inflammation—pain and stiffness that is worse after resting. Morning stiffness is a feature.

*Note:* The spondyloarthropathies have a similar clinical pattern to RA.

Synovectomy is a useful option with persistent boggy thickening of synovial membrane but without destruction of the articular cartilage.<sup>2</sup>

## § Baker cyst

A popliteal cyst (Baker cyst) is a herniation of a chronic knee effusion between the heads of the gastrocnemius muscle and usually is associated with osteoarthritis (most common), rheumatoid arthritis or internal derangement of the knee. It presents as a mass behind the knee and may or may not be tender or painful.

It tends to fluctuate in size.

A Baker cyst indicates intra-articular pathology and indicates a full assessment of the knee joint.

Rupture may result in pain and swelling in the calf, mimicking DVT.

Treat underlying knee inflammation (synovitis).

Surgical removal of the cyst is advisable for persistent problems.

## § Septic arthritis

This tends to be more common in the knee than other joints. Septic (pyogenic) arthritis should be suspected when the patient complains of intense joint pain, malaise and fever. In the presence of acute pyogenic infection the joint is held rigidly. The differential diagnosis includes gout and pseudogout (chondrocalcinosis).

## Principles of management

Most painful knee conditions are not serious and, providing a firm diagnosis is made and internal knee disruption or other serious illness discounted, a simple management plan as outlined leads to steady relief. For more serious injuries the primary goal is to minimise the adverse consequences of forced inactivity.

- First aid: RICE (avoid heat in first 48 hours).
- Lose weight if overweight.

- Adequate support for ligament sprains—supportive elastic tubular (Tubigrip) bandage or a firm elastic bandage over Velband.
- Simple analgesics—paracetamol (acetaminophen).
- Judicious use of NSAIDs and corticosteroid injections.
- Physiotherapy to achieve strength and stability.
- Attend to biomechanical abnormalities, inappropriate footwear and athletic techniques.
- Orthotics and braces to suit the individual patient.
- Specialised exercise techniques (e.g. the McConnell technique).<sup>2</sup>
- Quadriceps exercises: these simple exercises are amazingly effective.

## Quadriceps exercises (examples)

- Instruct the patient to tighten the muscles in front of the thighs (as though about to lift the leg at the hip and bend the foot back but keeping the leg straight). The patient should hold the hand over the lower quadriceps to ensure it is felt to tighten. This tightening and relaxing exercise should be performed at least 6 times every 2 hours or so until it becomes a habit. It can be done sitting, standing or lying (see FIG. 67.21).
- Sitting on a chair the patient places a weight of 2–5 kg around the ankle (e.g. a plastic bag with sand or coins in a sock) and lifts the leg to the horizontal and then gently lowers it (avoid in patellofemoral problems).

**FIGURE 67.21** A quadriceps exercise: with outstretched legs the quadriceps muscle is slowly and deliberately tightened by straightening the knee to position (a) from the relaxed position (b)

## When to refer

- Early referral is required for knees 'at risk' following acute injuries where one or more of the following are present:
  - locked knee
  - haemarthrosis
  - instability
- Clinical evidence of a torn cruciate ligament, third degree tear of the collateral ligaments or torn meniscus
- Undiagnosed acute or chronic knee pain
- Recurrent subluxation or dislocation of the patella
- Suspected septic arthritis
- Presence of troublesome intra-articular loose body

## Practice tips

- The absence of an effusion does not rule out the presence of severe knee injury.
- Examine the hip and lumbosacral spine if examination of the knee is normal but knee pain is the complaint.
- Always think of an osteoid osteoma in a young boy with severe bone pain in a leg (especially at night) that responds nicely to aspirin or paracetamol or other NSAID.
- Tears of the meniscus can occur, especially in middle age, without a history of significant preceding trauma.
- If a patient presents with a history of an audible 'pop' or 'crack' in the knee with an immediate effusion (in association with trauma) he or she has an ACL tear until proved otherwise.
- Haemarthrosis following an injury should be regarded as an anterior cruciate tear until proved otherwise.
- The 'movie theatre' sign, whereby the patient seeks an aisle seat to stretch the knee, is usually due to patellofemoral pain syndrome.
- The 'bed' sign, when pain is experienced when the knees touch while in bed, is suggestive of a medial meniscal cleavage tear.
- A positive squat test (medial pain on full squatting) indicates a tear of the posterior horn of the medial meniscus.
- Joint aspiration should not be performed on the young athlete with an acute knee injury.
- If an older female patient presents with the sudden onset of severe knee pain think of osteonecrosis.

- Reserve intra-articular corticosteroid injections for inflammatory conditions such as rheumatoid arthritis or a crystal arthropathy: regular injections for osteoarthritis are to be avoided. Do not give the injections when the inflammation is acute and diffuse or in the early stages of injury.
- Many inflammatory conditions around the knee joint, such as bursitis or tendonopathy, respond to a local injection of local anaesthetic and corticosteroid but avoid giving injections into the tendon, especially the patellar tendon.
- Keep in mind the technique of autologous cartilage transplantation: in this technique cartilage cells (chondrocytes) are taken from the patient, multiplied in a laboratory and eventually implanted into the damaged area. It can be used for damage in any major joint, especially the knee, being ideal for osteochondritis dissecans.

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

*The victim goes to bed and sleeps in good health. About two o'clock in the morning he is awakened by a severe pain in the great toe; more rarely in the heel, ankle, or instep . . . The part affected cannot bear the weight of the bed clothes nor the jar of a person walking in the room. The night is spent in torture.*

Thomas Sydenham (1624–89) on gout

Pain in the foot (podalgia) and ankle problems are a common occurrence in general practice. Various characteristics of the pain can give an indication of its cause, such as the description of gout by Thomas Sydenham. There are many traumatic causes of podalgia and ankle dysfunction, especially fractures and torn ligaments, but this chapter will focus mainly on everyday problems that develop spontaneously or through overuse. Forefoot pain is common especially in the elderly. The forefoot comprises the toes to the middle of the metatarsals and all of the supporting structures. Metatarsalgia is a term used to describe pain in the distal aspect of one or more of the metatarsal bones during weight-bearing.<sup>1</sup>

## Key facts and checkpoints

- Foot deformities such as flat feet (pes planus) are often painless.
- Foot strain is probably the commonest cause of podalgia.<sup>2</sup>
- A common deformity of the toes is hallux valgus, with or without bunion formation.
- Osteoarthritis is a common sequel to hallux valgus.
- Osteoarthritis affecting the ankle is relatively uncommon.
- All the distal joints of the foot may be involved in arthritic disorders.
- Many foot and ankle problems are caused by unsuitable footwear and lack of foot care.
- Ankle sprains are the most common injury in sport, representing about 25% of injuries.
- Severe sprains of the lateral ligaments of the ankle due to an inversion force may be associated with various fractures.
- Bunions and hammer toes are generally best treated by surgery.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in [TABLE 68.1](#).

## Probability diagnosis

Common causes include osteoarthritis, especially of the first metatarsophalangeal (MTP) joint, acute or chronic foot strain, plantar fasciitis, plantar skin conditions such as warts, corns and calluses and various toenail problems.

## Serious disorders not to be missed

The very important serious disorders to consider include:

- vascular disease—affecting small vessels
- diabetic neuropathy
- osteoid osteoma
- rheumatoid arthritis
- complex regional pain syndrome I

## Vascular causes

The main problem is ischaemic pain that occurs only in the foot. The commonest cause is atheroma. Vascular causes include:

- acute arterial obstruction
- chilblains
- atherosclerosis, especially small vessel disease
- functional vasospasm (Raynaud)—rare

## Symptoms:

- claudication (rare in isolation)
- sensory disturbances, especially numbness at rest or on walking
- rest pain—at night, interfering with sleep, precipitated by elevation, relieved by dependency

For treatment refer to [CHAPTER 67](#).

## Complex regional pain syndrome I

Also known as reflex sympathetic dystrophy or Sudeck atrophy, regional pain syndrome is characterised by severe pain, swelling and disability of the feet. It is a neurovascular disorder resulting in hyperaemia and osteoporosis that may be a sequela of trauma (often

trivial) and prolonged immobilisation. Complex regional pain syndrome I usually lasts 2 years and recovery to normality usually follows.

The clinical features include sudden onset in middle-aged patients, pain worse at night, stiff joints and skin warm and red. X-rays that show patchy decalcification of bone are diagnostic. Treatment includes reassurance, analgesics, mobility in preference to rest, and physiotherapy.

### Osteoid osteoma

Osteoid osteomas are rare but important little 'brain teasers' of benign tumours that typically occur in older children and adolescents. Males are affected twice as often as females. Any bone (except those of the skull) can be affected but the tibia and femur are the main sites. Nocturnal pain is a prominent symptom with pain relief by aspirin being a feature.

Diagnosis is dependent on clinical suspicion and then X-ray, which shows a small sclerotic lesion with a radiolucent centre. Treatment is by surgical excision.

### Pitfalls

There are many traps in the diagnosis and management of problems presenting with a painful foot. Common problems require consideration—these include gouty arthritis, chilblains, a stress fracture and a foreign body in the foot, especially in children. Nerve entrapment, as outlined in CHAPTER 66, is uncommon but Morton neuroma is reasonably common.

Less common disorders include complex regional pain syndrome, which is often misdiagnosed, the spondyloarthropathies (psoriasis, reactive arthritis, ankylosing spondylitis and the inflammatory bowel disorders) and osteochondritis of the calcaneus, navicular bone and metatarsal head. If there is an exquisitely tender small purple-red spot beneath a toenail, a glomus tumour (a benign hamartoma) is the diagnosis. It is worth noting that most of these conditions are diagnosed by X-rays.

### General pitfalls

- Failing to order X-rays of the foot.
- Failing to order X-rays of the ankle following injury.
- Failing to appreciate the potential for painful problems caused by diabetes—neuropathy and small vessel disease.
- Neglecting the fact that most of the arthritides can manifest in joints in the foot, especially the forefoot.

**Table 68.1** The painful foot and ankle: diagnostic strategy model

Q.	Probability diagnosis
A.	Acute or chronic foot strain Sprained ankle Osteoarthritis (esp. great toe) Plantar fasciitis Achilles tendonopathy Tibialis posterior tendonopathy Wart, corn or callus Ingrowing toenail/paronychia
Q.	Serious disorders not to be missed
A.	Vascular insufficiency: <ul style="list-style-type: none"> <li>• small vessel disease</li> </ul> Neoplasia: <ul style="list-style-type: none"> <li>• osteoid osteoma</li> <li>• osteosarcoma</li> <li>• synovial sarcoma</li> </ul> Severe infections (rare): <ul style="list-style-type: none"> <li>• septic arthritis</li> <li>• actinomycosis</li> <li>• osteomyelitis</li> </ul> Rheumatoid arthritis Peripheral neuropathy Complex regional pain syndromes Ruptured Achilles tendon Ruptured tibialis posterior tendon
Q.	Pitfalls (often missed)
A.	Foreign body (especially children) Gout Morton neuroma Tarsal tunnel syndrome Deep peroneal nerve entrapment Chilblains Stress fracture (e.g. navicular) Erythema nodosum Rarities: <ul style="list-style-type: none"> <li>• spondyloarthropathies</li> <li>• osteochondritis: navicular (Köhler), metatarsal head (Freiberg), calcaneum (Sever)</li> <li>• glomus tumour (under nail)</li> <li>• Paget disease</li> </ul>
Q.	Seven masquerades checklist
A.	Depression (?) Diabetes Drugs Spinal dysfunction
Q.	Is the patient trying to tell me something?
A.	A non-organic cause warrants consideration with any painful condition.

- Regarding the sprained ankle in adults and children as an innocuous injury: associated injuries include chondral fractures to the dome of the talus, impaction fractures around the medial recess of the ankle, avulsion fractures of the lateral malleolus and base of fifth metatarsal.
- Misdiagnosing a stress fracture of the navicular which, like the scaphoid fracture, causes delayed union and non-union. Cast immobilisation for 8 weeks initially may prevent the need for surgery.
- Misdiagnosing a complete rupture of the Achilles tendon because the patient can plantar flex the foot.
- Overlooking tibialis posterior tendonopathy as a cause of ankle pain.

### Seven masquerades checklist

The checklist has four conditions that should be considered, especially diabetes and spinal dysfunction. Diabetes may be responsible for a simple type of atherosclerotic pattern, possibly complicated by infection and ulceration. The neuropathy of diabetes can cause a burning pain with paraesthesia. It has a 'sock'-type pattern as opposed to the dermatome pattern of nerve root pressure arising from the lumbosacral spine. The common S1 pain is experienced on the outer border of the foot, into the fifth toe and on the outer sole and heel of the foot.

Drugs and anaemia could indirectly cause pain through vascular insufficiency. The drugs that could cause vasospasm include beta blockers and ergotamine. An alcoholic neuropathy also has to be considered.

### Red flag pointers for foot pain

- Pain in forefoot disturbing sleep
- Fever and systemic illness with bone pain
- Localised tenderness away from heel in child
- 'Burning' feet

### Psychogenic considerations

Any painful condition can be closely associated with psychogenic disorders, including depression.

### The clinical approach

#### History

This is very important, as always, since various characteristics of the pain can give an indication of its cause. Questions should address the quality of the pain, its distribution, mode of onset, periodicity,

relation to weight-bearing, and associated features such as swelling or colour change. It is relevant to enquire about pain in other joints such as the hand and spine, including the sacroiliac joints, which might indicate that the foot pain is part of a polyarthritis. A history of diarrhoea, psoriasis, urethritis or iritis may suggest that one of the spondyloarthropathies has to be excluded.

### Key questions

The practitioner should address the following questions:

- Does the pain arise from a local condition or is it part of a generalised disease?
- Is there a history of psoriasis, chronic diarrhoea or colitis, urethritis or iritis?
- Is pain also present in other joints, thus indicating the foot pain is part of a polyarthritis, such as rheumatoid arthritis?
- Is the problem related to unsuitable footwear?
- Does the nature of the pain point to the cause?
  - throbbing pain → inflammation
  - burning pain → nerve entrapment, diabetic neuropathy or regional pain syndrome
  - severe episodic pain → gout
  - pain worse at night → ischaemia (small vessel disease), regional pain syndrome, cramps or osteoid osteoma
  - pain worse at night, relieved by aspirin → osteoid osteoma
  - pain worse on standing after sitting and getting out of bed → plantar fasciitis

For ankle injuries it is important to ask about the nature of the injury:

- Did the foot twist in (invert) or twist out (evert)?
- Was the foot pointing down or up at the time of injury?
- Point with one finger to where it hurts (the finger-pointing sign).
- What happened immediately after the injury?
- Were you able to walk straight away?
- What happened when you cooled off?

If there has been a fall onto the foot from a height, consider the possibility of a fracture of the calcaneus or talus or disruption of the syndesmosis between the tibia and fibula.

### Examination

#### Inspection

Inspect the feet with the patient standing, sitting, walking (in shoes and barefooted) and lying down (note

plantar surfaces). Inspect the footwear (normally, a shoe wears first on the outer posterior margin of the heel).

*Note:*

- any gait abnormalities, including limping and abnormal toe in or toe out
- deformities, such as hammer toes, bunions—medial (hallux valgus) and lateral (Tailor bunion)—and claw toes
- swellings, including callosities
- muscle wasting
- skin changes and signs of ischaemia

### Palpation

Systematic palpation is very useful as most structures in the foot are accessible to palpation.

### Movements (active and passive)

The joints to test are:

- ankle (talar) joint
- hindfoot (subtalar) joint
- midfoot (midtarsal) joint

### Movements

- Plantar flexion (normal—50°) and dorsiflexion (20°) of foot (see FIG. 68.1)
- Inversion and eversion of hindfoot (mainly subtalar joint)—hold heel and abduct and adduct (see FIG. 68.2)
- Inversion and eversion of forefoot (midtarsal joint)—hold heel in one hand to fix hindfoot, hold forefoot in the other and abduct and adduct (rotation movement) (see FIG. 68.3)
- Test other joints individually (e.g. MTP, midtarsal)

FIGURE 68.1 Dorsiflexion and plantar flexion of the ankle joint

FIGURE 68.2 Testing inversion and eversion of the hindfoot

### Special tests

- Achilles tendon, including calf squeeze (Thompson or Simmond test) (see FIG. 136.17 in CHAPTER 136)
- Compress MTP joints from above and below
- Compress metatarsals mediolaterally between thumb and forefinger
- Press upwards from sole of foot just proximal to third and fourth MTP joints—Morton test
- Check circulation—test dorsalis pedis and posterior tibial pulses
- Neurological examination, including tests for L4, L5 and S1 nerve root function

### Investigations

The choice of investigations depends on the clinical features elicited by the history and examination. Select from the following list:

- for systemic diseases:
  - blood glucose
  - RA tests
  - ESR/C-reactive protein
  - HLA-B<sub>27</sub>
- serum uric acid
- radiology:
  - X-ray ± stress and weight-bearing views
  - radionuclide scans (for bone or joint pathology)
  - CT or MRI (especially helpful) scans
  - ultrasound (operator dependent)
- nerve conduction studies

*Note:* High-resolution ultrasound is used to diagnose disorders of the Achilles and posterior tibialis tendons and to locate foreign bodies such as splinters of wood and glass.

Radionuclide scanning may detect avascular necrosis in bones, stress fractures, osteoid osteomas, inflammatory osteoarthritis and similar lesions.<sup>3</sup>

FIGURE 68.3 Testing eversion and inversion of the forefoot

## Foot and ankle pain in children

Apart from the common problem of trauma, special problems in children include:

- foreign bodies in the foot
- tumours (e.g. osteoid osteoma, osteosarcoma, Ewing tumour)
- plantar warts
- osteomyelitis/septic arthritis
- ingrowing toenails
- osteochondritis/aseptic necrosis
- osteochondritis dissecans of talus (in adolescents)
- pitted keratolysis and juvenile plantar dermatosis (adolescents)
- stress fractures

Think of osteoid osteoma in children with night pain.

## OSTEOCHONDritis/ASEPTIC NECROSIS

Three important bones to keep in mind are:

- the calcaneum—Sever disorder
- the navicular—Köhler disorder
- the head of the second metatarsal—Freiberg disorder

Sever disorder is traction osteochondritis while the other disorders are a 'crushing' osteochondritis with avascular necrosis.

### § Sever disorder of the heel

This is calcaneal apophysitis, which presents in a child (usually a boy) aged 7–15 years (average of 10 years) with a painful tender heel at the insertion

of the tendoachilles. It is diagnosed by X-ray. The only treatment is to ensure that the child avoids wearing flat-heeled shoes and wears a slightly raised heel. Strenuous sporting activities should be restricted for 12 weeks and then reviewed.

### § Köhler disorder of the navicular

This disorder causes a painful limp (usually mild) with some swelling and tenderness around the navicular in a child (usually a boy) aged 3–6 years, although it is seen sometimes in older children. Complete recovery occurs with temporary resting. Sometimes a supportive strapping is helpful.

### § Freiberg disorder

This problem affects the head of the second metatarsal (rarely the third), which feels tender and swollen on palpation. It is more common in girls aged 12–16 years and can present in young adults as pain aggravated by standing on the forefoot. Plain X-ray shows the characteristic collapse of the metatarsal head. The treatment is restriction of activity, protective footwear and protective padding.

## Sprained ankle in a child

Children rarely sprain ligaments so it is important to assess apparent strains carefully, including an X-ray.

## The little athlete

The 'little athlete' can suffer a variety of injuries from accidents and overuse. Diffuse heel pain, which is common, is most often related to Sever apophysitis of the calcaneum. Occasionally, a juvenile-type plantar fasciitis may occur. Little athletes can develop tendonitis around the ankle, either on the lateral side (peroneals) or medially (tibialis posterior). Occasionally, a stress fracture of the metatarsals or other bones can occur.<sup>4</sup> Special attention must be paid to any developmental structural abnormalities and to footwear.

## Foot and ankle problems in the elderly

Foot problems are more prevalent in old age. Some are due to a generalised disease, such as diabetes or peripheral vascular disease, while others, such as bunions, hammer toes, calluses and corns, atrophy of the heel fat-pad and Morton neuroma, increase with ageing. The transverse arch may flatten out and the protective pads under the metatarsals may atrophy, resulting in painful callosities.

Unfortunately, many elderly people regard foot problems as a normal process but these problems actually require considerable care and attention, especially in the presence of peripheral vascular disease, diabetes or rheumatoid arthritis. Deformed toenails (onychogryphosis) are also common albeit not a painful condition.

Flat foot occurring in middle age is usually due to stretching or rupture of the tibialis posterior tendon.<sup>5</sup>

## § Sprained ankle

There are two main ankle ligaments that are subject to heavy inversion or eversion stresses, namely the lateral ligaments and the medial ligaments respectively. Most of the ankle 'sprains' or tears involve the lateral ligaments (up to 90%) while the stronger, tauter medial (deltoid) ligament is less prone to injury. It is important not to misdiagnose a complete rupture of the lateral ligaments.

Most sprains occur when the ankle is plantar flexed and inverted, such as when landing awkwardly after jumping or stepping on uneven ground. It is a very common sporting injury and is presented in more detail in CHAPTER 136. Note the Ottawa rules for taking an X-ray of the ankle in CHAPTER 136).

### Clinical features (sprained lateral ligaments)

- Ankle 'gives way'
- Difficulty in weight-bearing
- Discomfort varies from mild to severe
- Bruising (may take 12–24 hours) indicates more severe injury
- May have functional instability: ankle gives way on uneven ground

### Physical examination

Perform as soon as possible:

- note swelling and bruising
- palpate over bony landmarks and three lateral ligaments (see FIG. 136.12, CHAPTER 136)
- test general joint laxity and range of motion
- a common finding is a rounded swelling in front of the lateral malleolus (the 'signe de la coquille d'oeuf')
- test stability in AP plane (anterior draw sign)

### Is there an underlying fracture?

For a severe injury the possibility of a fracture—usually of the lateral malleolus or base of fifth metatarsal—must be considered. If the patient is able to walk without much discomfort straight after

the injury a fracture is unlikely. However, as a rule, ankle injuries should be X-rayed. See the Ottawa rules in CHAPTER 136.

## HEEL PAIN

Important causes of heel pain in adults (see FIG. 68.4)<sup>6</sup> include:

- Achilles tendon disorders:
  - tendonopathy/peritendonitis (see CHAPTER 136)
  - bursitis: postcalcaneal, retrocalcaneal
  - tendon tearing (see CHAPTER 136): partial, complete
- bruised heel
- tender heel pad:
  - usually atrophy
  - also inflammation
- neuropathies (e.g. diabetic, alcoholic)
- tenosynovitis (FHL, FDL)
- 'pump bumps'
- plantar fasciitis
- periostitis
- calcaneal apophysitis
- peroneal tendon dislocation
- nerve entrapments
  - tarsal tunnel
  - medial calcaneal nerve
  - nerve to abductor digiti minimi

Ultrasound examination is useful to differentiate the causes of Achilles tendon disorders.

## § Achilles tendonopathy<sup>6</sup>

The pathology is a combination of degenerative and inflammatory changes due to overuse and may occur either in the tendon itself or in the surrounding paratendon. It presents with tendon pain during and after weight-bearing activities with a tender local swelling of the tendon. The latter is called peritendonitis rather than tenosynovitis because there is no synovial sheath.

### Management

- Relative rest
- Course of NSAIDs for acute pain
- Heel padding
- Consider heel 'raisers'
- Consider continuous topical glyceryl trinitrate as patches
- Physiotherapy for stretching and an eccentric exercise program<sup>6</sup>
- Physiotherapy

## § Achilles tendon bursitis

Bursitis can occur at two sites:

- posterior and superficial—between skin and tendon
- deep (retrocalcaneal)—between calcaneus and tendon (see FIG. 68.4)

The former occurs mainly in young women from shoe friction and is readily palpated. Tenderness from the deep bursitis is elicited by squeezing in front of the tendon with the thumb and index finger: a swelling may be seen bulging on either side of the tendon.

### Treatment

- Avoid shoe pressure (e.g. wear sandals)
- 1–2 cm heel raise inside the shoe
- Apply local heat and ultrasound
- NSAIDs
- Inject corticosteroid into bursa with a 25 gauge needle

## § Fat-pad disorders

A tender heel pad or cushion causes a dull throbbing pain under the heel. It is localised more proximal to that of plantar fasciitis. Once established, it is very difficult to treat.

The fat-pad, which consists of globules of fat encapsulated in multiple U-shaped septi, acts as a hydraulic shock absorber on heel strike. It also

contains significant nerve endings.<sup>7</sup> It can undergo atrophy, especially in the elderly, and also become inflamed.

### Treatment

- Reduction of aggravating activity
- Weight loss (if applicable)
- Simple analgesics
- Orthotic (cushioning heel cup) ± foam insert
- Good footwear

Problems are treated with an orthotic or an insert and good footwear. Corticosteroids should be avoided as they can accelerate the atrophy.<sup>8</sup>

## § Plantar fasciitis

This common condition (also known as ‘policeman’s heel’) is characterised by pain on the plantar aspect of the heel, especially on the medial side; it usually occurs about 5 cm from the posterior end of the heel although it can be experienced over a wide area beneath the heel. The pain radiates into the sole.

### Clinical features

- Pain:
  - under the heel
  - first steps out of bed
  - relieved after walking
  - increasing towards the end of the day
  - worse after sitting

FIGURE 68.4 Important causes of the painful heel

- May be bilateral—usually worse on one side
- Typically over 40 years
- Both sexes
- Sometimes history of injury or overuse
- No constant relationship to footwear

### Signs<sup>8</sup>

- Tenderness:
  - localised to medial tuberosity
  - may be more posterior
  - may be lateral
  - may be widespread
  - not altered by tensing fascia (but this action may cause pain)
- Heel pad may bulge or appear atrophic
- Crepitus may be felt
- No abnormality of gait, heel strike, or foot alignment
- Patient often obese

### Treatment

Plantar fasciitis tends to heal spontaneously in 12–24 months. It has a variable response to treatment with NSAIDs, injections, ultrasound and insoles. Rest from long walks and from running is important. Systematic reviews to date indicate that taping is effective for short-term relief. Plantar fascia stretching exercises, when combined with prefabricated insoles and a short course of NSAIDs, are effective for short-term and long-term pain relief. For patients with chronic symptoms, newer extracorporeal shockwave therapy devices are effective.<sup>9</sup> Another systematic review supports a conservative approach based on maximising comfort during the 3-month period of considerable discomfort.<sup>10</sup>

### Protection

Symptomatic relief is obtained by protecting the heel with an orthotic pad to include the heel and arch of the foot (e.g. Rose insole). Otherwise, a pad made from sponge or sorbo rubber that raises the heel about 1 cm is suitable. A hole corresponding to the tender area should be cut out of the pad to avoid direct contact with the sole. The aim is to get all of the foot to take the stress.

### Injection technique

Disabling plantar fasciitis can be treated by injecting local anaesthetic and long-acting corticosteroid into the site of maximal tenderness in the heel. An alternative is to inject the corticosteroid into the anaesthetised heel and this is usually for temporary relief.

### § 'Cracked' heels

- Soak feet for 30 minutes in warm water containing an oil such as Alpha-Keri or Derma Oil.
- Pat dry, then apply a cream such as Nutraplus (10% urea) or Eulactol heel balm. Use hydrocortisone 0.5% cream for resistant cases.
- For severe cases use sorbolene cream with 20% glycerol and 30% urea (test skin sensitivity first).

## ARTHRITIC CONDITIONS

Arthritis of the foot or ankle is a rather meaningless diagnosis and specificity is required. Typical sites of arthritic targets are shown in FIGURE 68.5.

FIGURE 68.5 Typical sites of arthritic causes of podalgia on skeleton of right foot (plantar aspect)

### Osteoarthritis

Osteoarthritis may occur in any of the joints of the foot but it commonly involves the first MTP joint, leading to hallux rigidus. It can affect the subtalar joint, but the ankle joint proper is usually not affected by osteoarthritis.

## § Hallux rigidus

Osteoarthritis of the first MTP joint can lead to gradual loss of motion of the toe and considerable discomfort. Roomy protective footwear and relative rest is the basis of treatment, coupled with daily self-mobilisation (stretching toe into plantar flexion morning and night). Other measures include manipulation under general anaesthesia or surgery (arthrodesis or arthroplasty) for severe cases.

## Rheumatoid arthritis

Rheumatoid arthritis is typically a symmetrical polyarthritis presenting with pain in the MTP joints. It may also affect the ankle, mid-tarsal and tarsometatarsal joints. The interphalangeal joints are seldom affected primarily. It causes pain and stiffness under the balls of the feet, especially first thing in the morning.

## Gout

Gout typically affects the first MTP and should be considered with the sudden onset of pain, especially in the presence of redness, swelling and tenderness. It can affect any synovial joint and occasionally may be polyarticular. Gout is often dismissed by the patient as a 'sprain'. A history of alcohol consumption or diuretic treatment is relevant.

## Spondyloarthropathies

This group of arthritic disorders (reactive arthritis, ankylosing spondylitis, psoriatic arthritis and arthritides associated with chronic bowel disorders) may involve peripheral joints. Other foot involvement includes plantar fasciitis, Achilles tendonitis and sausage-shaped toes due to tenosynovitis, and arthritis of the proximal interphalangeal joints.

## 'Burning' feet

It is not uncommon for people, especially the elderly, to present with the complaint of 'burning' feet. A careful history is needed to elicit exactly what they mean by 'burning'—is it real pain, a cold sensation or paraesthesia?

A checklist of causes is as follow:

- vascular: ischaemic rest pain from small vessel disease, chilblains or other cold reaction, functional vasospasm (Raynaud phenomenon)
- diabetic neuropathy
- tarsal tunnel syndrome
- complex regional pain syndrome I or II
- Morton neuroma (localised pain between toes)
- psychogenic, especially anxiety

It is worth considering tarsal tunnel syndrome if there is anterior burning pain in the forefoot with associated aching in the calf. It is usually present in menopausal women and worse at night. It is caused by entrapment of the posterior tibial nerve near the medial malleolus, and may be associated with rheumatoid arthritis. Treat with physiotherapy, a medial arch support and a corticosteroid injection before contemplating surgery.

## FOOT STRAIN

Foot strain is probably the commonest cause of podalgia. A foot may be strained by abnormal stress, or by normal stress for which it is not prepared. In foot strain the supporting ligaments become stretched, irritated and inflamed. It is commonly encountered in athletes who are relatively unfit or have a disorder such as flat feet, or in obese adults.

## Symptoms and signs

- Aching pain in foot and calf during or after prolonged walking or standing
- Initial deep tenderness felt on medial border of plantar fascia (see FIG. 68.6)
- Worse with new shoes, especially a change to high heels

## § Acute foot strain

Acute ligamentous strain, such as occurs to the occasional athlete or to the person taking long unaccustomed walks, is usually self-limiting. It recovers rapidly with rest.

## § Chronic foot strain

Foot strain will become chronic with repeated excessive stress or with repeated normal stress on a mechanical abnormality. A common consequence is an everted foot, leading to flattening of the longitudinal arch on weight-bearing. It is important to establish whether the symptoms commenced after the patient began wearing a different type of footwear.

## Treatment

The treatment is basically the same as that of the adult flat foot. Acute strain is treated with rest and by reducing walking to a minimum. Try the application of cold initially and then heat. The management of chronic

**FIGURE 68.6** Typical sites of important causes of podalgia (other than arthritis)—right foot

strain is based on an exercise program and orthotics, including arch supports, to correct any deformity.

## Aching feet

- Avoid wearing high heels.
- Wear insoles to support the foot arch.
- Perform foot exercises.
- Soak the feet in a basin of warm water containing therapeutic salts (Epsom salts is suitable).
- Massage feet with baby oil followed by a special ribbed wooden foot massager.

## Flat feet (pes planus)

Flat feet are normal in young children. No treatment is required in flat feet in which the arch is restored by standing on tiptoe (see **CHAPTER 92**). If painful, treat with exercises and insoles. Refer if concerned. Hind foot fusion can be performed for severe pain.

## Claw foot (pes cavus)

High foot arch is usually of congenital origin. It may be secondary to polio or various neurological conditions.

The foot is inflexible and the toes may be 'hammer' or clawed. Treatment includes special orthotics with good shock-absorbing properties, appropriate footwear, foot exercises and padding under the metatarsal heads. Operative treatment involves soft tissue release or arthrodesis to strengthen toes.

## DISORDERS OF THE ANKLE TENDONS

Inflammation of a tendon sheath about the ankle may result from repetitive overuse, trauma such as a sprained ankle or unaccustomed stress, including sporting injuries.

Tenosynovitis commonly involves the tibialis posterior tendon over the medial compartment or the peroneal tendons over the lateral compartment. It may also affect the tibialis anterior and extensor digitorum longus tendons. Friction at the point where the tendons become angulated at the ankle causes the inflammation. The patient presents with pain, swelling and restricted movement. On examination there is swelling and tenderness where the tendon bulges out from behind and below the malleolus.

If necessary the diagnosis can be confirmed by ultrasound or MRI imaging.

Complications include tenovaginitis, weakness, ganglion formation, subluxation or dislocation and rupture.

Treatment of tendonitis includes partial immobilisation (rarely in a cast) or an orthotic device to support the arch of the foot.

A carefully directed injection of corticosteroid into the tendon sheath can be very effective.

### § Peroneal tendonitis

This occurs along the course of the tendon from behind the lateral malleolus to the outer side of the foot and is common in athletes and ballet dancers. Pain is reproduced on palpation, on stretching the tendons by passive inversion of the foot or by resisting eversion of the foot.

### § Peroneal tendon dislocation

It is most commonly a dislocated leg tendon as a result of forceful dorsiflexion. An audible painless snapping sensation may be experienced. Surgical repair is necessary.

### § Tibialis posterior tendonopathy

This is a common problem, especially in middle-aged females, in ballet dancers and in those with pes planus with a valgus deformity. The tendon (see

FIG. 68.7), which is an inverter of the foot, is attached to the navicular tuberosity.<sup>11</sup>

**FIGURE 68.7** Medial aspect of the foot illustrating tendon disorders: tendonopathy of tibialis anterior and tibialis posterior

### Clinical features<sup>6,11</sup>

- Pain and a feeling of weakness in the medial ankle and foot
- Pain aggravated by standing and walking
- Standing on toes is painful and difficult
- Pain on palpation anterior and inferior to the medial malleolus
- Pain on stretching into eversion
- Painful resisted active inversion
- May cause tarsal tunnel syndrome

### Diagnosis

Ultrasound examination—but MRI is the gold standard for delineating tendon tears and inflammation.<sup>12</sup>

### Treatment

This is basically conservative with a good outcome in 12–24 months.

- Orthotic correction (bilateral) with semi-rigid orthosis to support faulty arch
- Exercises under physiotherapist guidance
- Remedial massage

Consider ultrasonic guided injection of corticosteroids into tendon sheath (but best avoided) and a surgical opinion for failed conservative management.

### § Tibialis posterior tendon dislocation

This can occur with forceful ankle dorsiflexion and inversion. The patient usually experiences pain and cannot weight-bear. The dislocated tendon may be seen overlying the medial malleolus. Immediate surgical repair is recommended.

### § Tibialis posterior tendon rupture

Rupture of the tibialis posterior tendon after inflammation, degeneration or trauma<sup>13</sup> is a relatively common and misdiagnosed disorder, especially in middle-aged females. It causes collapse of the longitudinal arch of the foot, leading to a flat foot.<sup>5</sup>

It is uncommon for patients to feel obvious discomfort at the moment of rupture. They may subsequently present with the sudden appearance of an 'abnormal' flat foot. There is gross eversion of the foot.

A simple test is the 'too many toes' test whereby more toes are seen on the affected side when the feet are viewed from about 3 m behind the patient (see FIG. 68.8).<sup>5</sup>

The single heel raise test is also diagnostic. The most useful investigation is an ultrasound examination. Minor cases can be treated conservatively with orthotics, but severe problems respond well to surgical correction.

### § Sesamoiditis<sup>1</sup>

The two sesamoids that lie beneath the head of the first metatarsal may develop painful conditions such as chondromalacia, osteoarthritis and stress fractures. A special 'sesamoid' X-ray assists diagnosis. Painful callus can develop over here in the elderly. Well-designed insoles are usually effective as is surgical excision for persistent problems.

**FIGURE 68.8** Tibialis posterior tendon rupture (right foot): the 'too many toes' posterior view

### Metatarsalgia<sup>1</sup>

Metatarsalgia is a symptom rather than a disease and refers to pain and tenderness over the plantar heads of the metatarsals (the forefoot). Causes include

foot deformities (especially with depression of the transverse arch), leading to painful strain, arthritis of the MTP joints, trauma, Morton neuroma, Freiberg disorder and entrapment neuropathy. However it can occur in normal feet after prolonged standing.

Depression of the transverse arch results in abnormal pressure on the second, third and fourth metatarsal heads with possible callus formation. Repetitive foot strain, pes cavus and high heels may cause a maldistribution of weight to the forefoot.

Treatment involves treating any known cause, advising proper footwear and perhaps a metatarsal bar. Flat-heeled shoes with ample width seldom cause problems in the metatarsal region.

### § Stress fractures<sup>14</sup>

#### Clinical features

- The aches or pains may be slow in onset or sudden
- Common in dancers, especially classical ballet, and in unfit people taking up exercise
- Examination is often unhelpful: swelling uncommon<sup>12</sup>
- Routine X-rays often unhelpful
- A bone scan is the only way to confirm the suspected diagnosis
- Basis of treatment is absolute rest for 6 or more weeks with strong supportive footwear
- A walking plaster is not recommended

#### Avulsion fracture of base of fifth metatarsal

Known also as a Jones fracture, it is usually a traumatic fracture but can be a stress fracture and associated with severe ankle sprains.

#### March fracture of metatarsal

Stress or fatigue fracture of the forefoot usually involves the neck of the second metatarsal (sometimes the third). Swelling typically occurs along the bone shaft. X-ray changes are often delayed. Treat conservatively with support from a firm elastic bandage; avoid painful activities. Resolution may take many months.

#### Tarsals, especially navicular

Stress fracture of the navicular, which is a disorder of athletes involved with running sports, presents as poorly localised midfoot pain during weight-bearing. Examination and plain X-ray are usually normal. It is a recently recognised serious disorder due to

the advent of nuclear bone scans and CT scans. A protracted course of treatment can be expected.

### Calcaneum

Stress fractures of the os calcis usually have an insidious onset. Osteoporosis is a predisposing factor, as is an increased training program.<sup>14</sup>

### § Morton neuroma<sup>12</sup>

Morton interdigital neuroma is probably misdiagnosed more often than any other painful condition of the forefoot. It is not a true neuroma but a fibrous enlargement of an interdigital nerve, and its aetiology is still uncertain. It is related to overuse and inappropriate footwear. The diagnosis is made on clinical grounds. An ultrasound examination may detect a neuroma.

#### Clinical features

- Usually presents in adults <50 years
- Four times more common in women
- Bilateral in 15% of cases
- Commonest between third and fourth metatarsal heads (see FIG. 68.9), and second and third (otherwise uncommon)
- Severe burning pain (sometimes sharp and shooting) between third and fourth or second and third toes

FIGURE 68.9 Morton neuroma: typical site and pain and paraesthesia distribution

- Worse on weight-bearing on hard surfaces (standing and walking)
- Aggravated by wearing tight shoes
- Relieved by taking off shoe and squeezing the forefoot
- Localised tenderness between metatarsal heads

## Treatment

Early problems are treated conservatively by wearing loose shoes with a low heel and using a sponge rubber metatarsal pad. An orthosis with a dome under the affected interspace helps to spread the metatarsals and thus takes pressure off the nerve. Any biochemical abnormalities of the foot should be corrected. Most eventually require surgical excision, preferably with a dorsal approach. A corticosteroid injection can be considered.

## § Hallux valgus

Hallux valgus with associated bunion formation and splaying of the forefoot is common. It may be a consequence of poor-fitting footwear.

A bunionette, also caused by pressure, may form over the fifth metatarsal.

Pain, if present, may be due to shoe pressure on an inflamed bunion, a hammer toe, metatarsalgia or secondary arthritis of the first MTP joint.

Hallux valgus with bunions should be treated by correcting footwear prior to any surgical correction. Systematic evidence-based reviews found that preventive orthoses and night splints were unlikely to be beneficial but absorbable pin fixation was likely to be beneficial.<sup>9</sup>

## § Hammer toes<sup>1</sup>

Mainly involve the second toe with extended MTP joint, hyperflexed PIP joint and extended DIP joint. Painful corns will appear over the prominent joint.

They respond well to surgery if problematic and are not helped by good footwear.

## § Claw toes

Often follows polio. The feature is extended MTP joint, flexion PIP and DIP. Refer for surgical opinion.

## § Calluses, corns and warts

The diagnosis of localised, tender lumps on the sole of the foot can be difficult. The differential diagnosis of callus, corn and wart is aided by an understanding of their morphology and the effect of paring these lumps (see TABLE 68.2).

## Calluses

A callus (see FIG. 68.10) is simply a localised area of hyperkeratosis related to some form of pressure and friction. It is very common under the metatarsal heads, especially the second.

## Treatment

No treatment is required if asymptomatic. Remove the cause. Proper footwear is essential—wide enough shoes and cushioned pads over ball of foot. Proper paring gives relief, also filing with callus files. If severe, apply daily applications of 10% salicylic acid in soft paraffin with regular paring.

## Corns

A corn (see FIG. 68.11) is a small, localised, conical thickening. It is a horny plug of keratin in the epidermis. A corn develops in response to chronic

**Table 68.2** Comparison of the main causes of a lump on the sole of the foot

	Typical site	Nature	Effect of paring
Callus	Where skin is normally thick: beneath heads of metatarsals, heels, inframedial side of great toe	Hard, thickened skin	Normal skin 
Corn	Where skin is normally thin: on soles, fifth toe, dorsal projections of hammer toes	White, conical mass of keratin, flattened by pressure	Exposes white, avascular corn with concave surface 
Wart	Anywhere, mainly over metatarsal heads, base of toes and heels; has bleeding points	Viral infections, with abrupt change from skin at edge	Exposes bleeding points 

irritation, usually over a bony prominence of the foot, e.g. outer distal fifth toe. It is associated with poorly fitting footwear, excessive activity or faulty intrinsic foot mechanics. It may resemble a plantar wart but gives a different appearance on paring.

### Treatment

Remove cause of friction and use wide shoes to allow the foot to expand to its full width. Soften corn with a few daily applications of 15% salicylic acid in collodion or commercial 'corn removers' with salicylic acid and then pare. For soft corns between the toes (usually last toe-web) keep the toe-webs separated with lamb's wool or a cigarette filter tip at all times and dust with a foot powder.

FIGURE 68.10 Callus

FIGURE 68.11 Corn

### Plantar warts

A plantar wart (see FIGS. 68.12 and 68.13 and CHAPTER 126) is more invasive, and paring reveals multiple small, pinpoint bleeding spots.

FIGURE 68.12 Plantar wart

FIGURE 68.13 Plantar warts on the sole of the foot and toes showing a mosaic pattern

### Methods of removal<sup>15</sup>

There are many treatments for this common and at times frustrating problem. A good rule is to avoid scalpel excision, diathermy and electrocautery because of the problem of scarring. One of the problems with the removal of plantar warts is the 'iceberg' configuration—not all the wart may be removed.

- Salicylic acid 17%, lactic acid 17% in collodion:
  - apply daily, dry and cover
- Liquid nitrogen:
  - pare wart (a 21 gauge blade is recommended)
  - apply liquid nitrogen
  - repeat weekly

Can be painful and the results are often disappointing.

- Topical chemotherapy:
  - soak feet in warm water, then pare wart (particularly in children)
  - apply Upton's paste or salicylic acid (up to 27%) gel or cream to wart each night and cover

- review if necessary

(Upton's paste comprises trichloroacetic acid 1 part, salicylic acid 6 parts, glycerin 2 parts.)

- Topical chemotherapy and liquid nitrogen:
  - pare wart
  - apply paste of 70% salicylic acid in raw linseed oil
  - occlude for 1 week
  - pare on review, then apply liquid nitrogen and review
- Curettage under local anaesthetic:
  - pare the wart vigorously to reveal its extent
  - thoroughly curette the entire wart with a dermal curette
  - hold the foot dependent over kidney dish until bleeding stops (this always stops spontaneously and avoids a bleed later on the way home)
  - apply 50% trichloroacetic acid to the base

### Occlusion method

Occlusion with topical chemotherapy: a method of using salicylic acid alone or in a paste under a special occlusive dressing is described.

#### Equipment

- 2.5 cm (width) elastic adhesive tape
- 30% salicylic acid in Lassar's paste of plasticine consistency

#### Method

- 1 Cut two lengths of adhesive tape, one about 5 cm and the other shorter.
- 2 Fold the shorter length in half, sticky side out (see FIG. 68.14a).
- 3 Cut a half-circle at the folded edge to accommodate the wart.
- 4 Press this tape down so that the hole is over the wart.
- 5 Roll a small ball of the paste in the palm of the hand and then press it into the wart.
- 6 Cover the tape, paste and wart with the longer strip of tape (see FIGS. 68.14b).

This paste should be reapplied twice weekly for 2–3 weeks. The reapplication is achieved by peeling back the longer strip to expose the wart, adding a fresh ball of paste to the wart and then recovering with the upper tape.

The plantar wart invariably crumbles, and vanishes. If the wart is particularly stubborn, 50% salicylic acid can be used.

FIGURE 68.14 Treatment of plantar wart: (a) 'window' to fit the wart is cut out of shoulder of elastic adhesive tape, (b) larger strip covers the wart and shoulder strip

### § Ingrown toenail (onychocryptosis)

Ingrown toenail is a very common condition, especially in adolescent boys. Although not so common in adults, it may follow injury or deformity of the nail bed. It is typically located along the lateral edges of the great toenail and represents an imbalance between the soft tissues of the nail fold and the growing nail edge. The basic cause is a redundant skin fold. It is exacerbated by faulty nail trimming, constricting shoes and poor hygiene. A skin breach is followed by infection, then oedema and granulation tissue of the nail fold.<sup>5</sup>

#### Prevention

All patients should be instructed on correct foot and nail care. Foot hygiene includes foot baths, avoiding nylon socks and frequent changes of cotton or wool socks. Cotton wool pledgets can be placed beneath the nail edge to assist separation.

It is important to fashion the toenails so that the corners project beyond the skin (see FIG. 68.15). The end of the nail (not the corners) should be cut squarely so that the nail can grow out from the nail fold. Then each day, after a shower or bath, use the pads of both thumbs to pull the nail folds as indicated.

FIGURE 68.15 Method of fashioning toenails

### Treatment (surgical)<sup>15</sup>

- 1 *Excision of ellipse of skin.* This 'army method' transposes the skin fold away from the nail. The skin heals, the nail grows normally and the toe retains its normal anatomy.
- 2 *Electrocautery.* This is similar in principle to the preceding method but is simple, quick and very effective with minimal after-pain, especially for severe ingrowing with much granulation tissue. Under digital block the electrocautery needle removes a large wedge of skin and granulation tissue so that the ingrown nail stands free of skin (see FIG. 68.16).

FIGURE 68.16 Treatment of ingrown toenail: electrocautery of wedge of tissue

- 3 *Skin wedge excision.* Another similar method under digital block is to dissect away all the skin fold adjacent to the nail, starting from the nail base, extending proximally for about 4 mm and then sweeping around the side of the nail to under its tip, using a 3–4 mm margin all the way.
- 4 *Wedge of nail excision and phenolisation.* This method uses 80% phenol (concentrated solution)

to treat the nail bed following excision with scissors of a wedge for about one quarter of the length (rather than a standard wedge resection) of the ingrown nail. A cotton wool stick soaked in phenol is introduced deep into the space of the nail bed.

**Warning:** Take care not to spill the phenol onto the surrounding skin as it is very corrosive.

### § Paronychia

Initial treatment:

- antiseptic (e.g. Betadine-soaked) dressing
- elevation of nail fold to drain pus
- application of petroleum gauze dressing
- antibiotics if extensive or cellulitis developing

Sometimes the nail requires avulsion to establish free drainage of a periungual abscess. Refer to CHAPTER 129.

### Practice tips

- Good-quality X-rays are mandatory in all severely sprained ankle injuries.
- If in doubt about the diagnosis of a painful foot—X-ray.
- Children rarely sprain ligaments. All joint injuries causing pain and swelling in children need to be X-rayed.
- Think of the rare problem of a dislocating peroneal tendon if a sharp click and stab of pain is experienced just behind and below the lateral malleolus.
- Paraesthesia of part or whole of the foot may be caused by peripheral neuropathy, tarsal tunnel syndrome, mononeuritis (e.g. diabetes mellitus), rheumatoid arthritis or a nerve root lesion from the lumbosacral spine.
- Avoid giving injections of corticosteroids into the Achilles tendon.
- Avoid invasive procedures such as surgical excision, diathermy or electrocautery for plantar warts. Be aware of the limitations of liquid nitrogen.
- High-resolution ultrasound can help diagnose Achilles tendon disorders.
- Keep in mind the possibility of pain around the sesamoid bones of the first metatarsal.
- Beware of acral lentiginous melanoma on the sole of the foot, especially if amelanotic (see CHAPTER 127).

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education*  
6th edition:

- Bunions
- Calluses, corns and warts on feet
- Flat feet
- Ingrowing toenails
- Plantar fasciitis

*Would ye not think his cunning to be great that could restore this cripple to his legs again?*

William Shakespeare (1564–1616), *King Henry VI*, Part II, Act 2, Scene 1

The clinical evaluation of the patient presenting with difficulty walking can be very complex, especially for abnormal gaits caused by neurological conditions. Not all gaits fall into a single category; gait disturbances may be multifactorial, especially in the elderly.

Non-neurological conditions are the most common cause of walking difficulties. They include various arthritic conditions of the lower limbs, usually presenting as a limp, other mechanical factors, such as swelling of the legs, disorders of circulation such as intermittent claudication, and general debility (e.g. malignancy, anaemia and endocrine disorders such as hyperparathyroidism).

It is important for the general practitioner not to overlook hypokalaemia and drugs or the myopathies as a cause of walking difficulty. The drugs that require special consideration include alcohol, corticosteroids, chloroquine, colchicine, clofibrate, bretylium, HMG-CoA reductase inhibitors (the statins), gemfibrozil, penicillamine, diuretics, beta blockers and general anaesthetic agents.

## Abnormal gaits

It is convenient to classify abnormal gaits as painless or painful (antalgic). With antalgic gaits the rhythm is disturbed; with painless abnormal gaits the contour is affected. One type of skeletal mechanical abnormality is described as arthrogenic (due particularly to hip disorders) and a second type as osteogenic (due to a shortened limb).

Neurogenic gaits and myogenic gaits are considered together below, under the heading 'Neurological disorders of gait'.

Psychogenic or 'hysterical' gait may have to be considered if the gait is bizarre or seems greatly exaggerated. On the other hand, loss of confidence, especially in the elderly, is an important cause of gait disturbance. However, many abnormal gaits that are caused by neurological disease may also appear bizarre, and caution is advised. Doubtful cases should be referred for an expert opinion.

## Examination of gait and posture<sup>1</sup>

Disorders of gait and posture go hand in hand because of a common physiological process.

The source of the abnormality is indicated.

- 1 Ask the patient to stand.  
Note any difficulty in reaching a standing position. Difficulty = proximal muscle weakness.
- 2 Ask the patient to stand with eyes closed (Romberg test).  
If positive (sways or falls) = loss of proprioception (e.g. peripheral neuropathy).
- 3 Ask the patient to walk (ensure sufficient testing length).

Gait initiation:	hesitancy = basal ganglia or frontal cortex
Stride length:	very short = basal ganglia or frontal cortex irregular = cerebellar
Narrow or broad base:	narrow = UMN, muscle weakness, basal ganglia broad = cerebellum, proprioception, vestibular
Stiff or 'sloppy':	stiff = UMN, basal ganglia sloppy = LMN, muscle weakness
Heel strike:	loss of normal strike = UMN, LMN, myopathy
High stepping:	positive = LMN (distal), proprioception, muscle weakness
Arm swing:	decreased = basal ganglia, UMN (frontal lobes)
Pelvis control:	Trendelenburg gait = proximal muscle weakness

- 4 Ask the patient to walk using provocation tests.

'Tightrope' walk:	tests proprioception
Stand on tiptoes and back on the heels:	tests distal muscle weakness

Note: Peripheral neuropathy is a common cause of LMN lesion.

## Neurological disorders of gait

### Cerebellar (ataxic) gait

The patient has difficulty standing, has a broad-based stance and an unsteady gait, with swaying from side to side. It has been described as the 'dirty diaper' gait. The patient may stagger or bump into walls and may be accused of being drunk. When asked to walk in a straight line the patient tends to veer towards the side of the lesion. Ask the patient to walk 'heel to toe' in a straight line and perform a heel-knee-shin test to demonstrate cerebellar ataxia. Significant causes are multiple sclerosis, alcoholic cerebellar degeneration and space-occupying lesions. Cannot climb stairs.

### Basal ganglia gait (Parkinson type)

Identifying this disorder in its early stages can be difficult as the first sign may be a limp with one leg being described as weak or stiff or slow.<sup>2</sup> However, the typical gait is a shuffling of the feet with small steps in a forward flexed posture, rather like a person walking with a belt around the ankles. This leads to a hurrying (festinant) gait as though there is an impending feeling of falling forward. There is hesitation in starting.

### Spastic gait

Spastic gait may be regarded as the typical bilateral or paraplegic gait, or as a hemiplegic gait. With the former the gait affects both legs—they are stiff or weak, leading to slow, jerking walking, dragging of the feet and scraping of the toes. This scuffling can be heard as the front of the shoe drags along the ground. Every step can be a struggle and the patient may appear as though walking through glue on the floor.

A scissor-type gait will develop with bilateral hip adduction. Spasticity is caused by a UMN lesion, including multiple sclerosis and spinal cord compression. The typical UMN posture is of a flexed upper limb and an extended lower limb.

With hemiplegia the patient drags the affected leg stiffly with the hips adducted, the knee extended and the foot plantar flexed, leading to scraping of the toes. Mounting stairs can be very difficult, especially if clonus is induced with dorsiflexion of the foot.

### Foot drop gait

The patient cannot dorsiflex the foot, leading to a high-stepping gait with extra flexion of the hip and knee to lift the foot off the ground. The foot then slaps down on the ground.

### Vestibular gait

If unilateral the patient tends to veer off to the side of the lesion.

### Apraxia

With apraxia of gait (due to a prefrontal lobe lesion) there is a failure of control of the legs. The patient may stand up and try to walk but looks with bewilderment at the legs (the 'glued to the floor' effect) and moves them in an inappropriate manner with a broad-based, small-stepping unsteady gait. Turning is difficult. Apraxia is caused by bilateral cortical involvement, such as normal pressure hydrocephalus, multi-infarct states and tumours of the corpus callosum.<sup>2</sup>

### Neurogenic claudication

With intermittent claudication of the cauda equina, due to spinal canal stenosis, the patient develops pain in the leg after walking a certain distance. However, weakness and numbness are usually more prominent than pain.

### Drop attacks

In a drop attack the patient suddenly falls to the ground, without other symptoms, and gets up almost immediately. There is no loss of consciousness. Drop attacks can be caused by disorders such as epilepsy, Parkinson disease and vertebrobasilar insufficiency. However, in most cases, particularly middle-aged and elderly women, there is no obvious cause. (See CHAPTER 54.)

### Waddling (myopathic) gait

A waddling gait is usually caused by muscular dysfunction affecting the pelvic girdle muscles and trunk. There is a wide-based gait with a marked 'rocking and rolling' body swing from side to side and related compensatory movements of the pelvis, that is, a bilateral Trendelenburg gait. Cannot climb stairs.

### Proximal muscle weakness

The patient may complain when getting out of a low chair or going up or downstairs. The weakness can be demonstrated by asking the patient to squat down and, after a second, rise from the squatting position.<sup>2</sup> Waddling of gait reflects extreme cases. Causes include myopathies, motor neurone disease and Guillain-Barré syndrome.

### Distal muscle weakness

This causes a high-stepping gait as the foot is floppy and tends to flap, with walking similar to foot drop

gait. Causes include peripheral neuropathy, myotonic dystrophy and peroneal muscular atrophy.

## Limp

Limp is a symptom commonly associated with painful disorders of the lower limb, especially of the hip and knee joints. A limp implies an asymmetrical gait pattern caused by one of four general factors:

- 1 unequal leg length
- 2 antalgic (painful) gait (e.g. hip disorder)
- 3 restricted joint movement (e.g. ankylosed knee)
- 4 neuromuscular weakness (e.g. poliomyelitis)

Limp has an inseparable relationship with painful hip and buttock conditions, especially those of the hip. Painful hip and pelvic conditions that cause limp are presented in **CHAPTER 65**.

## Limp in adults

In adults the cause of limp is usually more obvious than in children and is commonly due to degenerative osteoarthritis of the hip or knee, to spinal disorders, especially sciatica caused by a disc prolapse, or to overuse disorders of the knee, ankle or foot. Other causes to consider are trauma to the back and legs, vestibular ataxia, Parkinson disease and intermittent claudication.

## Limp in children

The child who limps presents an interesting diagnostic dilemma. The limp must be considered to be due to a definite organic cause, although conversion reactions can be a factor.<sup>3</sup> It is appropriate to focus initially on the hip. The diagnostic strategy is presented in **TABLE 69.1**.

Limp can be considered as acute, subacute or chronic. An acute limp may be due to injury, infection (osteomyelitis, septic arthritis), spinal injuries, a fracture or an irritable hip (transient synovitis). Subacute causes include juvenile rheumatoid arthritis and tumour or leukaemia. Chronic causes include cerebral palsy, DDH, Perthes disorder and chronic SCFE.

### Key facts and checkpoints

- Trauma, sepsis and DDH are perhaps the most common reasons for an infant to limp and refuse to walk. However, a painless waddling gait suggests DDH or Perthes disorder, which usually begins with a painless limp.
- Multiple fractures and epiphyseal separations in toddlers are highly suggestive of child battering;

a skeletal survey should be ordered if this is suspected.

- Perthes disorder can present from ages 4–12 years but is usually found from 4–8 years with a peak age of 5–7 years.
- Infections of and around the hip joints are most common in infancy. Classically, the hip is held immobile in about 30° of flexion with slight abduction and external rotation. The commonest organism is *Staphylococcus aureus*, followed by *Haemophilus influenzae*.
- Tuberculosis may also occur in children (usually under 10 years) with a presentation similar to Perthes disorder.
- SCFE typically presents in the obese adolescent (10–15 years) with knee pain and a slight limp.
- Growing pains are a controversial issue but do appear to exist as an aching myalgia usually manifest in the leg muscles (anterior thigh, calf, posterior knee). The pain is bilateral, non-articular and usually unrelated to activity.

## A diagnostic approach

### History

The age of the patient gives a diagnostic pointer. A careful history, especially of trauma, may lead to the diagnosis. A history of injury is usually but not always available. The relationship of the limp to exercise and footwear is significant. The location of any associated pain is relevant: low back pathology can refer to the buttocks and hip pathology can cause knee pain.

### Examination

The hip and knee joints should be carefully examined if the source of limp has no specific localisation. Get the child to walk and run on the toes and heels (if appropriate). Note the gait and check whether it is antalgic (painful), hemiplegic (the arm is held out in a balancing action) or Trendelenburg (classic for DDH). Look for evidence of muscular dystrophy. Never forget to examine the soles of the feet and between the toes.

### Investigations

The following have to be considered:

- FBE and ESR
- blood culture
- needle aspiration of joint
- radiological: plain X-ray, ultrasound, bone scan, CT or MRI scan

**Table 69.1** Limp in children: diagnostic strategy (modified)

## Management

Management is based on the cause. Surgical drainage supplemented with antibiotics is essential for septic arthritis. If the child initially has a limp and cannot walk, admit them to hospital for:

- skin traction
- FBE and ESR
- ultrasound of hip
- blood culture

## SPECIFIC CONDITIONS

### § Osteomyelitis

Acute haematogenous osteomyelitis is mainly a disease of childhood, occurring in the proximal ends of long bones, particularly the femur and tibia. It should be suspected in a child with an acute febrile illness, unwillingness to move the limb and 'fingertip' tenderness near one of the large points (the metaphysis). Main organisms—*S. aureus*, *S. pneumoniae*, *Kingella kingae*. Sources of infection—boils, abscesses, septic toes, surgical procedures. Consider impaired immunity and diabetes.

Blood should be collected for FBE, ESR and culture (positive in 60%). A plain X-ray and nuclear scan are valuable but may not provide immediate confirmation of the diagnosis (may be normal for first 10 days). The child should be admitted to hospital, an IV line should be inserted and IV antibiotics commenced to cover the organisms involved—empirical therapy:

di(flucloxacillin):<sup>4</sup> 50 mg/kg up to 2 g IV 6 hourly; adjust according to culture and sensitivity results<sup>4</sup>

### § Septic arthritis

Septic arthritis should be suspected in a child with pyrexia and an acute arthritis with limited motion. Manage as for osteomyelitis.

### § Bone tumour

Chronic limp is a common presentation of malignant bone tumours. Radiological investigation is mandatory.

### § Irritable hip syndrome (transient synovitis)

Typical age is 3–8 years and the child presents with an acute limp with restricted hip motion. Plain X-ray is normal. Orthopaedic assessment is recommended.

### § Perthes disorder, SCFE and DDH

Refer to CHAPTER 65.

### § Paget disease

Paget disease of bone (osteitis deformans) is a chronic focal disorder of the adult skeleton in which new soft bone replaces localised areas of normal bone. The cause is unknown but a viral aetiology is suspected. There is a great increase in bone turnover with

osteoclastic resorption followed by increased but disorganised osteoblastic activity. The disorder is quite common:

- 1 in 200 of the population at 40 years
- 1 in 10 of population at 90 years

Paget disease is usually asymptomatic but some patients may present with deep aching pain in the lower back and lower limbs. They may also present with a disturbance of gait due to unequal leg length, osteoarthritis of associated joints such as the knee or hip, or a change in the distribution of mechanical forces in the lower extremities (see FIG. 69.1).

### Clinical features<sup>5</sup>

- Male:female ratio = 2:1.
- 95% asymptomatic (discovered by X-ray or raised serum alkaline phosphatase [ALP] level).
- Symptoms may include joint pain and stiffness (e.g. hips, knees), bone pain (usually spine), deformity, headache and deafness.
- Bone pain is typically deep and aching; it occurs at rest, particularly at night.
- Signs may include deformity, enlarged skull ('hats don't fit any more'), bowing of tibia, waddling gait, hyperdynamic circulation (see FIG. 69.2).
- Bones most commonly affected, in decreasing order, are the pelvis, femur, skull, tibia, vertebrae, clavicle and humerus.

### Diagnosis

- Raised serum ALP level (often very high >1000 U/L). A result >125 U/L suggests active disease.<sup>6</sup>

*Note:* calcium and phosphate normal.

**FIGURE 69.1** Paget disease of the left leg showing deformity of the tibia with a 'saber' tibia due to its enlargement of length and bulk

- Plain X-ray: dense expanded bone—best seen in skull and pelvis.

*Note:* Can mimic prostatic secondaries so every male Pagetic patient should have a DRE and serum PSA test.

- Bone isotopic scans: useful in locating specific areas.
- Watch for the uncommon complication of osteogenic sarcoma.

*Note:* screen siblings and children every 5 years after the age of 40.<sup>6</sup>

### Treatment<sup>5,6</sup>

The major goals are relief of pain, normal biochemical indices of bone turnover and prevention of long-term complication (e.g. deafness, deformities).

**FIGURE 69.2** Paget disease: possible clinical features

Localised and asymptomatic disease requires no treatment.

Three groups of drugs are currently available:

- the calcitonins
- the bisphosphonates—e.g. etidronate, pamidronate disodium (APD), alendronate, risedronate
- various antineoplastic agents (e.g. mithramycin)

Bisphosphonates have become the preferred drugs for first-line therapy and include:<sup>6</sup>

- alendronate 40 mg (o) daily for 6 months (oesophagitis can be problematic)
- pamidronate disodium 30–60 mg IV infused over 2–4 hours (usually the preferred option)
- risedronate 30 mg (o) daily for 2 months
- tiludronate 400 mg (o) daily for 3 months
- zoledronic acid 5 mg IV over at least 15 minutes, once yearly

All oral agents should be taken on an empty stomach.

Repeated doses may rarely be required in severe cases as judged by symptoms and disease activity (e.g. monitoring with serum ALP).

## Leg swelling

### Diagnostic features and pitfalls

- Not all swollen legs require investigation and treatment.
- The significance of leg swelling varies according to the age group, whether it is bilateral or unilateral, and whether the onset is sudden or gradual (see TABLE 69.2).
- If the onset of oedema is acute (often <72 hours) suspect DVT.<sup>7</sup>
- DVT must be considered in all unilateral cases and ultrasound examination performed if appropriate.
- If a DVT is present, consider occult malignancy (e.g. pancreatic cancer).
- Consider pelvic cancer causing lymphatic obstruction in a woman >40 years presenting with painless unilateral leg oedema.
- A drug history is essential as several drugs can cause oedema.
- Pitting oedema is a feature of venous thrombosis or insufficiency, not lymphatic obstruction.

### Investigations

Select from these first-line tests:

- urinalysis (? albumin)
- FBE and ESR

**Table 69.2** Leg and ankle swelling: diagnostic strategy

Q. Probability diagnosis
A. Physiological: <ul style="list-style-type: none"> <li>• dependency/gravitational</li> <li>• prolonged sitting, standing, walking</li> <li>• hot weather</li> <li>• pregnancy</li> <li>• mechanical (e.g. constricting clothing)</li> </ul> Chronic venous insufficiency (varicose veins) Congestive cardiac failure Drugs (e.g. calcium antagonists, NSAIDs, steroids, glitazones, beta blockers) Local trauma Obesity
Q. Serious disorders not to be missed
A. Vascular: <ul style="list-style-type: none"> <li>• deep venous thrombosis (DVT)</li> <li>• inferior vena cava thrombosis</li> <li>• thrombophlebitis</li> </ul> Infection: <ul style="list-style-type: none"> <li>• cellulitis</li> <li>• tropical infections (e.g. filariasis, hookworm)</li> </ul> Cancer: <ul style="list-style-type: none"> <li>• obstruction from pelvic cancer</li> <li>• localised malignancy</li> </ul> Other: <ul style="list-style-type: none"> <li>• kidney disease (e.g. nephrotic syndrome)</li> <li>• liver disease (e.g. cirrhosis)</li> <li>• skin allergy (e.g. angioneurotic oedema)</li> </ul>

## Calf swelling of sudden onset

Causes to consider:

- acute arterial occlusion
- ruptured Baker cyst
- ruptured medial head of gastrocnemius
- DVT (usually gradual)
- cellulitis/erysipelas
- compartment syndrome

Pain accompanies most of these conditions but the absence of pain does not exclude DVT or thrombophlebitis. Refer to **CHAPTER 66**.

## § Lipoedema and lipedemia

Lipoedema is the development of bilateral leg swelling that does not involve the feet (in lymphoedema the swelling develops in the most distal part of the foot). Lipoedema is fat and fluid while lipedemia is fat only.

### Clinical features

- Exclusive to obese women
- Sparing the feet
- Bilateral and symmetrical distribution of fat
- The legs are often painful and bruise easily
- The Stemmer sign (the ability to pick up a fold of skin at the base of the large toe) is usually negative<sup>8</sup>

*The most important requirement of the art of healing is that no mistakes or neglect occur. There should be no doubt or confusion as to the application of the meaning of complexion and pulse. These are the maxims of the art of healing.*

Palpitations are an unpleasant awareness of the beating of the heart. By definition it does not always imply 'racing' of the heart but any sensation in the chest, such as 'pounding', 'flopping', 'skipping', 'jumping', 'thumping' or 'fluttering' of the heart. The problem requires careful attention and reassurance (if appropriate) because heartbeat is regarded as synonymous with life. To the practitioner it may simply represent anxiety or it could be a prelude to a cardiac arrest. In many circumstances prompt referral to a cardiologist is imperative.

## Key facts and checkpoints

- The symptom of palpitations is suggestive of cardiac arrhythmia but may have a non-cardiac cause.
- Palpitations not related to emotion, fever or exercise suggest an arrhythmia.
- Perhaps the commonest arrhythmia causing a patient to visit the family doctor is the symptomatic premature ventricular beat/complex (ventricular ectopic).
- The commonest cause of an apparent pause on the ECG is a blocked premature atrial beat/complex (atrial ectopic).
- A 12-lead electrocardiographic diagnosis is mandatory. If the cause is not documented, an ambulatory electrographic monitor (e.g. Holter) may be used.
- Consider myocardial ischaemia as a cause of the arrhythmia.
- Consider drugs as a cause, including prescribed drugs and non-prescribed drugs such as alcohol, caffeine and cigarettes.
- Common triggers of paroxysmal supraventricular tachycardia (PSVT) include anxiety and cigarette smoking.
- The commonest mechanism of any arrhythmia is re-entry.
- Get patients to tap out the rate and rhythm of their abnormal beat.

Huang Ti (The Yellow Emperor) (2697–2597 BC)

## A diagnostic approach

A summary of the diagnostic strategy model is presented in **TABLE 70.1**, which includes significant causes of palpitations.

## Probability diagnosis

If the palpitations are not caused by anxiety or fever, the common causes are sinus tachycardia and premature complexes/ectopics (atrial or ventricular). Sinus tachycardia, which by definition is a rate of 100–160/min, may be precipitated by emotion, stress, fever or exercise.

PSVT and atrial fibrillation are also quite common arrhythmias. Some cardiologists claim that the commonest arrhythmia causing a patient to visit the family doctor is the symptomatic ventricular ectopic beat.<sup>1</sup>

Sinus tachycardia can be differentiated clinically from PSVT in that it starts and stops more gradually than PSVT (abrupt) and has a lower rate of 100–150 compared with 160–220.

Important causes of tachyarrhythmias are:

- ischaemic heart disease, especially acute coronary syndrome
- hypertension
- heart failure
- mitral disease
- thyrotoxicosis
- atrial septal deficit

## Serious disorders not to be missed

It is vital not to overlook acute coronary syndromes as a cause of the arrhythmia manifesting as palpitations. About 25% of infarcts are either silent or unrecognised.

Sinister life-threatening arrhythmias are:

- ventricular tachycardia
- atypical ventricular tachycardia (torsade de pointes)
- sick sinus syndrome (SSS)
- complete heart block

**Table 70.1** Palpitations: diagnostic strategy model

Q.	Probability diagnosis
A.	Anxiety Premature beats (ectopics) Sinus tachycardia Drugs (e.g. stimulants) Supraventricular tachycardia
Q.	Serious disorders not to be missed
A.	Myocardial infarction/angina Arrhythmias: • atrial fibrillation/flutter • ventricular tachycardia • bradycardia • sick sinus syndrome • torsade de pointes Long QT syndrome Wolff-Parkinson-White (WPW) syndrome Electrolyte disturbances: • hypokalaemia • hypomagnesaemia • hypoglycaemia (type 1 diabetes)
Q.	Pitfalls (often missed)
A.	Fever/infection Pregnancy Menopause (sudden vasodilatation) Drugs (e.g. caffeine, cocaine) Mitral valve disease Aortic incompetence Hypoxia/hypercapnia Rarities: • tick bites (T1–5) • phaeochromocytoma
Q.	Seven masquerades checklist
A.	Depression Diabetes (indirect) Drugs Anaemia Thyroid disorder (hyperthyroidism) Spinal dysfunction UTI (possible)
Q.	Is the patient trying to tell me something?
A.	Quite likely. Consider cardiac neurosis, anxiety.

It is also important not to miss:

- hypokalaemia
- hypomagnesaemia

## Pitfalls

There are many pitfalls in the diagnosis and management of arrhythmias, especially in the

elderly, where symptoms of infection may be masked. Palpitations associated with the menopause can be overlooked. Valvular lesions, usually associated with rheumatic heart disease, such as mitral stenosis, and aortic incompetence may cause palpitations. The rare tumour, phaeochromocytoma, presents with palpitations and the interesting characteristic of postural tachycardia (a change of more than 20 beats/min). The toxin from tick bites in dermatomes T1–5 can cause palpitations.

## General pitfalls

- Misdiagnosing PSVT as an anxiety state
- Overlooking a cardiac arrhythmia as a cause of syncope or dizziness
- Overlooking atrial fibrillation (AF) in the presence of a slow heartbeat
- Overlooking mitral valve prolapse in a patient, especially a middle-aged woman presenting with unusual chest pains and palpitations (auscultate in standing position to accentuate click(s) ± murmurs)

## Seven masquerades checklist

Surprisingly, all the masquerades have to be considered, either as direct or indirect causes: depression, especially with anxiety and in the postpartum period; diabetes, perhaps as an arrhythmia associated with a silent myocardial infarction or with hypoglycaemia; drugs as a very common cause (see TABLE 70.2); anaemia, causing a haemodynamic effect; hyperthyroidism; spinal dysfunction of the upper thoracic vertebrae T1–5; and urinary tract infection, especially in the elderly.

PSVT has been described as resulting from injury or dysfunction of the upper thoracic spine (especially T4 and T5) in the absence of organic heart disease.<sup>2</sup> The author has personally encountered several cases of PSVT alleviated by normalising function of the spine.

## Psychogenic considerations

Emotional factors can precipitate a tachycardia, which in turn can exaggerate the problem in an anxious person. Some people have a cardiac neurosis, often related to identification with a relative or friend. A family history of cardiac disease can engender this particular anxiety. Evidence of anxiety and depression should be sought in patients presenting with palpitations without clinical evidence of cardiovascular disease.

**Table 70.2** Some drugs that cause palpitations

Alcohol
Alendronate
Aminophylline/theophylline
Amphetamines
Antipsychotics (e.g. CPZ, haloperidol, olanzapine)
Antiarrhythmic drugs
Antidepressants:
• tricyclics
• MAO inhibitors
Atropine, hyoscine, hyoscyamine
Caffeine
Cocaine
Class 1a and 1c drugs
Digitalis
Diuretics → K ↓, Mg ↓
Glyceryl trinitrate
Sympathomimetics:
• in decongestants (e.g. pseudoephedrine, ephedrine)
• β-agonists (e.g. salbutamol, terbutaline)
Thyroxine

## The clinical approach

Careful attention to basic detail in the history and examination can point the way clearly to the clinical diagnosis.

## History

Ask the patient to describe the onset and offset of the palpitations, the duration of each episode and any associated features. Then ask the patient to tap out on the desk the rhythm and rate of the heartbeat experienced during the 'attack'. If the patient is unable to do this, tap out the cadence of the various arrhythmias to find a matching beat.

An irregular tapping 'all over the place' suggests atrial fibrillation, while an isolated thump or jump followed by a definite pause on a background of a regular pattern indicates premature beats (ectopics/extrasystoles) usually of ventricular origin. The thump is not the abnormal beat but the huge stroke volume of the beat following the compensatory pause.

## Key questions

- Do the palpitations start suddenly? How long do they last?
- What do you think brings them on?
- Are they related to stress or worry or excitement?
- What symptoms do you notice during an attack?
- Do you have pain in the chest or breathlessness during the attack?
- Do you feel dizzy or faint during the attack?
- What medications do you take?
- How much coffee, tea, Coke do you drink?
- Have you been using nasal decongestants?
- Did you eat Chinese food before the attack?
- Do you smoke cigarettes, and how many?
- Do you take any of the social drugs, such as cocaine or marijuana?
- Have you ever had rheumatic fever?
- Have you lost weight recently or do you sweat a lot?

Chest pain may indicate myocardial ischaemia or aortic stenosis; breathlessness indicates anxiety with hyperventilation, mitral stenosis or cardiac failure; dizziness or syncope suggests severe arrhythmias such as SSS and complete heart block, aortic stenosis and associated cerebrovascular disease.

## Examination

The ideal time to examine the patient is while the palpitations are being experienced. Often this is not possible and the physical examination is normal. Measurement of the heart rate may provide a clue to the problem.

As a working guide, a rate estimated to be about 150 beats/minute suggests PSVT, atrial flutter/fibrillation or ventricular tachycardia (see FIG. 70.1). A rate less than 150 beats per minute is more likely to be sinus tachycardia, which may be associated with exercise, fever, drugs or thyrotoxicosis.<sup>3</sup>

Assess whether the pulse is regular or irregular. If irregular, the possible causes are ectopic beats, atrial fibrillation and atrial flutter with varying degrees of block.

The nature of the pulse, especially the pulse pressure and rhythm, should be carefully evaluated (see FIG. 70.2). Look for evidence of fever and infection and features of an anxiety state or depressive illness.

Have the patient hyperventilate for 3 minutes to determine whether the arrhythmia is induced. Evidence of underlying disease such as anaemia, thyroid disorder, alcohol abuse or cardiac disease including the JVP and pulmonary congestion should be sought. Also look for evidence of a mitral valve

FIGURE 70.1 Heart rate guide to causes of various arrhythmias

FIGURE 70.2 Various pulse forms

**FIGURE 70.3** Signs to consider in a patient with palpitations

prolapse (mid-systolic click; late systolic murmur). Possible signs in the patient presenting with palpitations are shown in **FIGURE 70.3**.<sup>4</sup>

## Investigations

The number and complexity of investigations should be selected according to the problem and test availability. A checklist would include:

- blood tests (for underlying disease):
  - haemoglobin and film
  - thyroid function tests
  - serum electrolytes and magnesium
  - serum digoxin ? digitalis toxicity
  - virus antibodies ? myocarditis
- chest X-ray
- cardiac (ischaemia and function):
  - ECG (12 lead)
  - ambulatory 24-hour ECG monitoring
  - echocardiography (to look for valvular heart disease and assess left ventricular function)
  - electrophysiology studies
  - exercise stress test (? underlying CAD)
  - event monitor (can record up to 2 weeks)
  - implantable monitor (may last 1 year)

## Palpitations in children

Children may complain of palpitations which may be associated with exercise, fever or anxiety. Various arrhythmias can occur with three requiring

special consideration—PSVT, heart block and ventricular arrhythmias.<sup>5</sup>

PSVT is characterised by beats at 200–300 per minute, the fastest rates occurring in infants. The cause is often not found but some children have ECG abnormalities compatible with the Wolff–Parkinson–White (WPW) syndrome. The recommended first-line treatment of PSVT is vagal stimulation via the application of ice packs to the upper face (forehead, eyes and nose) of the affected infant. Intravenous adenosine will usually terminate the episode.

A particular concern is these children who have the familial long QT syndrome. They are prone to develop ventricular tachyarrhythmias, which may lead to sudden death. Consider it in children developing syncope on exertion.

## Palpitations in the elderly

The older the patient, the more likely is the onset of palpitations due to cardiac disease such as myocardial infarction/ischaemia, hypertension, arrhythmias and drugs, especially digoxin. Occasional atrial and ventricular arrhythmias, especially premature complexes (ectopics), occur in 40% of old people<sup>6</sup> and treatment is rarely required. Atrial fibrillation occurs in 5–10% of patients over 65 years of age, 30% of whom have no clinical evidence of cardiovascular disease. A rapid ventricular rate with symptoms is the only indication for digoxin in the elderly but beware of SSS, especially if dizziness or syncope accompanies the fibrillation.

In the elderly, thyrotoxicosis may present as sinus tachycardia or atrial fibrillation with only minimal signs—the so-called ‘masked thyrotoxicosis’—so it is easy to overlook it. The only clue may be bright eyes (‘thyroid glitter’) due to conjunctival oedema (see CHAPTER 23).

## Arrhythmias

### Facts and figures

- See FIGURE 70.4 for tracings of important arrhythmias.
- Cardiac arrhythmias account for about 25% of management decisions in cardiology (see TABLE 70.3).
- Commonest are premature (ectopic) ventricular beats and atrial fibrillation.
- PSVT is next most common—6 per 1000 of population.
- The commonest mechanism of paroxysmal tachycardias is re-entry (see FIG. 70.5).

**Table 70.3** Types of arrhythmias

Non-pathological sinus rhythms

Sinus arrhythmia

Sinus bradycardia

Sinus tachycardia

Pathological bradyarrhythmias

Sinus node disease (sick sinus syndrome)

Atrioventricular (AV) block:

- first degree AV block
- second degree AV block
- third degree (complete) AV block

Pathological tachyarrhythmias

1 Atrial:

- atrial premature (ectopic) complexes
- PSVT
- atrial flutter
- atrial fibrillation (AF)

2 Ventricular:

- ventricular premature (ectopic) complexes
- ventricular tachycardia
- ventricular fibrillation
- torsade de pointes (twisting of points)

- Electrophysiological studies are the gold standard investigation for tachycardias but are rarely needed for diagnosing most arrhythmias.
- Almost all antiarrhythmic drugs have a proarrhythmic potential (i.e. they may worsen existing arrhythmias or provoke new arrhythmias in some patients) (see TABLE 70.4). Always consider the no-treatment option.
- Avoid digoxin in cases with an accessory pathway.
- If ‘quinidine syncope’ occurs, consider torsade de pointes as the cause.
- Any patient commencing antiarrhythmic therapy should have a 12-lead ECG 1–2 weeks later to check the QT interval. If prolonged, treatment should usually be ceased.
- The two main indications for permanent pacemaking are SSS (only if symptomatic) and complete heart block.

### Management strategies

- Treat the underlying cause.
- Give appropriate reassurance.
- Provide clear patient education.
- Explain about the problems of fatigue, stress and emotion.

normal sinus rhythm

sinus bradycardia and sinus arrhythmia—rate approx. 55 per minute

sinus tachycardia—rate approx. 100 per minute

complete heart block

atrial flutter

atrial fibrillation

FIGURE 70.4 Tracings of important arrhythmias

*continued*

FIGURE 70.4 Tracings of important arrhythmias *continued*

- Advise moderation in consumption of tea, coffee, caffeine-containing soft drinks and alcohol.
- Advise about cessation of smoking and other drugs.

### § Sinus bradycardia

Look for causation (e.g. hypothyroidism and drugs). Correct the cause. Treatment is required only if symptomatic, which is uncommon at rates >40–45 beats/min. Use IV atropine if acute treatment is

required. However, mild or transient bradyarrhythmias may be asymptomatic or even physiological, such as in a healthy athlete. Palpitations are not a feature but they can cause dizziness, fatigue or syncope (e.g. Stokes–Adams attack—transient bradycardia due to complete heart block).

### Stokes–Adams attack

- Sudden onset without warning
- Patient falls to ground

**FIGURE 70.5** Diagrammatic mechanism of re-entry tachycardia

- Collapse with loss of consciousness
- Pallor and still as if dead with slow or absent pulse
- Recovery—in seconds back to normal
- Patient flushes as pulse increases
- Refer for management as attacks may be recurrent

## PREMATURE (ECTOPIC) COMPLEXES

### § Premature (ectopic) atrial complexes

- These are usually asymptomatic.
- Management is based on reassurance.
- Check lifestyle factors such as excess alcohol, caffeine, stress and smoking; avoid precipitating factors.
- Treatment is rarely required and should be avoided if possible.
- At present there is no ideal anti-ectopic agent.
- They may be a forerunner of other arrhythmias (e.g. PSVT, atrial fibrillation).
- For intolerable symptoms give:<sup>6</sup>

atenolol or metoprolol 25–100 mg (o) daily  
or  
verapamil SR 160–480 mg (o) daily

**Table 70.4** Electrophysiological classification of common antiarrhythmic drugs (after Vaughan Williams)

Class	Drug	Usual dosage	Common side effects
I	Membrane depressant drugs (sodium-channel blockers)		
Ia	Disopyramide Procainamide Quinidine	100–200 mg qid 1 g qid IV use 2–3 SR tabs (0.25 g) bd	Blurred vision, dry mouth, urinary problems in males (avoid in men >50) Anorexia, nausea, urticaria Diarrhoea, headache, tinnitus
Ib	Lignocaine Mexiletine	IV use 200 mg tid	Nausea, dizziness, tremor Nausea, vomiting, tremor, dizziness
Ic	Flecainide	100 mg bd	Nausea, dizziness, rash
II	β-blockers	various	Fatigue, insomnia, nightmares, hypotension, bronchospasm Avoid in asthmatics
III	Prolong action potential Amiodarone Sotalol	SVT: 200 mg daily VT: 400 mg daily 80–160 mg bd	Rash, pulmonary fibrosis, thyroid, hepatic and CNS effects As for β-blockers
IV	Calcium channel blockers Verapamil Diltiazem	(SR) 160–480 mg daily (CR) 180–360 mg daily	Constipation, dizziness, hypotension Hypotension, headache

*Note:* Sotalol is a β-blocker and thus is a class II and III agent. All drugs are taken orally unless IV indicated. Adenosine and digoxin are not classified.

## § Premature (ectopic) ventricular complexes

- These are also usually asymptomatic (90%).
- They occur in 20% of people with 'normal' hearts.
- Symptoms are usually noticed at rest in bed at night.
- Check lifestyle factors as for atrial premature beats.
- Drugs that can cause both types of premature beats include digoxin and sympathomimetics.
- Look for evidence of ischaemic heart disease, mitral valve prolapse (especially women), thyrotoxicosis and left ventricular failure.
- Ventricular premature complexes may be a forerunner of other arrhythmias (e.g. ventricular tachycardia).
- If symptomatic but otherwise well with a normal chest X-ray and ECG, reassure the patient.
- Drug therapy. Never commence drug therapy without performing an echocardiograph. This will help to guide the choice of agent. Class 1 agents can make the arrhythmia worse or even life-threatening if there is reduced ventricular function. If this is the case, the patient should be referred to a cardiologist.
- For troublesome symptoms the  $\beta$ -blockers, atenolol or metoprolol, can be used e.g. atenolol 25–100 mg (o) daily.

## Supraventricular tachycardia<sup>7</sup>

- SVT can be paroxysmal or sustained.
- Rate is 150–220/min.
- There are at least eight different types of SVT with differing risks and responses to treatment.
- PSVT commonly presents with a sudden onset in otherwise healthy young people.
- Passing copious urine after an attack is characteristic of PSVT.
- Look for predisposing factors such as an accessory pathway and thyrotoxicosis.
- Approximately 60% are due to atrioventricular (AV) node re-entry and 35% due to accessory pathway tachycardia (e.g. WPW).<sup>8</sup>
- Look for evidence of accessory pathways after reversion because accessory pathways can lead to sudden death (avoid digoxin in WPW).
- Consider SSS in a patient with SVT and dizziness.

## Wolff–Parkinson–White syndrome

The structural basis for the arrhythmia of SVT in WPW syndrome is an accessory pathway that

bypasses the AV node. A typical ECG shows a short PR interval and slurred upstroke of the QRS complex (delta wave). Patients are prone to sudden attacks of SVT. Up to 30% of patients will develop atrial fibrillation or flutter. Even one episode of PSVT requires consideration for radiofrequency ablation.<sup>9</sup>

## Management of PSVT

- 1 Vagal stimulation can be attempted. Carotid sinus massage is the first treatment of choice. Other methods of vagal stimulation include:
  - Valsalva manoeuvre (easiest for patient)
  - self-induced vomiting
  - ocular pressure (avoid)
  - cold (ice) water to face or swallowing ice
  - immersion of the face in water
- 2 If vagal stimulation fails
 

give adenosine IV (try 6 mg first over 5–10 seconds, then 12 mg in 2 minutes if unsuccessful, then 18 mg in 2 minutes if necessary and well tolerated). Second-line treatment is verapamil IV 1 mg/min up to 10–15 mg (provided patient is not taking a beta blocker).<sup>8</sup>

Precautions

  - Adenosine causes less hypotension than verapamil but may cause bronchospasm in asthmatics
  - Use only if narrow QRS and BP >80 mm Hg
  - Carefully monitor blood pressure
  - AVOID verapamil if taking  $\beta$ -blockers and persistent tachycardia with QRS complexes >0.14 s (suggests ventricular tachycardia)
- 3 In the rare event of failure of medical treatment, consider DC cardioversion or overdrive pacing.

## Prevention

To prevent recurrences (frequent episodes) use atenolol or metoprolol, flecainide (only if no structural heart damage) or sotalol. If these agents fail, consider amiodarone. Do an echocardiograph first to exclude structural heart disease. Radiofrequency catheter ablation, which is usually curative, is indicated for frequent attacks not responding to medical therapy.

## Carotid sinus massage<sup>1</sup>

Carotid sinus massage causes vagal stimulation and its effect on SVT is all or nothing. It has no effect on ventricular tachycardia. It slows the sinus rate and breaks the SVT by blocking AV nodal conduction.

### Method

- Locate the carotid pulse in front of the sternomastoid muscle just below the angle of the jaw (see FIG. 70.6).
- Ensure that no bruit is present.
- Rub the carotid with a circular motion for 5–10 seconds.
- Rub each carotid in turn if the SVT is not 'broken', but never both together.

In general, right carotid pressure tends to slow the sinus rate and left carotid pressure tends to impair AV nodal conduction.

### Precautions

Avoid in the elderly (risk of embolism or bradycardia).

FIGURE 70.6 Carotid sinus massage

## § Atrial fibrillation

### Facts and figures

- A common problem (9% incidence in the over-70 age group).
- It usually presents with an irregular ventricular rate of about 160–180 beats/minute in untreated patients with a normal AV node.
- Apart from acute AF (new onset <48 hrs), it tends to fall into one of the 'three Ps' patterns:
  - paroxysmal AF: abrupt onset, spontaneous return to normal rhythm (lasts <48 hrs)

- persistent AF: abrupt onset, lasts >7 days
- permanent (chronic) AF: cannot be converted to normal rhythm

All types appear to have a similar risk for thromboembolism.

- Remember to look for the underlying cause: myocardial ischaemia (15% of cases), mitral valve disease, thyrotoxicosis, hypertension, pericarditis, cardiomyopathy including chronic alcohol dependence, alcohol binge.
- No cause is found in 12%—isolated<sup>9,10</sup> atrial fibrillation.
- All patients should have thyroid function tests and an echocardiograph to help find a cause.
- With sustained atrial fibrillation there is a 5% chance per annum of embolic episodes. There is a fivefold risk of CVA overall.
- The risk of CVA is greater in those with previous CVA, valvular heart disease, prosthetic mitral valve and cardiac failure.
- For reversion anticoagulate with warfarin for 4 weeks beforehand and maintain for 4 weeks afterwards.
- Digoxin controls the ventricular rate but does not terminate or prevent attacks.
- Sotalol, flecainide and amiodarone are used for conversion of atrial fibrillation and maintenance of sinus rhythm. Flecainide should never be prescribed in patients with reduced LV function.
- Evidence basis: RCTs showed that digoxin was beneficial for lowering the ventricular rate in the short term but no better than placebo in restoring rhythm. Beta blockers and calcium-channel antagonists benefited rate control but verapamil was much less effective than amiodarone at restoring cardiac rhythm.<sup>11</sup>

## § Atrial flutter

The ECG of atrial flutter has a regular saw-tooth baseline ventricular rate of 150 with narrow QRS complexes. This is a 2:1 AV block. It is often misdiagnosed as SVT. Rarely, conduction occurs 1:1, giving a ventricular rate of 300/min.

### Treatment for atrial fibrillation/flutter<sup>8,9</sup>

To address rate and rhythm control and prevent stroke it is best to refer or consult a specialist. The treatment needs to control the arrhythmia either as the rate or the rhythm and also from the viewpoint of prophylaxis against thromboembolic complications.

The AFFIRM<sup>12</sup> study confirmed that there was no statistically significant difference between the rate and rhythm of control groups. However, patients fare marginally better (in terms of mortality) with just rate control rather than trying to get them back into sinus rhythm if they are asymptomatic in atrial fibrillation.

## Rate control

### Rapid, urgent control of ventricular rate:

verapamil 1 mg/min IV up to maximum 15 mg then orally

or

metoprolol 5 mg (1 mg/min) IV to max 20 mg (provided no evidence of heart failure and well-monitored BP)

### Routine control and maintenance<sup>8</sup>

verapamil SR 160–480 mg (o) daily

or

diltiazem CR 180–360 mg (o) daily

or

atenolol or metoprolol 25–100 mg (o) bd

Digoxin still has a place in the elderly, especially with cardiac failure:

digoxin 0.0625–0.25 mg (o) daily according to age, plasma creatinine and digoxin level

## Rhythm control

This should be considered if the patient is symptomatic and the arrhythmia is of recent onset—less than 6 months.

### Medical cardioversion

Sotalol or amiodarone or flecainide.

If the rate cannot be well controlled despite maximal medical therapy, consider AV node ablation and a permanent pacemaker. Atrial fibrillation with a rapid ventricular response over a long period gradually causes left ventricular dysfunction.

### Electrical DC cardioversion

This can be given for first-line treatment or for failed medical conversion.

### The use of oral anticoagulation in atrial fibrillation<sup>8</sup>

(Refer to CHAPTER 133.)

The decision to use an oral anticoagulant or an antiplatelet agent (e.g. aspirin), especially in the

younger patient, is difficult and should be made in consultation with a cardiologist. If aspirin is indicated, use:

aspirin 100–300 mg (o) daily

If oral anticoagulation is indicated, use:

warfarin, start with a low dose (e.g. 2–4 mg) and maintain a relatively low INR of 2–3 with regular checks.

or

a new oral anticoagulant (NOAC)

## Advances in treatment of arrhythmias

Apart from special rate-responsive pacemakers for bradycardia, there are several new modalities of treatment for complex arrhythmias, including means of blocking the re-entry phenomenon.

### Surgery

Guided by electrophysiological monitoring, surgeons can dissect a small section of the AV ring to ensure that all aberrant connections between the atria and the underlying ventricular muscle are severed.

### Catheter electrode ablation

Specific abnormal foci in the conducting pathways can be ablated using direct current electrical surgery or radiofrequency ‘burns’ via a catheter electrode. Radiofrequency ablation, which will probably supplant surgery as a form of treatment, is indicated for recurrent episodes of supraventricular tachycardia, accessory pathways and nodal re-entry tachycardia with success rates of up to 95%. Catheter ablation for atrial fibrillation is more complex and still evolving. Success rates at best are 60–80%.

### Automatic implantable cardiac defibrillator (AICD)

This expensive implant is the most effective therapy yet devised for the prevention of sudden cardiac death in patients with documented sustained ventricular tachycardia or fibrillation. Operative mortality should be less than 10%, after which survival at 1 year is over 90%. These new defibrillators incorporate an antitachycardia pacemaker. Patients can either be paced out of arrhythmia or, if they develop ventricular fibrillation, they can be defibrillated using higher energy.

TABLE 70.5 presents summary of the treatment of arrhythmias.

**Table 70.5** Summary of treatment of arrhythmias<sup>7,8</sup>

Arrhythmia		First line	Second line	Third line
Sinus tachycardia		Treat cause Reduce caffeine intake	Metoprolol or atenolol or Verapamil (rarely indicated)	
Bradycardia				
Sick sinus syndrome		Permanent pacing if symptomatic		
AV block				
First degree		No treatment		
Second degree:				
• Mobitz I		No treatment		
• Mobitz II		Consider pacing	Pacing if problematic	
Third degree:				
• acute (e.g. MI)		Temporary pacing	Adrenaline IV	
• chronic		Permanent pacing		
Atrial tachyarrhythmias				
PSVT		Valsalva Carotid sinus massage	Adenosine IV or Verapamil IV	DC cardioversion Class III drug ? Ablation
Atrial fibrillation } Atrial flutter }	Rate control Rhythm control	$\beta$ -blocker or verapamil (with care) to control rate  Rhythm control with cardioversion, electrical or drugs	Add digoxin (if necessary)  Cardioversion $\rightarrow$ or Maintenance of sinus rhythm $\rightarrow$	AV node ablation + permanent pacemaker Electrical or chemical Sotalol, flecainide, amiodarone
Atrial premature complexes		Treat cause Check lifestyle	Metoprolol or atenolol or Verapamil	
Ventricular tachyarrhythmias				
Ventricular premature beats		Treat cause Check lifestyle	$\beta$ -blocker (especially mitral valve prolapse)	Class I or III drugs (rarely needed)
Ventricular tachycardia: • non-sustained • sustained		$\beta$ -blocker or amiodarone or sotalol if stable—if not: DC shock	Lignocaine IV	DC cardioversion
Ventricular fibrillation		DC cardioversion (see <b>CHAPTER 88</b> )	IV adrenaline if fine VF then DC cardioversion	Amiodarone (maintenance) Class III (if recurrent)

## When to refer<sup>13</sup>

Patients should be referred to a cardiologist<sup>12</sup> when:

- a sustained supraventricular tachycardia is suspected
- a sustained ventricular tachycardia is suspected
- an ECG shows sustained delta waves of WPW syndrome, even if asymptomatic
- syncope or dizziness suggests a cardiovascular cause

- a paroxysmal arrhythmia may be the cause of unexplained cardiovascular symptoms
- anticoagulation has to be considered

## Practice tips

- Atrial fibrillation and dizziness (even syncope) are suggestive of SSS (bradycardia–tachycardia syndrome), which is made worse by digoxin.

*continued*

*continued*

- Consider thyrotoxicosis as a cause of atrial fibrillation or sinus tachycardia even if clinical manifestations are not apparent.
- Check for a history of palpitations in a patient complaining of dizziness or syncope (and vice versa). Consider an arrhythmia, especially in the elderly.
- PSVT is rarely caused by organic heart disease in young patients.
- Arrhythmia of sudden onset suggests PSVT, atrial flutter/fibrillation or ventricular tachycardia.
- A normal ECG in sinus rhythm does not exclude an accessory pathway.
- Consider conduction disorders such as the WPW syndrome in PSVT. Avoid digoxin in WPW syndrome.
- Common triggers of premature beats and PSVT are smoking, anxiety and caffeine (especially 8 or more cups a day).

*Sleep . . . is the first great natural resource to be exhausted by modern man. The erosion of the nerves, not to be halted by any reclamation project, public or private.*

Irwin Shaw, 'The Climate of Insomnia', *The New Yorker*, 1949

Sleep is one of the five great innate drives in humans. Disorder of this basic function is one of the most common health-related problems presenting to the GP. It may represent the clue to some very important disorders, such as depression, anxiety, adverse drug reactions, drug abuse and obstructive sleep apnoea (OSA). About half of the population report having some sleep-related problem in a year, with 25% of the Australian population reporting trouble getting enough sleep.<sup>1</sup> Normal sleep requirement varies considerably.

Sleep is divided into rapid eye movement (REM—also called dream sleep), as shown by EEG studies, and non-rapid REM sleep, which is subdivided into stages 1, 2 and 3. Most stage 3 sleep (deepest) occurs in the first hours. REM sleep is accompanied by dreaming and physiological arousals.

Disorders of the sleep–wake cycle, which are invariably caused by a disruption of the body's endogenous time clock, can result in insomnia or hypersomnolence (excessive sleepiness) or a combination of both. This is a feature of people experiencing the jet lag of international travel and shift workers.

## Key facts and checkpoints

- Normal sleep: in a fit young person the ideal is 7.5–8 hours; latency <30 minutes; wakefulness within sleep usually <5% of time.
- Humans can stay awake without a problem for 16–18 hours. Sleepiness is wake-state instability.
- The evaluation of sleep disorders involving the sleep–wake cycle is enhanced by the patient keeping a sleep chart.
- It is important to take a drug history from patients complaining of insomnia or hypersomnolence.
- Drugs that can disturb sleep include alcohol, nicotine, antihistamines, selective serotonin reuptake inhibitors (SSRIs), caffeine, hypnotics, venlafaxine, selected  $\beta$ -blockers,  $\beta_2$ -agonists,

theophylline, corticosteroids, sympathomimetic agents.

- Sleep disorders in children, including snoring, should be taken seriously and investigated. They have many consequences, such as learning difficulties, hyperactivity, behavioural disorders, failure to thrive and short stature.
- Be wary of young people and others presenting with insomnia with some urgency, especially requesting temazepam capsules—they may be dependent on benzodiazepines.
- People with OSA usually present with the TATT syndrome—'tired all the time'. These patients are often unaware of waking or becoming aroused during the night.
- A patient who snores, has witnessed apnoeas and sleepiness is likely to have OSA.
- The majority of cases of excessive somnolence are caused by OSA and narcolepsy.<sup>2</sup>
- Non-pharmacological therapies, which include basic education and practice of sleep hygiene and behavioural therapy, should be used in management wherever possible.
- Referral to the new generation, specialist sleep disorder centres provides enhanced objective evaluation, diagnosis and treatment of the more complex disorders.
- It is illegal for a driver with a commercial driver's licence to continue to drive while suffering from untreated OSA.

## Sleep-related disorders

Disorders of sleep are a common and significant contribution to community illness and death. For example, it is known that untreated moderate to severe OSA has an 11–13% 5-year mortality and a 37% 8-year mortality, mainly from cardiovascular and motor vehicle accident related deaths.<sup>3,4</sup> A classification of sleep disorders is presented in TABLE 71.1.<sup>5</sup>

**Table 71.1** Classification of sleep and wake disorders (DSM-5)<sup>5</sup>

Insomnia disorder
Hypersomnolence disorder
Narcolepsy
Breathing-related sleep disorders
• obstructive sleep apnoea/hypopnoea
• central sleep apnoea
• central alveolar hypoventilation syndrome
Circadian rhythm sleep disorders
Non-REM* sleep arousal disorder
Nightmare disorder
REM* sleep behaviour disorder
Restless legs syndrome
Substance- or medication-induced sleep disorder

\* REM = rapid eye movement

Many conditions may disturb breathing during the night (see FIG. 71.1). Nocturnal dyspnoea may

result from cardiac causes (mitral stenosis, ischaemic cardiomyopathy, cardiac arrhythmias, fluid overload or retention), which usually present with orthopnoea, pulmonary crepitations and peripheral oedema. Asthma is another common cause of nocturnal dyspnoea, cough (with or without wheeze) occurring classically between 2 am and 5 am. Gastro-oesophageal reflux with or without aspiration may disturb respiration at night, but it usually presents with daytime or postural reflux. All these conditions can usually be differentiated from sleep apnoea clinically or with further investigation.

The sleep apnoea syndromes are a common group of disorders that result in periodic hypoventilation during sleep. They occur in about 2% of the general population in all age groups, and in about 10% of middle-aged men.

## Insomnia

Insomnia is defined as the inability to initiate or maintain sleep. Insomniac patients may complain of difficulty getting to sleep or staying asleep, of frequent intermittent nocturnal arousals, early morning awakening or combinations of these.

**FIGURE 71.1** Significant causes of sleep disturbance

A careful history is required because some patients have unrealistic expectations about the required amount of sleep they need or have misperceptions of how long they have slept.

When taking the history, explore lifestyle factors, especially psychological reasons, painful conditions, drug use and abuse, appetite, energy, sexual issues and physical factors. Check thyroid status, especially hyperthyroidism.

### Management<sup>6</sup>

- 1 Contract with the patient: discuss and agree to the therapeutic objective with the patient (e.g. to reinstate sleep without medication).
- 2 Sleep–wake history: take a sleep–wake history (preferably with a sleep diary) and evaluate daytime functioning.
- 3 Exclude and treat any underlying problem (see TABLE 71.2).
- 4 Explanation and reassurance, including patient education handout.
- 5 Sleep hygiene advice:
  - Try to recognise what helps patient to settle best (e.g. warm bath, listening to music).
  - Establish a routine before going to bed.
  - Regular daytime exercise.
  - Regular time of arising.
  - Avoid daytime naps.
  - Avoid strenuous exercise close to bedtime.

**Table 71.2** Common causes of insomnia

Drugs (prescribed, illicit, addictive)

Anxiety, stress

Depression

Delirium and dementia

Restless legs syndrome

Pain e.g. carpal tunnel syndrome

Sleep apnoea

Parasomnias—nightmares, sleepwalking

Physical disorders (e.g. CCF, arthritis, asthma)

Bed-wetting

Reflux disease

Thyroid disorders (e.g. thyrotoxicosis)

Menopausal symptoms

Snoring partner

Lower urinary tract symptoms with nocturia

- Avoid alcohol and drinks containing caffeine in evening, especially close to retiring.
- Avoid a heavy evening meal within 3 hours of bedtime.
- Avoid smoking.
- Remove pets from the bedroom.
- Use a suitable mattress and pillow for comfort and support.
- Avoid lights, including poorly screened windows and highly illuminated clocks in the room.

Sleep-promoting adjuvants:

- Try a drink of warm milk before retiring.
- Organise a comfortable, quiet sleep setting with the right temperature.
- Try a warm bath before bed.
- Sex as the last thing at night where appropriate is usually helpful.

### 6 Non-pharmacological treatment.

There are various techniques that should be adopted according to patient personality and preference, clinician's expertise and available resources. These include relaxation therapy, meditation and stress management, which are all highly recommended. Other measures include cognitive behaviour therapy, structured problem solving and electromyographic feedback. Hypnosis is worth considering.

### 7 Pharmacological treatment.<sup>6</sup>

It is advisable to avoid hypnotic agents as first-line treatment. If any form of continuous agent is necessary it is best to limit it to 2 weeks.

Options:

temazepam 10 mg tablets (o) nocte

or

zopiclone 3.75–7.5 mg (o) nocte

or

zolpidem 5 mg (o) or CR 6.25 mg nocte

or

melatonin prolonged release 2 mg (o) 1–2 hrs before bedtime (best >55 years)

Note:

- The cyclopyrrolone derivative zopiclone and the imidazopyridine derivative, zolpidem, are non-benzodiazepine hypnotics with a similar action to the benzodiazepines represented by temazepam. However, warnings have been issued about adverse neurological and psychiatric reactions.<sup>4</sup>
- Tricyclic antidepressants with sedative effects (e.g. amitriptyline) are often used as hypnotics but should generally be avoided in the absence of depressive disorders.

## Sleep apnoea<sup>7</sup>

The term 'sleep apnoea' is used to describe cyclical brief interruptions of ventilation, each cycle lasting 15–90 seconds and resulting in hypoxaemia, hypercapnia and respiratory acidosis, terminating in an arousal from sleep (often not recognised by the patient). The interruption is then followed by the resumption of normal ventilation, a return to sleep, and further interruption of ventilation.

Sleep apnoea is broadly classified into obstructive and central types.

*Obstructive sleep apnoea* (OSA) refers to the presence of apnoeas and hypopnoeas during sleep together with daytime dysfunction, predominantly excessive daytime sleepiness. The effects include snoring (see FIG. 71.2).

Predisposing causes include:

- diminished airway size (e.g. macroglossia obesity, tonsillar-adenoidal hypertrophy)
- upper airway muscle hypotonia (e.g. alcohol hypnotics, neurological disorders; see FIG. 71.3)
- nasal obstruction

FIGURE 71.2 Normal airway when sleeping

FIGURE 71.3 Sleep apnoea: obstructed airway when sleeping

*Central sleep apnoea* (CSA), which is characterised by periodic loss of respiratory effort, is less common

(accounts for <10% of sleep-disordered breathing) and is due mainly to neurological conditions such as brain stem disorders leading to reduced ventilatory drive, and neuromuscular disorders such as motor neurone disease. Cardiorespiratory disease is also a risk factor. It requires specialist referral. Treatment of CSA is based on optimal therapy for these underlying conditions and attending to lifestyle modification as outlined below.

## Clinical effects of sleep apnoea syndromes<sup>5</sup>

Important clinical presentations include:

- excessive daytime sleepiness and tiredness
- nocturnal problems (e.g. loud snoring, thrashing, 'seizures', choking, pain reactions)
- morning headache
- subtle neuropsychiatric disturbance—learning difficulties, loss of concentration, personality change, depression
- sexual dysfunction
- occupational and driving problems

Causes of excessive daytime sleepiness are presented in TABLE 71.3. In OSA, sleepiness results from repeated arousals during sleep and the effects of hypoxaemia and hypercapnia on the brain. Physical examination may reveal few or no signs.

Table 71.3 Causes of excessive somnolence

Inadequate sleep duration
Sleep apnoea syndromes
Narcolepsy
Endocrine (e.g. hypothyroidism)
Drug induced
Purposeful sleep deprivation
Nocturnal myoclonus
Bereavement
Idiopathic

## Management of sleep apnoea<sup>7</sup>

Referral to a comprehensive sleep disorder centre especially for sleep polysomnography is advisable if this disorder is diagnosed or suspected.

The general principles are as follows:

- 1 Lifestyle modification
  - Weight loss (e.g. loss of 10–15% e.g. 7–10 kg can significantly reduce severity).
  - Achieve physical fitness with regular exercise.

- Good sleep hygiene and adequate sleep hours.
  - Reduce or cease sedatives/hypnotics.
  - Avoid alcohol for up to 3 hours before going to sleep.
  - Cease cigarette smoking (increases nasal resistance).
  - Medical management of nasal obstruction (e.g. short-course nasal decongestants) or 6-week trial intranasal topical corticosteroids.
  - Avoid supine sleep.
- 2 Continuous positive airway pressure (CPAP)
- CPAP is currently the most effective treatment for OSA (consider it for CSA).
  - Delivered by nasal (or facial) mask.
  - Provides an air splint to the upper airway and prevents pharyngeal collapse.
  - Sleepiness and neurocognitive function improved.
  - Not tolerated by all patients.
- 3 Surgery
- In children, OSA is usually due to tonsillar and/or adenoid hypertrophy and is relieved by surgery (see FIG. 71.4). In adults, depending on the cause, the options are:
- correction of the specific upper airway anatomical problem—up to 2% of problems
  - correction of nasal obstruction (improves snoring and OSA)
  - palatal surgery: uvulopalatopharyngealplasty—conventional or laser assisted
  - nasal polypectomy
  - tonsillectomy
  - base of tongue surgery
  - radiofrequency treatment to soft palate and base of tongue ('somnoplasty')

**FIGURE 71.4** Influence of tonsils and adenoids on airways

- 4 Oral appliances
- The mandibular advancement splint—a custom-made dental device that supports the mandible and tongue during sleep to increase pharyngeal dimensions.

## 5 Medication

There are no reliable drug treatment options for OSA. Consider:

- amitriptyline 25–100 mg (o) nocte, in severe cases during REM sleep and intolerance of CPAP
- trial of corticosteroid sprays in children with mild OSA

## § Narcolepsy

Narcolepsy is a specific, permanent neurological disorder that is characterised by brief spells of irresistible sleep during daytime hours in inappropriate circumstances, even during activity and usually at times when the average person simply feels sleepy. It is uncommon with an incidence of two to five per 100 000.

### Features

Usual onset between adolescence and 30 years of age—in teens and 20s (but has been reported in children as young as 2 years).

### Tetrad of symptoms

- Daytime hypersomnolence: sudden brief sleep attacks (15–20 minutes).
- Cataplexy: a sudden decrease or loss of muscle tone in the lower limbs that may cause the person to slump to the floor, unable to move. These attacks are usually triggered by sudden surprise or emotional upset.
- Sleep paralysis: a frightening feeling of inability to move while drowsy (between sleep and waking).
- Hypnagogic (terrifying) hallucinations on falling asleep or waking up (hypnopompic hallucination).

Several attacks per day are possible.

### Diagnosis

The diagnosis is clinical through the taking of an appropriate history. If doubtful, include:

- EEG monitoring
- sleep laboratory studies (sleep latency test—rapid eye movement is a hallmark)

### Treatment<sup>6</sup>

Treatment is mainly symptomatic and initiated by a consultant. Central nervous system psychostimulants are of proven effectiveness in increasing alertness:

dexamphetamine 5–10 mg (o), half an hour before breakfast and lunchtime; up to 40 mg daily may be required in slowly increasing doses

or

methylphenidate (Ritalin) 10–20 mg (o) half an hour before breakfast and lunchtime; up to 60 mg daily may be required

Drug holidays from these drugs may be necessary.

- Tricyclic antidepressants are used to treat cataplexy, sleep paralysis and hypnagogic hallucinations (e.g. clomipramine 20–100 mg (o) daily).
- Modafinil is used successfully in some countries.

Reflect on driving licence issues as appropriate.

### § Idiopathic hypersomnia<sup>8</sup>

This type of excessive daytime sleepiness (EDS) can present similarly to narcolepsy without cataplexy. The condition, which accounts for 5–10% of patients in sleep clinics with EDS is diagnosed despite adequate sleep and exclusion of other causes. They usually have non-refreshing deep nocturnal sleep but, unlike narcolepsy, naps are not refreshing. The onset is usually insidious before 30 years and persists for life. Treatment is usually based on psychostimulant therapy to improve EDS.

### § Snoring

#### Definition

Snoring is a sonorous sound with breathing during sleep, caused by vibrations in the upper airways from the nose to the back of the throat. It is caused by partially obstructed breathing during sleep (see FIG. 71.5).

FIGURE 71.5 Snoring: vibrations of tongue and soft palate

#### Features

- Sometimes indicates OSA, especially in perimenopausal women<sup>7</sup>
- Three times more common in obese persons
- Generally harmless, but if very severe, unusual or associated with periods of no breathing (>10 s) assessment is advisable

### Aggravating factors<sup>9</sup>

- Obesity
- Old age
- Sleeping on the back
- Sleep deprivation
- Excess alcohol
- Neck problems, especially a 'thick', inflexible neck
- Various drugs, especially sedatives and sleeping pills
- Hay fever and other causes of nasal congestion
- Problems in the upper airways, such as nasal polyps, enlarged tonsils or a foreign body (e.g. a piece of plastic or metal)
- Endocrine abnormalities (e.g. acromegaly, hypothyroidism)

### Management

If an examination rules out a physical problem causing obstruction in the back of the nose and OSA, then the following simple advice can be given to patients.

- Obtain and keep to ideal weight.
- Avoid drugs (including sedatives and sleeping tablets), alcohol in excess and smoking.
- Treat nasal congestion (including hay fever) but avoid the overuse of nasal decongestants.
- For neck problems, keep the neck extended at night by wearing a soft collar.
- Consider a trial of an intranasal device such as the Breathing Wonder, which is a hollow intranasal plastic insert. Pharmacists can advise about the range of such devices.
- Try to sleep on your side. If you tend to roll on to your back at night, a maverick method is to consider sewing ping pong balls or tennis balls on the back of the nightwear. Others wear a bra (with tennis balls) back to front.

### § Periodic limb movements (nocturnal myoclonus)

Periodic limb movements (PLMs) and restless legs syndrome are important causes of insomnia and excessive daytime sleepiness. They may coexist in the same patient. Periodic limb movements, which are also referred to as nocturnal myoclonus or 'leg jerks', tend to occur usually in the anterior tibialis muscles of the leg but can occur in the upper limbs. The prevalence increases with age. Most people with PLMs are completely asymptomatic. The diagnosis is often made during sleep studies.<sup>10</sup> If troublesome, referral to a sleep clinic or neurologist may be appropriate.<sup>10</sup>

## Medication

Medication that may help includes:

levodopa plus carbidopa (e.g. Sinemet 100/25,  
2 tablets before bedtime)

or

clonazepam 1 mg (o) nocte increasing to 3 mg (o)  
nocte

or

sodium valproate 100 mg (o) nocte

## § Restless legs syndrome (RLS)

RLS, also known as Ekbom syndrome, is a rather common movement disorder of the nervous system where the legs feel as though they want to exercise or move when the body is trying to rest. Sensations that may be experienced include 'twitching', 'prickling' and 'creeping'.<sup>11</sup> The major complaint of sufferers is of disruption both to sleep and of relaxing activities, such as watching television or reading a book. Prolonged car or airplane travel can be difficult.

RLS is frequently an undiagnosed disorder because people often don't complain about it to their doctor. A Canadian study reported that 15% of people sampled reported 'leg restlessness' at bedtime.

The diagnosis is made from the history—there are no special diagnostic tests.

Its prevalence increases with age so it mainly affects elderly people. Women are more prone to get RLS and it is aggravated by pregnancy. The exact cause of primary RLS is not clear. It is not related to exercise and does not appear to follow strenuous exercise.

## Symptoms

There is an urge to move legs upon resting, particularly after retiring to bed. This urge is a response to unpleasant sensations in the legs, especially in the calves. The sensations are commonly and variously described as crawling, creeping, prickly, tingling, itching, contractions, burning, pulling or tugging, electric shock-like. However, sometimes patients are unable to describe the sensation or refer to it as simply a compulsion to move the legs.

In some patients the arms are affected in a similar way. The symptoms seem to be aggravated by warmth or heat. Many patients with RLS also experience nocturnal myoclonus.

Secondary (medical) causes include:

- anaemia (common)
- iron deficiency (common)
- uraemia
- hypothyroidism

- pregnancy (usually ceases within weeks of delivery)
- drugs (e.g. antihistamines, anti-emetics, selective antidepressants, lithium, selective major tranquillisers and antihypertensives)

## Management

Iron studies should be performed and, if low, treat with iron and vitamin C tablets. Advise patients that although RLS can come and go for years, it usually responds well to treatment.

## Self-help advice

- Perform activities that can reduce symptoms, for example, a modest amount of walking before bedtime, massage or prescribed exercises (see FIG. 71.6). *Note:* getting out of bed and going for a walk or run does not seem to help RLS.

FIGURE 71.6 Stretching exercises for restless legs

- Good sleep hygiene, namely regular sleeping hours, gradual relaxation at bedtime, avoidance of non-sleep activities in bed (e.g. reading, eating).

- Diet: follow a very healthy diet. Avoid caffeine drinks, smoking and alcohol.
- Try keeping the legs cooler than the body for sleeping.
- Exercises: a popular treatment is gentle stretching of the legs, particularly of the hamstring and calf muscles, for at least 5 minutes before retiring. This can be done by using a wide crepe bandage, scarf or other length of material around the foot to stretch and then relax the legs.

### Pharmacological treatment<sup>6</sup>

The following may be effective if simple measures fail: (taken before bedtime)

clonazepam 0.5–1 mg (o) 1 hour before retiring  
 or  
 levodopa (+ benserazide or carbidopa)  
 100–200 mg (o) (especially if limb movements at sleep onset are infrequent)

For more severe symptoms consider low-dose dopamine antagonists:

pramipexole 0.125 mg (o) daily, increasing as tolerated to 0.75 mg  
 or  
 ropinirole 0.5 mg (o) → 4 mg daily

Cabergoline, gabapentin, codeine, baclofen and propranolol may be helpful. Carbamazepine, quinine, antipsychotics (avoid), antihistamines (avoid) and antidepressants are generally unhelpful.

### § Bruxism (teeth grinding)

Bruxism is the habit of grinding, clenching or tapping teeth, which may occur while awake (especially in children) or more commonly while asleep. The usual symptom is annoying, teeth-grinding noises during sleep that disturb family members. It may result in headaches and TMJ dysfunction in the person during the day. The cause may be a habit or a response to subconsciously correct a faulty bite by making contact between the upper and lower teeth when the jaws are closed. It is aggravated by stress and is more common in heavy alcohol drinkers.

### Management

- Educate the patient to recognise, understand and try to overcome the habit.
- Practise keeping the jaws (and teeth) apart.
- Slowly munch an apple before retiring.
- Practise relaxation techniques, including meditation, before retiring.
- Consider other stress-management techniques (e.g. counselling, relaxation exercises, yoga and tai chi).
- Place a hot towel against the sides of the face before retiring to achieve relaxation.
- If this fails and bruxism is socially unacceptable, a plastic night-guard mouthpiece can be fashioned by a dentist to wear at night.

## PARASOMNIAS

Parasomnias are defined as dysfunctional episodes associated with sleep, sleep stages or partial arousal. They are more common in children.

### § Nightmares (dream anxiety)

These dream-related anxiety episodes usually occur later in the REM sleep period and are accompanied by unconscious body movements, which usually cause the person to awaken.

Associations include traumatic stress disorders, fever, drug withdrawal (e.g. alcohol, barbiturates, drugs such as zolpidem, SSRIs,  $\beta$ -blockers, benzodiazepines). Violent behaviour can occur during these dreams due to a REM behaviour disorder and this requires a sleep study.

Psychological evaluation with cognitive behaviour therapy (CBT) is appropriate. Medication that may help includes phenytoin, clonazepam or diazepam.

### § REM sleep behaviour disorder

A feature is complex and elaborate motor activity associated with dreams. The behaviour may be violent with profane verbalisation. It is more common in older males and among those with CNS degeneration disorders (e.g. dementia, Parkinson disease). Diagnosis is by sleep studies and treatment is low-dose clonazepam.

### § Somnambulism (sleepwalking)<sup>2</sup>

This is a complex motor activity in which the person performs some repetitive activity in bed or walks around freely while still asleep. There is amnesia for the event. No treatment is usually required but, if it is repetitive and potentially dangerous, then the sleeping environment should be rendered safe. Psychological assistance is required for recurring episodes. Benzodiazepines such as diazepam may be useful but withdrawal usually leads to rebound problems.

## § Sleep terrors

These are part of the same non-REM sleep cycle disorder as somnambulism. Characteristics of night terrors are sharp screams, violent thrashing movements and autonomic overactivity, including sweating and tachycardia. The sufferers, usually pre-adolescent, may or may not wake and usually cannot recall the event. They also require psychological evaluation and therapy. Similar medication as used for nightmares may help (e.g. a 6-week trial of phenytoin, diazepam or clonazepam).

## Sleep disorders in children

Sleep disorders in children are very common in late infancy, toddlerhood and early preschool age groups. By 3 months 70% begin to sleep through the night. The majority do not sleep throughout the night until 6 months of age. Over 50% of toddlers and preschool children resist going to bed.<sup>12</sup> At least 30% of infants and toddlers wake at least once during the night every night. Toddlers begin to have dreams coinciding with language development in the second year of life.<sup>12</sup>

The child who wakes during the night needs reassurance, protection and the parent's presence, but it must be given discreetly. Although psychosocial stresses can trigger sleep problems, serious psychological problems in children with sleep disorders are uncommon.<sup>13</sup>

## Management<sup>12</sup>

Aim to see both parents together and get them to agree on the approach, including sharing the workload.

Advice to parents:

- Resist taking the child into bed during the night unless they are happy to encourage this.
- Avoid giving attention to the child in the middle of the night—it encourages attention seeking.
- Avoid extra feeding or other pacifiers during the night.
- Return the child to bed promptly and spend only a brief time to give reassurance.
- A rigid series of rituals performed before bedtime helps the child to develop a routine. Settling to sleep may be assisted by soft music, a soft toy and a gentle night light.
- Take the child into the bedroom while still awake.
- Encourage the parents to keep a sleep diary.

Sedative medication has a minimal place in the management of sleep disturbances,<sup>6</sup> and is not

recommended for children <2 years although the judicious use of a sedative/hypnotic for a short term may break the sleepless cycle. Such drugs include promethazine 0.5 mg/kg (max. 10 mg) and trimeprazine (Vallergan) 1–2 mg/kg per dose (not for infants under 6 months).<sup>12</sup>

## Parasomnias (sleep terrors, sleep walking and sleep talking)<sup>2</sup>

These are not true sleep disorders or night-time arousals. They occur in deep non-REM sleep. With sleep terrors, which usually develop within 2 hours of sleep and last 1–2 minutes, the child is usually inconsolable and has no memory of the event. These events cluster in age ranges:

- sleep terrors 4–8 years
- sleep walking 8–12 years
- sleep talking 6–10 years
- nightmares 3–6 years

They are self-limiting over a period of months. Usually, no active treatment is needed but for persistent, severe problems a 6-week trial of phenytoin, diazepam or imipramine is worthwhile.

## Sleep problems in the elderly

The elderly constitute the bulk of long-term users of hypnotics and benzodiazepines. Two key issues to consider are sleep in the elderly and confusion in the elderly. Problems associated with long-term benzodiazepine use are dependence, confusion, memory impairment and falls.

A study of elderly patients with insomnia showed that:<sup>14</sup>

- 25% had insomnia either coexisting with or related to other sleep disorders, such as sleep apnoea or periodic limb movement disorder
- 10% had insomnia related to medical or psychiatric conditions
- 13% had insomnia associated with an inability to stop taking sedative-hypnotic agents

## Principles of management in the elderly

- Exclude underlying causes of sleep disturbance.
- Educate patients and carers about the changing needs with ageing and the rational use of medicines.
- Avoid hypnotics if possible.
- Avoid hypnotics combined with alcohol.
- Beware of risks of long-term use and drug accumulation.

- Consider non-drug measures where possible (e.g. CBT).
- Avoid the 'why bother' factor when carers and patients are comfortable with hypnotics.
- In nursing homes, practise 'bothering' and use team effort to encourage less prescribing.

## Medication<sup>6</sup>

If medication is necessary, prescribe a short-acting benzodiazepine for as limited a time as possible. An alternative non-benzodiazepine hypnotic (e.g. zopiclone or zolpidem) taken just before retiring may be useful in the elderly (beware of adverse effects). Consider melatonin prolonged release medication. Tricyclic antidepressants with a sedative action are frequently used, especially if there is coexistent depression, but side effects limit their use. However, commonsense prescribing needs to be used and the best option may be to continue the long-term prescribing of hypnotics in those with chronic medical problems or long-term dependents on a low effective dose.

*The key to managing diseases of the oral mucosa is to evaluate lifestyle factors carefully, including causes of immune suppression.*

Dr Jonathan Tversky 2002

Evaluating the sore mouth and tongue is basically an understanding of disorders of the oral mucosa. Disorders of the oral mucosa are a common problem in general practice, with recurrent aphthous ulceration being the most common oral mucosal disease in humans.

There are three types of stratified squamous epithelium in the oral mucosa:<sup>1</sup>

- 1 masticatory—surface layer, cornified (orthokeratinised), attached to underlying periosteum (e.g. hard palate and gingivae)
- 2 lining—(e.g. lip and buccal mucosa, alveolar mucosa, floor of mouth, soft palate and tongue—lateral and undersurface)
- 3 specialised—with taste buds and papillae e.g. on dorsum of tongue

## Key facts and checkpoints

- Dental trauma or neglect is an important cause of many oral mucosal disorders, such as ulceration, bleeding gums and hyperplasia.
- Non-healing oral ulcers warrant biopsy to exclude squamous cell carcinoma (SCC).
- If oral mucosal cancer is suspected, palpate the lesions to check for induration or a firm, discrete edge and check regional nodes.
- Erythroplasia or leucoplakia persisting for 3 weeks after injury, e.g. sharp tooth or denture, should have an incisional biopsy.
- Any oral ulcer or soft-tissue lesion that persists 3 weeks after the apparent cause has been removed should be biopsied.
- Consider Epstein-Barr virus (EBV) infection with unusual faucial ulceration and petechial haemorrhages of the soft palate.
- Aphthous ulcers are usually 3–5 mm in diameter—minor ones have an erythematous margin.
- Intraoral bony exostoses, other than palatal and mandibular tori, are often variations from normal

or less commonly part of a syndrome, for example, Gardner syndrome. No treatment is usually required.<sup>2</sup>

- Shared care of more complex lesions of the mouth and tongue with an oral or dental surgeon is best practice.

## Red flag pointers for oral conditions

- Dehydration in children with herpetic gingivostomatitis
- Petechiae on soft palate with gingivostomatitis or pharyngotonsillitis
- Oral ulcers and skin disorders
- Oral ulcers (especially solitary) or soft tissue lesions persisting for >3 weeks
- Oral ulcers and bowel dysfunction
- Oral candidiasis (may indicate diabetes or other immunosuppression)
- Glossodynia may indicate psychological disorder (e.g. depression)

## Oral ulceration

The histology of oral ulceration is usually non-specific, with fibrin slough covering granulation tissue, and the aetiology is varied. The ulceration is a breach in the epithelial compartment with inflammatory cell infiltrate in the submucosa. The most common form is recurrent aphthous ulceration. Always inquire about a history of skin problems, medication, bowel function and psychological stress.

A list of causes is presented in the diagnostic strategy model (see TABLE 72.1). Depending on the clinical picture, investigations may include FBE, swabs, autoantibody screen, syphilis serology, blood sugar, vitamin B12 and folate levels, and biopsy.

**Table 72.1** Mouth ulcers: diagnostic strategy model

Q. Probability diagnosis
A. Recurrent aphthous ulceration
Trauma
Acute herpes gingivostomatitis
Candidiasis
Q. Serious disorders not to be missed
A. Cancer: SCC, leukaemia
Agranulocytosis
HIV
Syphilitic—chancre or gumma
Tuberculosis
Q. Pitfalls (often missed)
A. Aspirin burn
Inflammatory bowel disease (e.g. Crohn)
Herpes zoster virus
Glandular fever (EBV)
Lichen planus
Coxsackie virus:
• herpangina
• hand, foot and mouth disease
Immunosuppression therapy
Lupus erythematosus
Rarities:
• Behçet syndrome
• pemphigoid and pemphigus vulgaris
• erythema multiforme
• radiation mucositis
Q. Seven masquerades checklist
A. Diabetes ( <i>Candida</i> )
Drugs
Anaemia (iron-deficiency)
Q. Is the patient trying to tell me something?
A. Unlikely.

## § Recurrent aphthous ulceration

Aphthous ulcers are round/oval ulcers usually 3–5 mm in diameter with an erythematous margin and sloughing base.

Aphthous ulcers occur in all ages on un(para)keratinised mucosa such as the buccal and labial mucosa and the floor of the mouth (not on orthokeratinised mucosa) (see FIG. 72.1). The frequency of aphthous ulcers in the population varies from 5% to 25% (average 20%). The cause is unknown although human herpes virus 6 has been implicated, as have nutritional and autoimmune factors.<sup>3</sup> People with recurrent aphthous ulcers have a genetic predisposition.

**FIGURE 72.1** Aphthous ulcer located on unkeratinised (movable) mucosa in a 5-year-old girl

Source: Usatine 41.4.

## Precipitating factors

- Trauma (e.g. cheek and tongue biting, toothbrush, dental pressure)
- Drug reaction (e.g. new medication)
- Stress
- Allergy
- Systemic factors (e.g. iron, folate, vitamin B12 deficiency, hormonal)

*Note:* Exclude blood dyscrasias, Crohn disease, Behçet syndrome, coeliac disease, drug therapy (e.g. phenytoin, cytotoxics, corticosteroids, immunosuppressants).

## Rules

- Minor ulcer <5 mm in diameter: lasts 5–10 days and heals without scarring
- Major ulcer >8 mm: can persist for up to 6 weeks<sup>3</sup>
- Major ulcers usually occur on lips, soft palate and fauces and sometimes on the tongue
- Minor ulcers are usually found on the buccal and labial mucosa and the floor of the mouth
- Non-healing ulcers: consider SCC (biopsy required)
- Recurrent ulcers: consider Behçet syndrome. Check serum iron and folate

**DxT** recurrent oral and genital ulcers +  
uveitis + arthritis → Behçet syndrome

## Treatment

There are multiple methods but none are specific.

### Symptomatic relief

topical lignocaine (e.g. 2% jelly or 5% ointment) with cotton bud: after 2 minutes apply lignocaine gel or paint (e.g. SM-33 adult paint formula or SM-33 gel children) every 3 hours  
 or  
 eutectic EMLA cream 5%—apply on a cotton bud or gauze for 5 minutes

### Healing: options

- Triamcinolone 0.1% (Kenalog in Orabase) paste, apply three times daily after meals and nocte (preferred method but be careful of herpes simplex ulcers).
- Other topical steroids (e.g. betamethasone 0.5% ointment, hydrocortisone 1%).
- Hydrocortisone lozenges (if available)—dissolve in contact with ulcer, qid.
- 10% chloramphenicol in propylene glycol—apply with cotton bud for 1 minute (after drying the ulcer) 6 hourly for 3–4 days.
- Beclomethasone dipropionate 50 mcg spray onto ulcer tds.
- Sucralfate 1 g in 20–30 mL of warm water—use this as a mouthwash.
- Diclofenac 3% in hyaluronan 2.5%.

All of the above treatments have been shown to be effective in controlled trials.

### Major ulceration

Consider:

injection of steroids into the base of the ulcer  
 and/or  
 oral prednisolone 25mg daily, 5–7 days<sup>4</sup>

Referral: Patients with a non-healing ulcer within 3 weeks of presentation.

### Complementary measures

- 1 *Teabag method*. Consider applying a wet, squeezed-out, black teabag directly to the ulcer regularly (the tannic acid promotes healing). Must be used when ulcer is worse.
- 2 *Melaleuca (tea-tree) oil*. 1% tea-tree oil used as a mouth rinse for 1 minute has been shown to prevent secondary infection.<sup>2,5</sup>
- 3 *Acupuncture*. This is advocated by its protagonists. It has been proven to improve salivary flow.

### § Traumatic ulceration

- This is commonly caused by sporting injuries, biting of the cheek, and lip, and hot food.

- Factitious causes include scratching of an 'itchy' mouth or over-brushing of the teeth.
- Other relevant causes include dentures, sharp tooth surface, orthodontic bands and sharp objects, such as pencils and hard food.
- Aspirin 'burns' are caused by people leaving salicylate-based tablets to dissolve against oral mucosa.
- Iatrogenic causes include surgical procedures, such as intubation and endoscopy, and dental treatment, such as retractors and removing dry cotton rolls.

### Management<sup>1</sup>

- Explanation, including removal of the cause.
- Warm salt-water mouthwashes, and/or local anaesthetic mouthwashes:  
 benzocaine compound (Cepacaine), swirl in mouth 10–15 mL for 10–15 seconds and expel, every 3 hours prn

or

benzylamine hydrochloride (Difflam), swirl in mouth 15 mL for 30 seconds and expel

These ulcers can take up to 10 days to resolve.

### Lichenoid drug reaction

Several drugs can induce a lichenoid drug reaction of the oral mucosa, that is, cause shallow mucosal erosions similar to lichen planus. The drugs include gold, the NSAIDs, carbimazole, selected antihypertensives and cytotoxics.

### § Herpes infection

- It is important to beware of herpes simplex virus lesions.
- Primary herpetic gingivostomatitis is usually obvious but herpes infection has an extraordinary ability to present in many ways. It can spread from the hands to the mouth.
- Application of a topical corticosteroid, such as Kenalog in Orabase, can aggravate and spread the herpetic lesion.
- Treatment: aciclovir or similar antiviral if seen early, e.g. 48 hours from onset; fluids + + + ; analgesic mouth rinses, e.g. Difflam; consider admission for IV aciclovir and hydration.
- Lesions of herpes zoster virus affecting the maxillary division of the trigeminal nerve, for example, can involve the buccal mucosa in a unilateral pattern.

## Red patches

A reduction in the surface epithelial layer causes erythematous patches. Causes include trauma (e.g. cheek biting), infection (e.g. *Candida albicans*), geographic tongue, haematologic disorders, the dermatoses and neoplasia.

Neoplasia that can look red includes squamous cell carcinoma, Kaposi sarcoma and erythroplakia. Erythroplakia is similar in significance to leucoplakia except for the erythematous feature. It is an important condition to recognise since about 90% of cases are either dysplastic or cancer.<sup>6</sup>

## White patches

White patches occur where the epithelial compartment thickens. Causes include inflammation due to trauma or infection, especially *Candida*, dermatoses and neoplasia.

An interesting condition is hyperkeratotic burns on the dependent floor of the mouth, which appear white. Causes include tea-tree oil mouthwash and the sucking of aspirin.

Leucoplakia is any white lesion that cannot be removed by rubbing the mucosal surface (unlike oral candidiasis). About 5% of cases represent either dysplasia or early SCC.<sup>6</sup> Any persistent white patch should be biopsied (see FIG 72.2).

Specific conditions causing red and/or white patches follow.

FIGURE 72.2 Leucoplakia showing white patch below tongue

## § Oral candidiasis (thrush)

This is usually tender and looks like white or yellowish curd-like patches overlying erythematous mucosa. Unlike lichen planus or leucoplakia, they are usually

readily rubbed off and hence only the underlying red patch may be seen.

Patients may also complain of a bad metallic taste or halitosis and dysphagia. They often complain of sensitivity to toothpaste or acidic substances in general.

Consider predisposing factors:

- immunodeficiency and cytotoxic therapy
- medication, especially broad-spectrum antibiotics and corticosteroids, including inhalers
- debility and anaemia (iron, folic acid, vitamin B6 deficiency)
- diabetes mellitus and HIV infection

The carriage rate of *Candida albicans* in the oral cavity is 60–75%. The diagnosis is made clinically but a wet preparation using potassium hydroxide will reveal spores and perhaps mycelia.

## Treatment

Attend to underlying cause. Consider multivitamin preparations.

## Topical therapy

nystatin suspension, rinse and swallow qid

or

miconazole oral gel (as directed by manufacturer)

or

amphotericin 10 mg or nystatin 100 000 U lozenges dissolved slowly in oral cavity, 6 hourly, for 7–14 days

## Oral therapy

Use if unresponsive to topical therapy and the immunocompromised:

fluconazole 50 mg (o) daily

## Denture therapy<sup>1</sup>

Dentures need to be decontaminated, especially if acrylic. Use:

- chlorhexidine denture scrub (care with bleaching), or
- dilute Milton's denture scrub (e.g. ¼ teaspoon White King in a cup of water)

If oral thrush, brush the dentures each night with a thin coat of nystatin cream or oral miconazole.

## § Angular cheilitis

Feature is redness, soreness and maceration of the corners of the mouth. Usually associated with oral

candidiasis. Consider poor-fitting dentures, diet—vitamin B deficiency, iron deficiency and dermatitis. Treat with topical nystatin or miconazole. ‘Golden’ crusting indicates *S. aureus*.

## Bleeding or painful gums

Erythematous bleeding gums are a common worldwide problem, which is almost always a localised inflammation associated with poor dental hygiene.<sup>7</sup> Systemic problems usually as part of a bleeding diathesis need to be considered.

The causes are summarised in the diagnostic strategy model (see TABLE 72.2).

**Table 72.2** Bleeding/painful gums: diagnostic strategy model (modified)

Q. Probability diagnosis
A. Gingivitis/periodontal (gum) disease
Trauma: poor-fitting or partial dentures
Factitious: excessive brushing
Drugs: warfarin overdose
Q. Serious disorders not to be missed
A. Oral cancer/benign neoplasms (e.g. epulis)
Blood dyscrasias (e.g. AML)
Acute herpetic gingivostomatitis
Q. Pitfalls (often missed) but uncommon
A. Acute ulcerative gingivitis (Vincent infection, trench mouth)
Autoimmune disease (e.g. lichen planus, SLE)
Hereditary haemorrhagic telangiectasia
Malabsorption
Scurvy

Acute necrotising ulcerative gingivitis (Vincent infection or trench mouth) caused by anaerobic organisms is rarely seen but is more common in undernourished or ill young adults under stress.

## § Gingivitis

Caused by plaque (bacterial biofilm) with calculus (tartar secondary to poor oral hygiene).

### Features

- Red, swollen gingivae adjacent to teeth (see FIG. 72.3)
- Bleeds with gentle probing
- Halitosis
- Usually no pain

### Treatment<sup>4,7</sup>

- Dental care—remove plaque and clean
- Cease smoking

FIGURE 72.3 Gingivitis, showing plaque and gingivitis

- Mouthwash: chlorhexidine 0.2 or 0.12% aqueous solution 10 ml for 1 minute 8–12 hourly for 10 days or until pain abates (beware of superficial discolouration of teeth with prolonged use)

## § Acute ulcerative gingivitis

This is a very painful form of gingivitis. Treatment is as for gingivitis but add antibiotics e.g. metronidazole 400 mg (o) 12 hourly or tinidazole 2 g (o) single dose and drain pus from abscess.<sup>4</sup>

## § Periodontitis

This is inflammation of the periodontal space. It is a sequel to gingivitis and shows periodontal ligament breakdown with recession or periodontal pocketing and alveolar bone loss. There is possible loosening of teeth and periodontal abscess formation (see FIG. 72.4). An underlying medical condition must be suspected.

Risk factors are smoking and diabetes.

FIGURE 72.4 Periodontitis with more widespread gingival inflammation that invades the supporting alveolar bone

Treatment is meticulous dental treatment and mouthwashes. Antibiotics are rarely required.<sup>4</sup>

### Prevention of gingival disease

- Use a fluoride, abrasive type of toothpaste.
- Brush with a medium-to-soft, nylon-tufted, small-headed toothbrush.
- Direct at gingival margin with a small horizontal motion.
- Keep interdental spaces clean with dental flossing in a vertical direction or tooth picking.
- Regular dental review—eliminate plaque.

### § Oral dermatoses

The dermatoses include lichen planus, pemphigus vulgaris (uncommon), mucous membrane pemphigoid (uncommon) and lupus erythematosus. The clinical appearance of these conditions in the mouth is quite different to the skin condition because of the environment, especially due to the presence of saliva.

### Diagnosis

Histopathological examination (after appropriate biopsy) with immunofluorescence is recommended, especially because of the similarity of the lesions of lupus erythematosus and lichen planus, which are both considered to be potentially premalignant in the mouth.<sup>8</sup>

### Clinical features

Lichen planus:

- affects 2% of the population, usually over 45 years
- can vary from asymptomatic to severely painful
- usually white lace-like patterns on mucosa, cheeks and tongue
- may form superficial erosions

Lupus erythematosus:

- oral lesions may be first sign of SLE
- usually on lateral aspects of the hard palate
- can resemble lichen planus

### Treatment

Consider specialist referral.

Oral hygiene and pain control:

chlorhexidine mouthwash

or

tetracycline/nystatin mouthwash

or

topical analgesics (e.g. lignocaine preparation)

Corticosteroids:

- topical (e.g. Kenalog in Orabase; betamethasone dipropionate 0.05%)
- intralesional (e.g. triamcinolone 10 mg/mL, especially for lichen planus)
- systemic—may be necessary in severe cases

### § The painful tongue<sup>9</sup>

Pain in the tongue is a reasonably common symptom in general practice. The cause is usually obvious upon examination but there are some obscure causes. As for many other oral mucosal problems, shared care with a dental or oral medical specialist is important. The causes of a sore or painful tongue are similar to that of the sore throat or mouth. Xerostomia is common in the elderly.

Investigations may include an FBE, serum vitamin B<sub>12</sub>, folate and ferritin levels, a swab or a biopsy of a suspicious lesion.

A diagnostic strategy with lists of causes is presented in **TABLE 72.3**.

**Table 72.3** Sore tongue: diagnostic strategy model

Q. Probability diagnosis
A. Geographic tongue
Atrophic glossitis
Trauma (bites, teeth, hot food/drink)
Aphthous ulceration
Herpes simplex virus (children)
Fissured tongue
Q. Disorders not to be missed
A. Cancer
HIV
Q. Pitfalls (often missed)
A. Anaemia: iron, vitamins B6 and B12, folate deficiency
Glossopharyngeal neuralgia
Lichen planus
Fissured tongue (rarely causes soreness)
Median rhomboid glossitis
Behçet syndrome
Crohn disease
Coeliac disease
Q. Seven masquerades checklist
A. Depression
Diabetes ( <i>Candida</i> )
Drugs (mouthwashes, aspirin)
Anaemia (various)
Q. Is the patient trying to tell me something?
A. Possible with glossodynia.

## Tongue tips

- Look for evidence of trauma, especially from a sharp tooth.
- A miserable child with a painful mouth and tongue is likely to have acute primary herpetic gingivostomatitis or hand, foot and mouth disease.
- When taking the history, take note of self-medications, especially sucking aspirin, a history of skin lesions (e.g. lichen planus) and consider underlying diabetes or immunosuppression.
- A long history of soreness with spicy or other foods indicates benign migratory glossitis (geographic tongue) or median rhomboid glossitis (see FIG. 72.5).
- Any non-healing or chronic ulcer requires urgent referral.
- Macroglossia (large tongue): consider acromegaly, myxoedema, amyloidosis, lymphangioma.
- Strawberry tongue: consider scarlet fever, Kawasaki disease.
- Glossodynia (painful tongue): characteristically presents as a burning pain on the tip of the tongue.<sup>9</sup> It can be a real 'heartsink' presentation. Consider depressive illness as an underlying cause.

## § Erythema migrans (geographic tongue)

Also known as benign migratory glossitis, this benign condition shows changing patterns of desquamated areas and erythema on the dorsum and edges of the tongue. With the smooth red patches and raised whitish grey edges, the pattern resembles a relief map with mountain ridges. The border changes shape within weeks. It is irregular and slightly reddened.

It is considered to be a hypersensitivity reaction but the offending allergen has not been identified. Stress, tobacco, alcohol, marijuana and spicy foods can aggravate the condition in some individuals.

## Management

- The condition is self-limiting and there is no specific therapy.
- Explanation and reassurance is important.
- No treatment is recommended if asymptomatic.
- If tender, benzocaine compound (Cepacaine) gargle 10 mL tds.
- If persistent and troublesome, low-dose inhaled glucocorticoid (e.g. beclomethasone 50 mcg tds—don't rinse after use).

## § Black or hairy tongue

This is due to overgrowth of papillae or reduced wear of papillae, e.g. debility and lack of fibrous foods.

- Appearance: dark, elongated filiform papillae giving brownish appearance to dorsum (posterior) of tongue.
- Symptoms: bad tastes and malodorous oral cavity.

## Causes

- Unknown
- Poor oral hygiene/debility
- Iatrogenic (e.g. antibiotics, major tranquillisers, corticosteroids)

## Treatment

Brush or scrape tongue to remove stained papillae. Use a topical keratolytic agent such as salicylate, with pineapple being the most practical (95% cases are helped).

FIGURE 72.5 Disorders of the tongue: (a) median rhomboid glossitis, (b) geographic tongue, (c) black tongue

## Method

- Cut a thin slice of pineapple into eight segments. Slowly suck a segment on the back of the tongue for 40 seconds and then slowly chew it. Repeat until all segments are completed. Do this bd for 7–10 days.<sup>1</sup> Repeat if recurs.

*Note:* The salicylate in pineapple can aggravate irritable bowel syndrome.

Consider sodium bicarbonate mouthwash.

## § Oral dysaesthesia

The classic chronic burning sensation of the oral cavity appears to have a neuropathic and/or psychological basis.<sup>1</sup> Symptoms include:

- altered sensitivity—burning pain or ‘raw’ sensation
- altered taste—sweet, salty or bitter
- altered saliva (subjective)—quality and quantity
- altered tooth sensation (e.g. ‘phantom tooth pain’)

Consider the underlying cause:

- haematinic deficiency—iron, folate, vitamin B12
- autoimmune disorder (e.g. Sjögren syndrome)
- endocrine disorder (e.g. diabetes)
- psychological disorder

## Treatment

Consider:

clonazepam 0.5–1 mg bd  
or, if resistant  
gabapentin (Neurontin)

## § Oral cancer

Cancer of the lip and oral cavity accounts for 2–3% of all newly diagnosed cancers in Australia.<sup>10</sup>

SCC is the most common malignancy of the oral cavity, accounting for 90% of cases. It has a 5-year survival rate of 65% without lymph node involvement and 50% with local node metastases.<sup>11</sup> Cancer of the lip is usually treated successfully by excisional biopsy but intraoral cancer has significant morbidity and mortality.<sup>10</sup>

Other malignancies include mucoepidermoid carcinoma, lymphoma, Kaposi sarcoma and malignant melanoma, which is usually found on the palate.

Predisposing or associated factors for SCC include tobacco and marijuana abuse, alcohol abuse, excessive sunlight and immune suppressive disorders such as HIV, lymphoma and various medications.

SCC is usually found as a chronic indurated ulcer on the ventral and lateral surfaces of the tongue followed by

the floor of the mouth and buccal mucosa. It may present as a white patch or, more commonly, as a speckled white and red nodular patch or a red velvety patch.

The red patches of erythroplakia (in particular) and the white patches of leucoplakia may be premalignant or early invasive cancer and necessitate further investigation, particularly incisional biopsy.

Treatment for oral cancer is surgery ± radiotherapy and chemotherapy.

## Benign intraoral swellings and tumours

### § Epulis

An epulis is a benign, localised gingival swelling. It is a very ancient term with no pathological significance, meaning a ‘tumour situated on the gum’. There are two distinct types—a fibrous epulis and giant cell epulis. An epulis emerges between two teeth from the periodontal membrane where there is usually dental decay or a site of irritation, such as a partial denture. It appears to be more common during pregnancy where the epulis has a more vascular appearance.

Treatment is usually by excision, with histological examination, curettage of the origin and extracting associated teeth. The ‘pregnancy’ epulis should be left for several weeks after childbirth before treatment.

Typical locations of intraoral tumours are shown in **FIGURE 72.6**.

### § Pyogenic granuloma

These may occur on the gums or oral mucosa of the lips and look like pyogenic granulomas of the skin, which also are associated with minor trauma. It is best treated by excision.

### § Retention cysts (mucous cysts)

The oral mucosa contains numerous mucous cysts and accessory mucous and serous salivary glands.

Small retention cysts are probably caused by minor trauma to the duct. They may rupture spontaneously. They commonly occur on the mucosa of the lower lip. Treatment is by incision and enucleation under local anaesthesia. Larger ones require marsupialisation. Others occur on the tonsils where they usually appear as sessile yellow swellings. A special type of retention cyst is the ranula.

### § Ranula

A ranula is a large transparent mucocele occurring in the floor of the mouth. A blue colour and small tortuous veins stretched across the surface is typical.

FIGURE 72.6 Typical location of swellings in the oral cavity

It is usually unilateral and simple but may extend into the tissues of the floor of the mouth and neck (plunging ranula). Patients may give a history of a cyst that bursts and then returns.

Treatment is usually by marsupialisation.

### § Fibrous (fibroepithelial) hyperplasia

Hyperplasia of the oral mucosa, a very common condition, is usually seen on the floor of the mouth and is due to chronic irritation from ill-fitting dentures. Removal of the offending irritation is necessary. The hyperplasia may resolve but if it doesn't, surgical removal of the residual mass is necessary.

### § Haemangioma

These appear as a dark blue/purple sessile or modular swelling anywhere in and around the mouth, especially on the vermilion border of the lips, floor of the mouth and tongue. They blanch on pressure. No treatment is needed except for pressing cosmetic reasons. Copious bleeding can occur with attempted removal.

### Other soft tissue swellings

Swelling that may be encountered includes squamous papillomas (like viral warts), fibroepithelial polyps (inner side cheek), mixed salivary tumours, vascular haematomas and giant cell granulomas.

The most common benign intraoral salivary neoplasm is the pleomorphic adenoma usually presenting as an asymptomatic swelling of the hard palate or cheeks.<sup>2</sup> Excision is recommended.

### Bony exostoses

Bony outgrowths of the maxilla and mandible are reasonably common and the hard intraoral lump may cause concern. The most common is known as torus palatinus (see FIG 72.7), which is situated in the centre of the hard palate. A similar exostosis is torus mandibularis, which occurs inside the mandible, opposite the premolar teeth and is usually bilateral. These lesions are hamartomas and do not require removal except if there is impending dental obstruction.

FIGURE 72.7 Torus palatinus in a woman aged 66 years. An incidental finding: it was asymptomatic.

### § Xerostomia (dry mouth)

This is a symptom rather than a disease entity. It occurs in about 10% of the population and approximately 70% of patients have a systemic cause.<sup>12</sup>

The most common cause is a side effect of drug therapy and it is relative rather than absolute. Some patients who have a dry mouth on clinical examination do not complain of it while others who do complain of it may be found to have a normal salivary flow rate (a feature of depressive illness).

Other obvious causes are dehydration, mouth breathing and psychogenic.

## Primary xerostomia

### Causes

- Salivary gland atrophy due to ageing
- Salivary gland infections
- Autoimmune salivary gland disease (e.g. Sjögren syndrome)

**DxT** dry eyes + dry mouth + arthritis  
→ Sjögren syndrome

## Secondary xerostomia

### Causes

- Mouth breathing
- Drugs: antidepressants (especially tricyclic agents), diuretics, anticholinergics, tranquillisers, antihistamines, anti-emetics, antihypertensives (some), antimigraine (some), antiparkinson, lithium and opioids
- Depression and anxiety (e.g. public speaking)
- Thirst/hunger
- Dehydration (e.g. diabetes, diarrhoea, kidney failure)
- Anaemias: iron, folate, vitamin B12 deficiency

### Consequences

Xerostomia interferes with speech, mastication and swallowing and causes difficulty in managing oral hygiene, especially dentures.

Symptoms include a burning sensation, a decrease in taste or a bad taste and fetid breath.

There is an increase in dental decay and perhaps a tendency to *Candida albicans* infection.

### Treatment

This involves education, especially the need for meticulous oral hygiene, including topical fluoride preparations to the teeth and regular dental checks.

The cause must be diagnosed and treated if possible, especially a review of (and replacement of if necessary) drug therapy.

Avoid decongestants and antihistamines.

## Strategies to consider

- Suck ice or lozenges, sip sugarless fluids frequently and chew sugarless gum (avoid mouthwashes containing sugars and alcohol).
- Use a saliva substitute (e.g. Aquae, Saliva Orthana) or frequent mouthwashes (e.g. lemon and glycerin, 5–10 mL in 100 mL water as required—can be used in a plastic squeeze bottle).
- Use sodium fluoride 0.5% mouthwash for 5 minutes each day.
- Topical applications of glycerin or paraffin oil to the lips.

## Halitosis<sup>4</sup>

### Causes

The diagnostic strategy model for chronic halitosis (bad breath) is presented in **CHAPTER 17**. The commonest causes are orodental disorders secondary to poor oral hygiene and inappropriate diet. Bacterial putrefaction of dental and food debris, together with inflammation of the gums, is largely responsible for the oral malodour. Smoking, alcohol and a dry mouth will aggravate the problem. [A 1999 survey showed that 87% of patients with halitosis had an oral cause, 8% an ear, nose and throat cause with 5% having other or unidentified causes.]

### Management

- First exclude dental disease, malignancy (esp. nasopharyngeal cancer), pulmonary TB, hairy tongue, nasal and sinus infection.
- Refer for a dental check. Treat gingivitis.
- Consider drugs such as isosorbide dinitrate and various antidepressants as a cause.
- Cease smoking if this is a factor.
- Avoid or limit onions, garlic, peppers, curries, spicy salami and similar meats.
- Avoid or limit strong cheeses.
- Avoid smoking and excessive nips of alcohol.
- Brush teeth regularly during the day—immediately after meals.
- Gently brush the dorsum of the tongue with special, available soft brushes.
- Rinse mouth out with water after meals.
- Avoid fasting for long periods during the day.
- Drink copious amounts of water during the day.
- Chew sugarless gum.
- Gargle with mouthwash regularly (e.g. Listerine; Cepacol Mint mouthwash; 0.2% aqueous chlorhexidine).

- Use dental floss regularly to clean the teeth.
- Chew sugarless gum to help moisten the mouth.

*Tip:* use an oil/water wash (e.g. equal volumes of cetylpyridinium chloride (Cepacol) and olive oil), gargle a well-shaken mixture and spit out, qid.

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Aphthous ulcers
- Halitosis
- Hand, foot and mouth disease
- Tongue soreness

## Practice tips

- Recurrent herpes simplex ulceration is not common in the oral mucosa and if suspected should be confirmed by laboratory investigation. The treatment is different to aphthous ulceration so clinical distinction is important. Herpes simplex virus is aggravated by topical steroids.
- For unusual mouth ulceration consider acute leukaemia, cancer, blood dyscrasias, Crohn disease and drug therapy such as anti-epileptics and antihypertensives.

# 73 Sore throat

*I believe there are hundreds of young adults who have erroneously suffered tonsillectomy because of the tonsillitis of undiagnosed glandular fever.*

Sceptical GP (anonymous)

A sore or painful throat is one of the commonest symptoms encountered in general practice. The most usual cause is viral pharyngitis, which is self-limiting and usually only requires symptomatic treatment.

- As a general rule antibiotics should not be prescribed to treat a sore throat, excluding evidence of group A beta-haemolytic *Streptococcus* (GABHS) infection.<sup>3</sup>

## Definitions

**Pharyngitis** Inflammation of pharynx  $\pm$  tonsils.

**Quinsy** A peritonsillar abscess.

**Tonsillitis** Inflammation of tonsils only.

## Key facts and checkpoints

- In the National Morbidity Survey (UK)<sup>1</sup> nine episodes per annum of acute pharyngitis or acute tonsillitis were diagnosed for every 100 patients.
- Sore throats account for about 5% of consultations in general practice per annum.<sup>2</sup>
- In one UK general practice it was the third most common new presenting symptom—5.4% of presenting problems.
- Although throat infections are common from infancy, children under 4 years of age rarely complain of a sore throat.
- Complaints of a sore throat are prevalent in children between 4 and 8 years and in teenagers.
- Sore throats continue to be common up to the age of 45 and then decline significantly.
- The common causes are viral pharyngitis (approximately 60–65%) and tonsillitis due to *Streptococcus pyogenes* (approximately 20%).
- The sore throat may be the presentation of serious and hidden systemic diseases, such as blood dyscrasias, HIV infection and diabetes (due to candidiasis).
- A very important cause is tonsillitis caused by Epstein–Barr mononucleosis (EBM). Treating this cause with penicillin can produce adverse effects.

## Presentation

Sore throat may be present as part of a complex of the common upper respiratory infections, such as the common cold and influenza. However, sore throat often presents as a single symptom. The pain is usually continuous and aggravated by swallowing. In those under 4 years of age the presentation of acute pharyngitis or tonsillitis may be confusing as the presenting complaints may be vomiting, abdominal pain and fever rather than sore throat and swallowing difficulty.

It is appropriate to consider sore throat as acute or chronic. Most presentations come as acute problems, the causes of which are listed in [TABLE 73.1](#).

## A diagnostic approach

A summary of the diagnostic strategy model is presented in [TABLE 73.2](#).

## Probability diagnosis

At least 50% of sore throats, mainly pharyngitis, will be caused by a virus. A viral infection is supported by the presence of coryza prodromata, hoarseness, cough, conjunctivitis and nasal stuffiness.

## Serious disorders not to be missed

It is vital to be aware of *Haemophilus influenzae* infection in children, especially between 2 and 4 years, when the deadly problem of epiglottitis can develop suddenly. These patients present with a short febrile illness, respiratory difficulty (cough is not a feature) and are unable to swallow.

Apart from acute epiglottitis it is important not to overlook cancer of the oropharynx or tongue, or the blood dyscrasias, including acute leukaemia

(see CHAPTER 26). The severe infections not to be missed include streptococcal pharyngitis with its complications, including quinsy, diphtheria and HIV infection (including AIDS).

A foreign body may stick in the supraglottic area and may not be seen on oral examination.

## Pitfalls

There are many pitfalls, the classic being to diagnose the exudative tonsillitis of EBM as streptococcal tonsillitis and prescribe one of the penicillins, which may precipitate a severe rash. Primary HIV infection can present with a sore throat along with other

**Table 73.1** Causes of acute sore throat

Bacteria  
Beta-haemolytic streptococci (GABHS)  
Diphtheria (rare)  
Gonococcal pharyngitis  
*Haemophilus influenzae*  
*Moraxella catarrhalis*  
Quinsy  
*Staphylococcus aureus* (rare)  
Syphilis (rare)  
Acute ulcerative gingivitis (Vincent angina infection)

### Viral

Severe–moderate soreness  
Epstein–Barr mononucleosis  
Herpangina  
Herpes simplex pharyngitis

### Mild–moderate soreness

Adenovirus  
Cytomegalovirus  
Coronavirus  
Enterovirus  
Influenza virus  
Picornavirus  
Rhinovirus  
Human immunodeficiency virus  
Varicella (chicken pox)

### Other infections

*Candida albicans*, especially in infants  
*Mycoplasma pneumoniae*  
*Chlamydia pneumoniae*

Blood dyscrasias  
Agranulocytosis  
Leukaemia

### Irritants

Tobacco smoke  
Antiseptic lozenges (oral use)

**Table 73.2** Sore throat: diagnostic strategy model

- Q. Probability diagnosis  
A. Viral pharyngitis  
Streptococcal (GABHS) tonsillitis  
Chronic sinusitis with postnasal drip  
Oropharyngeal candidiasis  
Epstein–Barr mononucleosis
- 
- Q. Serious disorders not to be missed  
A. Cardiovascular:  
• angina  
• myocardial infarction  
Neoplasia:  
• cancer of oropharynx, tongue  
Blood dyscrasias (e.g. agranulocytosis, acute leukaemia)  
Severe infections:  
• acute epiglottitis (children and adults)  
• peritonsillar abscess (quinsy)  
• pharyngeal abscess  
• diphtheria (very rare)  
• HIV/AIDS  
• Vincent angina
- 
- Q. Pitfalls (often missed)  
A. Trauma—foreign body (e.g. fish bone)  
Epstein–Barr mononucleosis  
*Candida*:  
• common in infants  
• steroid inhalers  
STIs:  
• gonococcal pharyngitis  
• herpes simplex (type II)  
• syphilis  
Irritants (e.g. cigarette smoke, chemicals)  
Reflux oesophagitis → pharyngolaryngitis  
Tonsilloliths  
Cricopharyngeal spasm  
Kawasaki disease  
Chronic mouth breathing  
Aphthous ulceration  
Thyroiditis  
Glossopharyngeal neuralgia  
Rarities:  
• scleroderma  
• Behçet disease  
• sarcoidosis  
• malignant granuloma  
• tuberculosis
- 
- Q. Seven masquerades checklist  
A. Depression  
Diabetes (*Candida*)  
Drugs  
Anaemia (possible)  
Thyroid disorder (thyroiditis)  
Spinal dysfunction (cervical)
- 
- Q. Is the patient trying to tell me something?  
A. Unlikely, but the association with depression is significant.

symptoms. Adenovirus pharyngitis can also mimic streptococcal pharyngitis, especially in young adults.

Traumatic episodes are important but are often not considered, especially in children. They include:

- a foreign body—may cause a sudden onset of throat pain, then drooling and dysphagia
- vocal abuse—excessive singing or shouting can cause a sore throat and hoarseness
- burns—hot food and drink, acids or alkalis

### Red flag pointers for sore throat

- Persistent high fever
- Failed antibiotic treatment
- Medication-induced agranulocytosis
- Mouth drooling: consider epiglottitis (don't examine the throat)
- Sharp pain on swallowing (? foreign body)
- Marked swelling of quinsy
- Candidiasis: consider diabetes or immunosuppression

Various irritants, especially cigarette smoke in the household and smoke inhalation from fires, can cause pharyngeal irritation with sore throat, especially in children.

The mouth and pharynx may become dry and sore from mouth breathing, which is often associated with nasal obstruction (e.g. adenoid hypertrophy, allergic rhinitis).

Tonsilloliths are concretions of debris entrapped within deep tonsillar crypts. They are a common cause of halitosis, vague sore throat and possibly recurrent bouts of tonsillitis.

### Seven masquerades checklist

Depression may be associated with a sore throat. Diabetes and aplastic anaemia and drugs are indirectly associated through candidiasis, neutropenia and agranulocytosis respectively. NSAIDs can cause a sore throat. The possibility of thyroiditis presenting as a sore throat should be kept in mind.

### Making a diagnosis

The issues of making a reliable diagnosis and prescribing antibiotics are rather contentious and at times difficult. It is difficult to distinguish clinically between bacterial and viral causes. The main issue is to determine whether the sore throat has a treatable cause by interpretation of the clinical and epidemiological data.

The appearance of the pharynx and tonsils is not always discriminating. A generalised red throat may be caused by a streptococcal or a viral infection, as may tonsils that are swollen with follicular exudates. On probability, most sore throats are caused by a virus and generally do not show marked inflammatory changes or purulent-looking exudates (see FIG. 73.1). Such throats should be treated symptomatically.

## The clinical approach

### History

It is necessary to determine whether the patient has a sore throat, a deep pain in the throat or neck pain. Instruct the patient to point to exactly where the pain is experienced. Enquire about relevant associated symptoms such as metallic taste in mouth, fever, upper respiratory infection, other pain such as ear pain, nasal stuffiness or discharge and cough.

Note whether the patient is an asthmatic and uses a corticosteroid inhaler, or is a smoker, or exposed to environmental irritants. Check the immunisation history, enquiring especially about diphtheria.

The history should give a clue to the remote possibility that the painful throat is a manifestation of angina.

### Examination

An inspection should note the general appearance of the patient, looking for 'toxicity', the anaemic pallor of leukaemia, the nasal stuffiness of infectious mononucleosis, the characteristic halitosis of a streptococcal throat.

Palpate the neck for soreness and lymphadenopathy, inspect the ears and check the sinus areas.

Then inspect the oral cavity and pharynx. Look for ulcers, abnormal masses and exudates. Note whether the uvula and soft palate, tonsils, fauces or pharynx are swollen, red or covered in exudate. The typical appearances of various conditions causing a sore throat are shown in FIGURES 73.1 to 73.7, and important causes to exclude in FIGURE 73.8.

### Guidelines

- Small patches of exudate on the palate or other structure indicate *Candida albicans* (oral thrush) (see FIG. 73.2).
- A large whitish-yellow membrane virtually covering both tonsils indicates EBM (see FIG. 73.3).

**FIGURE 73.1** Viral pharyngitis: the signs may be minimal but mild redness of pharynx and prominent lymphoid patches on the oropharynx are typical

**FIGURE 73.2** Oral thrush due to *Candida albicans* in a diabetic patient. Small patches of yellow-white exudate are seen on the palate, dorsum of the tongue, pharynx and mucosa.

Photo courtesy Hugh Newton-John

**FIGURE 73.3** Tonsillitis of Epstein-Barr mononucleosis showing swollen red tonsils, with a whitish-yellow membranous exudate, swollen uvula and petechiae on the soft palate

Photo courtesy Hugh Newton-John

**FIGURE 73.4** Acute follicular tonsillitis due to *Streptococcus pyogenes*: the tonsils are red and swollen with pockets of pus

Photo courtesy Hugh Newton-John

**FIGURE 73.5** Streptococcal tonsillopharyngitis: severe inflammation involves both tonsils and pharynx with marked redness, swelling and exudate. Consider herpes simplex and mononucleosis as alternative diagnoses.

- A generalised red, swollen appearance with exudate indicates GABHS infection (see FIG. 73.4 and 73.5).

## Investigations

Investigations can be selected from:

- throat swab
- haemoglobin, blood film and white cell count
- mononucleosis test
- random blood sugar (?diabetes)
- biopsy of suspicious lesions

### To swab or not to swab

Throat swabs are about 90% effective in isolating GABHS from the infected throat. Authorities are divided about management. Some recommend that throat cultures be performed for all sore throats and antibiotics given only when GABHS is found. Others regard throat cultures as being unnecessary and recommend therapy based on clinical judgments. Swabs are seldom helpful because the isolation of GABHS often represents asymptomatic carriage.<sup>4</sup> Still others recommend throat cultures for selected patients only.<sup>5</sup>

Generally, throat cultures are not necessary except to verify the presence of *S. pyogenes*, especially in closed institutions such as boarding schools, or if diphtheria is suspected in the non-immunised. One study has found that toothbrushes harbour GABHS and should not be shared.<sup>6</sup> A positive culture and a fourfold rise in the ASO titre are necessary for a precise diagnosis.

### Epstein-Barr mononucleosis screening

It is important initially if tonsillar exudate is present to consider the possibility of EBM. If suspected, an IgM antibody test should be ordered, rather than the older tests, such as a Paul-Bunnell test.

### Supportive symptomatic treatment

Supportive measures include:

- adequate soothing fluids, including icy poles
- analgesia: adults—2 soluble aspirin; children—paracetamol elixir (not alcohol base) or ibuprofen
- rest with adequate fluid intake
- soothing gargles (e.g. soluble aspirin used for analgesia)
- advice against overuse of OTC throat lozenges and topical sprays, which can sensitise the throat; limited use (3 days) of decongestants for nasal decongestion is helpful

### Sore throat in children

An acute sore throat in a child usually means a viral or, less commonly, bacterial infection of the tonsillopharynx. A bacterial cause is more common in children aged 3–13 years than in children <3 years. Other causes to consider are:

- gingivostomatitis, especially primary herpes simplex
- epiglottitis
- laryngotracheobronchitis (croup)
- laryngitis
- oral candidiasis (more a bad taste than pain)

- aphthous ulcers
- foreign bodies
- postnasal drip (e.g. allergic rhinitis)
- irritation: low environmental humidity, smoke (e.g. household smoke)

### Sore throat in the elderly

Sore throat in the elderly may be caused by a viral infection but otherwise needs to be treated with considerable respect. It is important to exclude pharyngeal cancer which can present with the classic triad.

**DxT** painful swallowing + referred ear pain + hoarseness → pharyngeal cancer

Oropharyngeal lesions may occur with herpes zoster but vesicles are usually present on the face.

A metallic taste in the mouth with or without a complaint of a sore throat indicates *C. albicans* and hence diabetes must be excluded.

### Bacterial causes of sore throat

#### § Streptococcal tonsillopharyngitis

This infection may involve the pharynx only and vary from mild to severe, or it may involve both tonsils and pharynx. It is uncommon under 3 years or over 40 years.<sup>7</sup>

### Guidelines for streptococcal throat

The four diagnostic features are:

- constitutional symptoms:
  - fever  $\geq 38^{\circ}\text{C}$
  - toxicity
- tender anterior cervical lymphadenopathy
- tonsillar swelling and exudate
- absence of cough

Other symptoms include:

- difficulty in swallowing
- significant pain, including pain on talking
- foul-smelling breath

### Examination

- Pharynx very inflamed and oedematous
- Tonsils swollen with pockets of yellow exudate on surfaces (see FIGS. 73.4 and 73.5)
- Very tender enlarged tonsillar lymph nodes

### Treatment

Indications for antibiotic therapy:<sup>4</sup>

- severe tonsillitis with above features of GABHS

- existing rheumatic heart disease at any age
- scarlet fever
- peritonsillar cellulitis or abscess (quinsy)
- patients 2–25 years with presumptive GABHS from special communities (e.g. remote Indigenous) with a high incidence of acute rheumatic fever

One evidence-based review recommended that if a cold follows its natural course, no antibiotics will be helpful. If there is a sore throat with no cough, but fever  $>38^{\circ}\text{C}$ , tender neck glands and white spots in the throat, antibiotics are indicated.<sup>8</sup> Treatment should be with penicillin or an alternative antibiotic (see TABLE 73.3).<sup>4</sup>

Antibiotic treatment has a variable effect on the resolution of symptoms. It does not protect against glomerulonephritis but does protect against rheumatic fever.<sup>7</sup> Amoxycillin should be avoided in tonsillitis because of confusion caused should mononucleosis be present. Frequent fluids are advisable.

### Recurrent tonsillitis<sup>4,7</sup>

Treat with prophylactic penicillin for patients with more than five episodes of presumptive bacterial tonsillitis in a year. The decision should be based on the severity of the episode, time lost from work or school, infectivity and response to antibiotics.

**Table 73.3** Treatment for streptococcal throat (proven or suspected)<sup>4</sup>

#### Children

phenoxymethyl penicillin 50 mg/kg/day (o) in 2 divided doses for 10 days (to max. 1 g/day) or (if hypersensitive to penicillin) roxithromycin 4 mg/kg up to 150 mg (o) bd for 10 days

#### Adults

phenoxymethyl penicillin 500 mg (o) 12 hourly for 10 days (can initiate treatment with one injection of procaine penicillin) or (if hypersensitive to penicillin) roxithromycin 300 mg (o) daily for 10 days

#### In poorly compliant patients:

benzathine penicillin 900 mg IM as a single dose in adults

#### In severe cases:

procaine penicillin 1–1.5 mg IM daily for 3–5 days *plus* phenoxymethyl penicillin (as above) for 10 days

*Note:* Although symptoms and most evidence will disappear within 1–2 days of treatment, a full course of 10 days should be given to provide an optimal chance of eradicating *S. pyogenes* from the nasopharynx and thus minimising the risk of recurrence or complications such as rheumatic fever.<sup>4</sup> Some studies indicate that 7 days may be sufficient.

Tonsillectomy in children results in only a modest reduction in the number of subsequent sore throats.<sup>9</sup>

### Quinsy

Quinsy is a peritonsillar abscess characterised by marked swelling of the peritonsillar area with medial displacement of tonsillar tissue (see FIG. 73.6). It is usually caused by GABHS or anaerobes, occasionally *Haemophilus* sp. and *Staphylococcus aureus*. A typical picture of tonsillitis is followed by increasing difficulty in swallowing and trismus.

### Treatment

Antibiotics (e.g. procaine penicillin IM or clindamycin) plus aspiration or drainage in hospital under local anaesthetic if it is pointing. Oral penicillin treatment is likely to fail. Subsequent tonsillectomy may, but not always, be necessary. The cover can be broadened by adding metronidazole.<sup>4</sup>

**FIGURE 73.6** Peritonsillar abscess (quinsy): a tense red bulging mass is noted and the uvula is displaced from the mid-line; a site of incision for drainage is indicated

### Acute epiglottitis

In children this is a life-threatening infection. It may be overlooked in adults where, unlike children, the airway is usually not obstructed and the patient presents with a severe sore throat, dysphagia, drooling of saliva and a tender neck. Examination of the throat may appear quite normal. However, it is a severe infection requiring hospitalisation and parenteral antibiotics (e.g. cefotaxime).

## § Diphtheria

Due to the bacterium *Corynebacterium diphtheriae*, the potentially fatal form of this disease almost always occurs in non-immunised people. The clinical presentation may be modified by previous immunisation or by antibiotic treatment.

### Clinical features

- Insidious onset
- Mild to moderate fever
- Mild sore throat and dysphagia
- Patient looks pale and ill
- Enlarged tonsils
- Pharynx inflamed and oedematous
- Pseudomembrane (any colour but usually grey-green) can spread beyond tonsils to fauces, soft palate, lateral pharyngeal wall and downwards to involve larynx (see FIG. 73.7)
- Enlarged cervical lymph nodes
- Soft tissue swelling of neck → 'bull neck' appearance

FIGURE 73.7 Diphtheria: tonsils and pharynx are red and swollen; a thick grey-green exudate forms on the tonsils as a spreading membrane

### Management

- Throat swabs
- Antitoxin
- Penicillin or erythromycin 500 mg qid for 10 days
- Isolate patient

## Viral causes of sore throat

### § Epstein–Barr mononucleosis

The angiose form of EBM is a real trap and must be considered in patients aged 15–25 years (peak incidence) with a painful throat that takes about 7 days to reach its peak. Refer to CHAPTER 28.

### Clinical features

- Sore throat
- Prodromal fever, malaise, lethargy
- Anorexia, myalgia
- Nasal quality to voice
- Skin rash

### Examination

- Petechiae on palate (not pathognomonic)
- Enlarged tonsils with or without white exudates (looks, but isn't, purulent)
- Peri-orbital oedema
- Lymphadenopathy, especially posterior cervical
- Splenomegaly (50%)
- Jaundice ± hepatomegaly (5–10%)

### The rash

- Primary rash (5%)
- Secondary rash:
  - with ampicillin, amoxycillin (90–100%)
  - with penicillin (50%)

*Note:* This rash is not synonymous with penicillin hypersensitivity.

### Diagnosis

- Blood film—atypical lymphocytes
- White cell count—absolute lymphocytosis
- Heterophil antibodies

or

Monospot test

or

- EBV IgM test (more specific)

### Treatment<sup>4</sup>

Symptomatic e.g. paracetamol for pain. Parenteral corticosteroids only in most severe cases.

## § Herpangina

An uncommon infection caused by the Coxsackie virus. Presents as small vesicles on soft palate, uvula and anterior fauces. These ulcerate to form small ulcers. The problem is benign and rapidly self-limiting.

## Herpes simplex pharyngitis

In adults primary infection is similar to severe streptococcal pharyngitis but ulcers extend beyond the tonsils.

## Other viral pharyngitis

Typically, the signs are fewer than with other causes. The typical case has mild redness without exudate and

prominent (sometimes pale) lymphoid patches on the posterior pharynx (see FIG. 73.1). Tonsillar lymph nodes are usually not enlarged or tender. This picture is the commonest encountered in general practice.

## Candida pharyngitis

Oral candidiasis typically presents as milky-white growths on the palate, buccal and gingival mucosae, pharynx and dorsum of the tongue (see FIG. 73.2). If scraped away, a bleeding ulcerated surface remains. A bad (metallic) taste is a feature but the patient may complain of a sore throat and tongue and dysphagia.

Causes or predisposing factors to consider:

- HIV infection
- diabetes mellitus
- broad-spectrum antibiotics
- corticosteroids, including inhalers
- dentures
- debility

## Management

- Determine underlying cause.

Nystatin suspension, rinse and swallow qid  
or

amphotericin 10 mg lozenge dissolved slowly in oral cavity, 6 hourly, for 7–14 days

## When to refer

- Acute epiglottitis in children (a medical emergency)
- Inaccessible foreign body
- Abscess: peritonsillar or retropharyngeal
- Recurrent attacks of tonsillitis and adenoid hypertrophy for an opinion about tonsillectomy and/or adenoidectomy
- Suspicion or evidence of HIV infection or diphtheria
- Patients not responding to treatment
- Patients with more generalised disorders that are not yet diagnosed<sup>9</sup>

## Guidelines for tonsillectomy<sup>10</sup>

- Repeated attacks of acute tonsillitis
- Enlarged tonsils and/or adenoids causing airway obstruction, including OSA
- Chronic tonsillitis
- More than one attack of peritonsillar abscess
- Biopsy excision for suspected new growth

Antibiotic treatment is aimed primarily at streptococcal pharyngitis and this is often based on clinical judgment.

## Practice tips

- Consider severe tonsillitis with a covering membrane as EBM.
- If an adult presents with an intensely painful throat with a heavy exudate and seems toxic, consider primary herpes simplex as well as streptococcal throat.
- Reserve swabs of the throat for verification of a streptococcal throat where it is important to do so, for suspected diphtheria and for suspicion of other serious infections such as tuberculosis.
- Be aware of possible complications, such as febrile convulsions in children and abscess formation.
- Do not misdiagnose unusual causes of a sore throat, such as cancer (see FIG. 73.8).
- The triad: hoarseness, pain on swallowing and referred ear pain = pharyngeal cancer.
- The two major considerations in managing the acute sore throat are:
  - Can diphtheria be excluded?
  - Should the patient be treated with an antibiotic?

FIGURE 73.8 General causes of a sore throat: note the importance of excluding cancer

*Chronic fatigue syndrome is not tiredness: there is a difference between feeling tired and 'fatiguey'. Fatigue involves a heaviness in the limbs, a sense of inability to think or move, pain in muscles and joints, nausea etc. Please understand the difference.*

CFS patient to author, January 1995

Tiredness, which basically means 'a desire to rest', or chronic fatigue is not a diagnosis but rather a symptom of illness: it may occur as either a presenting or a supporting symptom. Tiredness is interchangeable with terms such as weariness, lethargy, loss of energy, listlessness and exhaustion. It is a common and difficult presenting symptom often known by the acronym TATT—'tired all the time'. The symptom of tiredness is likely to be 'hidden' behind the request for a tonic or a physical check-up.<sup>1</sup>

Tiredness can be a symptom of a great variety of serious and uncommon diseases, including malignant disease. The challenge for the family doctor is to diagnose such disorders quickly without extravagant investigation.

## Key facts and checkpoints

- The commonest cause of tiredness is psychological distress, including anxiety states, depression and somatisation disorder.
- An Australian study showed that fatigue presents at a rate of 1.4 per 100 encounters.<sup>2</sup>
- The study by Hickie et al<sup>3</sup> showed that 25% of a sample of attendees visiting general practices had chronic fatigue. Of these, 70% had psychological distress. The others were more likely to have a current depressive disorder.
- In Jerrett's study<sup>4</sup> no organic cause was found in 62.3% of patients presenting with lethargy; the constant factors were sleep disturbance and the presence of stress in their lives. Many of them turned out to be suffering from psychological problems or psychiatric illnesses, including depression, anxiety state or bereavement.
- An important cause of daytime tiredness is a sleep disorder such as obstructive sleep apnoea, which results in periodic hypoventilation during sleep. It occurs in 2% of the general population in all age groups and in about 10% of middle-aged men.<sup>4</sup> A history of snoring is a pointer to the problem. See CHAPTER 71.

- Underlying disorders that need to be considered as possible causes of chronic fatigue are endocrine and metabolic disorders, malignancy, chronic infection, autoimmune disorders, primary psychiatric disorders, neuromuscular disorders, anaemia, drugs and cardiovascular disorders.
- Prolonged or chronic tiredness is characterised clinically by disabling tiredness, typically lasting more than 2 weeks, associated with non-restorative sleep, headaches and a range of other musculoskeletal and neuropsychiatric symptoms.<sup>3</sup>
- Sociodemographic correlates are concurrent psychological distress, female sex, lower socioeconomic status and fewer total years of education.<sup>3</sup>
- Chronic fatigue syndrome (CFS) is defined as debilitating fatigue, persisting or relapsing over 6 months, associated with a significant reduction in activity levels of at least 50%, and for which no other cause can be found.

## Causes of tiredness

Analysing the symptom and reaching a diagnosis demands considerable skill, since tiredness may indicate the first subtle manifestation of a serious physical disease or, more commonly, may represent a patient's inability to deal with the problems of everyday life. Chronic tiredness or fatigue is a feature of the 'high pressure' nature of many people's lifestyles.

Careful consideration must be given to the differentiation of physiological tiredness, as a result of excessive physical activity, from psychological tiredness. Furthermore, before diagnosing tiredness as psychological, pathological as well as physical causes must be excluded.

A summary of causes of chronic tiredness is presented in TABLE 74.1.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in TABLE 74.2.

**Table 74.1** Causes of chronic tiredness/fatigue

## Psychogenic/non-organic

## Psychiatric disorders:

- anxiety states
- depression/dysthymia
- other primary disorders
- bereavement
- somatisation disorder

## Lifestyle factors:

- workaholic tendencies and 'burnout'
- lack of exercise/sedentary lifestyle
- mental stress and emotional demands
- exposure to irritants (e.g. carbon monoxide, 'lead' fumes)
- inappropriate diet
- obesity
- sleep deprivation

## Organic

Congestive cardiac failure

Anaemia

Malignancy

HIV/AIDS

Subacute to chronic infection (e.g. hepatitis, malaria, Lyme disease)

Endocrine: various, especially thyroid (hyper and hypo), Addison disease and diabetes mellitus

Nutritional deficiency

Kidney failure

Liver disorders: chronic liver failure, chronic active hepatitis

Respiratory conditions (e.g. asthma, COPD)

Neuromuscular (e.g. MS, myasthenia gravis, Parkinson disease)

Metabolic (e.g. hypokalaemia, hypomagnesaemia)

Drug toxicity, addiction or side effects (see **TABLE 74.3**)

Autoimmune disorders

Sleep-related disorders

Postinfectious fatigue syndrome (e.g. influenza, mononucleosis)

## Unknown

Fibromyalgia

Chronic fatigue syndrome

Somatisation disorder

Irritable bowel syndrome

**Table 74.2** Tiredness/chronic fatigue: diagnostic strategy model

Q. Probability diagnosis

A. Stress and anxiety  
Depression

Inappropriate lifestyle and psychosocial factors

Viral/postviral infection

Sleep-related disorders (e.g. sleep apnoea)

Q. Serious disorders not to be missed

A. Vascular:

- cardiac arrhythmias
- cardiomyopathy
- incipient CCF

Infection:

- hidden abscess
- HIV/AIDS
- hepatitis B and C (others)

Cancer

Other:

- anaemia
- haemochromatosis

Q. Pitfalls (often missed)

A. 'Masked' depression

Food intolerance

Coeliac disease

Chronic infection (e.g. Lyme disease)

Incipient CCF

Fibromyalgia

Lack of fitness

Drugs: alcohol, prescribed, withdrawal

Menopause syndrome

Pregnancy

Neurological disorders:

- post-head-injury
- CVA
- Parkinson disease

Kidney failure

Metabolic (e.g. hypokalaemia, hypomagnesaemia)

Chemical exposure (e.g. occupational)

Rarities:

- hyperparathyroidism
- Addison disease (see **CHAPTER 23**)
- Cushing syndrome
- narcolepsy
- multiple sclerosis
- autoimmune disorders

Q. Seven masquerades checklist

A. Depression

Diabetes

Drugs

Anaemia

Thyroid disease (other endocrine)

Spinal dysfunction

UTI

Q. Is the patient trying to tell me something?

A. Highly likely.

## Probability diagnosis

The most probable diagnoses to consider are:

- tension, stress and anxiety
- depression
- inappropriate lifestyle and psychosocial factors
- viral or postviral infection
- sleep-related disorders

Research studies have reported that over 50% (and in some cases as many as 80%) of reported cases of fatigue have been of psychological causation.<sup>3</sup> Overwork is a common cause of fatigue and is often obvious to everyone but the patient. The modern approach to sleep-related disorders has revealed several important factors causing excessive tiredness.

## Serious disorders not to be missed

Many serious disorders such as anaemia, malignant disease and subacute or chronic infections (e.g. hepatitis, bacterial endocarditis and tuberculosis) can be 'hidden' or masked in the initial stages or not readily apparent. Neuromuscular diseases such as myasthenia gravis and multiple sclerosis, connective tissue disorders and HIV infection also have to be excluded.

## Pitfalls

The symptom of tiredness is fraught with pitfalls. Common ones include depression and other psychoneurotic disorders, and incipient congestive cardiac failure. Drug intake is a very common pitfall, whether it be by self-administration (including alcohol) or iatrogenic.

Tiredness is a feature of pregnancy in many women, so this association is worth keeping in mind, especially in the early stages when a change in menstrual history is not given or a young single woman will attempt to conceal the fact. It is also a presenting symptom of the menopause syndrome, which should not be misdiagnosed. Two classic causes of tiredness are haemochromatosis and coeliac disease.

## Seven masquerades checklist

All these important problems are capable of being responsible for tiredness, especially depression, diabetes, drugs, anaemia and urinary infection. Thyroid disorder could certainly be responsible. Spinal pain can indirectly cause tiredness. Drugs that commonly cause tiredness are listed in **TABLE 74.3**.

Antihypertensives require special consideration. Drug withdrawal, especially for illicit drugs such as amphetamines, marijuana, cocaine and heroin, has to be considered.

**Table 74.3** Drugs that can cause tiredness

Alcohol
Analgesics
Antibiotics
Anticonvulsants
Antidepressants
Anti-emetics
Antihistamines
Antihypertensives e.g. $\beta$ -blockers
Anxiolytics
Corticosteroids
Digoxin
Ergot alkaloids
Hormones (e.g. oral contraceptives)
Hypnotics
Nicotine
NSAIDs
Vitamins A and D (early toxic symptoms)

*Note:* Most drugs have a considerable capacity to cause tiredness.

## Psychogenic considerations

Tiredness is a symptom that may represent a 'ticket of entry': a plea for help in a stressed, anxious or depressed patient. Any of the primary psychiatric disorders can present as tiredness.

## Red flag pointers for tiredness

- Unexplained weight loss
- Sleep disturbance
- Symptoms of depression
- Drug and alcohol abuse
- Persistent fever

## The clinical approach—key history

In routine history taking, it is mandatory that questions be asked about the following if the information is not volunteered by the patient:

- sleep pattern (it is not uncommon for patients to say they sleep well and yet on questioning it is found they have initial insomnia, or middle insomnia, or both, with or without early morning waking). It is most relevant to talk to any sleeping partners to obtain a history of sleep disturbance
- weight fluctuations
- energy—performance—ability to cope

- sexual activity/sexual problems
- suicidal ideas
- self-medication—OTC preparations (e.g. bromides, stimulants, analgesics, alcohol, cigarettes, other drugs); this is particularly important in the drug addiction-prone group: doctors, chemists, nurses, workers in the liquor industry, truck drivers
- fears (including phobic symptoms, hypochondriasis)
- precipitating factors (present in over 50% of patients with depressive illness):
  - postpartum
  - postoperative
  - associated with chronic physical illness
  - bereavement
  - pain—chronic pain conditions
  - retirement
  - medication
  - post trauma (e.g. motor vehicle accident)
  - postviral infections, especially hepatitis, mononucleosis, influenza
- work history—determine whether the patient is a workaholic; ask about bullying at work
- dietary history—determine pattern, including fad diets or skipped meals
- psychological history—stress, anxieties, phobias, depression
- menstrual history and symptoms related to the menopause syndrome
- final questions: 'Is there anything else you feel you should tell me?' 'Do you have any explanation for your tiredness?'
- self-question: 'Is this patient depressed?'

### Physical examination—key features

- General inspection noting facial features, skin appearance and colour, hyperpigmentation, conjunctivae
- Vital signs
- Anthropometric measurements
- Basic respiratory and cardiovascular
- Abdominal examination with focus on masses and inguinal lymphadenopathy
- Urinalysis

### Key investigations (screening) guidelines<sup>5</sup>

- FBE
- ESR/CRP
- Blood sugar
- Serum electrolytes, calcium, magnesium

- Kidney function tests
- Liver function tests
- Iron studies
- Gluten sensitivity screening blood tests
- Faecal occult blood
- Thyroid function tests
- CXR
- Urine—dipstick/MCU

Consider others according to clinical features e.g. chronic infection and HIV screening, autoimmune disorders, cancer markers and sleep disorder studies.

The diagnosis of CFS can be made only when the minimum investigations have been shown to be normal or to demonstrate minor abnormalities in liver function or blood film (atypical lymphocytes).

### Tiredness in children

Tiredness in children is caused by a range of predictable conditions, such as physiological factors (excessive exercise, lack of sleep, poor diet), infections, allergies including asthma, drugs, depression and various illnesses in general.

Overweight children are likely to fatigue more rapidly than children of normal weight.<sup>6</sup> Any bacterial, viral or other infection may be associated with tiredness, with EBV being very significant in adolescents. Chronic EBV infection causing recurrent episodes of fever, pharyngitis, malaise and adenopathy can occur, especially in teenagers, who present with chronic exhaustion that is frequently mistaken for malignancy.<sup>6</sup>

Tiredness is a presenting feature of depression in adolescents, a serious problem that often goes unrecognised. Tonsillar-adenoidal hypertrophy may be large enough to compromise air exchange, particularly during sleep. Snoring may be a feature plus tiredness and lethargy in the waking state.

### Tiredness in the elderly

Elderly people tend to tire more quickly and recover more slowly and incompletely than younger ones. Sleep in older people is generally shorter in duration and of lesser depth, and they feel less refreshed and sometimes irritable on awakening.

Fatigue may be present as a result of emotional frustration. Whenever the prospect of gratification is small, a person tends to tire quickly and to remain so until something stimulating appears. Since the prospects for gratifying experience wane with the years, easy 'fatigueability' or tiredness is common in this age group.

## § Bereavement

Although a bereavement reaction is common and a normal human response that occurs at all ages, it is more frequently encountered in the elderly, with the loss of a spouse or a child (young or middle-aged!). Fatigue that occurs during the initial mourning period is striking and might represent a protective mechanism against intense emotional stress. With time, usually around 6 to 12 months, a compensated stage is reached, fatigue gradually abates, and the patient resumes normal activities as the conflicts of grief are gradually resolved. Freud pointed out the complexities of mourning as the bereaved person slowly adjusts to the loss of the loved one. In others, various symptoms persist as an 'abnormal grief reaction', including persistence of fatigue. Some factors that may lead to this include:

- unexpected death
- high dependence upon the dead person
- guilt feelings, especially in a love/hate relationship

Studies in general practice have shown that widows see their family doctors for psychiatric symptoms at three times the usual rate in the first 6 months after bereavement. The consultation rate for non-psychiatric symptoms also increases, by almost 50%.

## Role of the family doctor

Following bereavement it is important to watch for evidence of depression, drug dependency, especially on alcohol, and suicidal tendencies. In cases of expected death, management should, if possible, start before the bereavement. Supportive care and ongoing counselling are very important.

## § Burnout

### Definition

Burnout is a clinical syndrome with three components:

- long-term emotional exhaustion
- depersonalisation of others and
- lack of personal accomplishment<sup>7</sup>

It is similar to stress-related depression but mood lowering is temporary and work-specific.

Burnout is not a recognised disorder in the DSM-5 criteria, although the ICD-10 classifies it under 'problems related to life management' as a 'state of vital exhaustion'.<sup>8</sup>

Patients sometimes claim that they feel 'burnout'. Burnout can mean many things and include a

whole constellation of psychogenic symptoms, such as exhaustion, boredom and cynicism, paranoia, detachment, heightened irritability and impatience, depression and psychosomatic complaints, such as headache and tiredness. Ellard<sup>9</sup> defines burnout as the syndrome that arises when a person who has a strong neurotic need to succeed in a particular task becomes confronted with the impossibility of success in that task. This seems a realistic explanation, but the important factor is to clarify the nature of the problem with care and determine whether the patient has a psychoneurotic disorder, such as hypomania, anxiety state or depression, or a personality disorder or simply unrealistic goals.

Another viewpoint is that it is caused by chronic emotional stress resulting from prolonged intensive involvement with people.<sup>10</sup> Burnout can be work related. Those who tend to be prone to it are musicians, authors, health professionals, teachers, athletes, engineers, emergency service workers, soldiers, reporters and high-technology professionals. Management involves appropriate counselling, which aims to help the patient to identify life stressors, set realistic personal goals and develop good support mechanisms.

## § Chronic fatigue syndrome

This complex syndrome, which causes profound and persistent tiredness, is also referred to as myalgic encephalomyelitis, chronic neuromuscular viral syndrome,<sup>10</sup> postviral syndrome, chronic EBV syndrome, viral fatigue state, epidemic neuromyasthenia, neurasthenia, Icelandic disease, Royal Free disease and Tapanui disease. CFS is not to be confused with the tiredness and depression that follow a viral infection such as infectious mononucleosis, hepatitis or influenza. These postviral tiredness states are certainly common but resolve within 6 months or so.

Typical features of CFS (see FIG. 74.1):<sup>11</sup>

- extreme exhaustion (with minimal physical effort)
- headache or a vague 'fuzzy' feeling in the head
- aching in the muscles and legs
- poor concentration and memory
- hypersomnia or other sleep disturbance
- waking feeling tired
- emotional lability/anxiety
- depressive-type illness, mood swings
- arthralgia (without joint swelling)
- sore throat
- subjective feeling of fever (with a normal temperature)

**FIGURE 74.1** Chronic fatigue syndrome: characteristic symptoms

- shortness of breath
- tender, swollen lymph nodes
- usually occurs between 20 and 40 years of age

Epidemiologically it has been related to Coxsackie B virus infections. The responsible organism is referred to as a slow virus infection by some authorities.<sup>8</sup>

In approximately two-thirds of patients the illness follows a clearly defined viral illness. However, no single virus has been consistently associated with the development of the syndrome, which is known to develop following a wide range of viral and non-viral infective illness. Immune system dysfunction with chronic overproduction of cytokines (e.g. interferon) is a possible pathogenetic mechanism.

Every family doctor probably has patients with this disorder and the syndrome has been observed in isolated endemics from time to time. Hickie et al<sup>3</sup> found that only 0.3% of those with prolonged fatigue had been diagnosed with CFS by their family doctor.

There is no doubt that the syndrome is real in these patients. One of the major problems confronting clinicians is that there is no diagnostic test for this illness, so it remains a clinical diagnosis backed up by normal baseline investigations.

Diagnostic criteria for CFS have been published<sup>12</sup> (see **TABLE 74.4**), which emphasise the positive clinical features of the syndrome and the chronicity of symptoms (greater than 6 months), in addition to the need for careful exclusion of alternative diagnoses by history, physical examination and laboratory investigation.

**Table 74.4** Criteria for the diagnosis of chronic fatigue syndrome<sup>12</sup>

#### Fatigue

Clinically evaluated, unexplained, persistent or relapsing fatigue persistent for 6 months or more, that:

- is of new or definite onset
  - is not the result of ongoing exertion
  - is not substantially alleviated by rest
  - results in substantial reduction in previous levels of occupational, educational, social or personal activities
- and

#### Other symptoms

Four or more of the following symptoms that are concurrent, persistent for 6 months or more and which did not predate the fatigue:

- impaired short-term memory or concentration
- sore throat
- tender cervical or axillary lymph nodes
- muscle pain
- multi-joint pain without arthritis
- headaches of a new type, pattern, or severity
- unrefreshing sleep
- post-exertional malaise lasting more than 24 hours

### Examination and investigation

Apart from mild pharyngeal infection, cervical lymphadenopathy or localised muscle tenderness, the physical examination is normal.

Investigations should be directed towards excluding possible diagnoses for that patient, such as chronic infection, autoimmune disorders, endocrine and metabolic disorders, primary neuromuscular disorders, malignancy and primary psychiatric disorders. The last mentioned is the most difficult of the differential diagnoses and psychiatric referral will often need to be considered.

### Management

Patients who have CFS are really suffering and unhappy people, similar to those with fibromyalgia (see **CHAPTER 37**). They require considerable understanding and support. Multidisciplinary intervention is recommended. Symptoms last approximately 2½ years.

Management strategies include:<sup>11</sup>

- CFS recognition—explain that the illness is real but the cause unknown and tests are likely to be normal
- explanation and reassurance that the illness is usually self-limiting with no permanent

complications; and that a slow, steady improvement can be anticipated, with most CFS patients returning to normal health

- provide continued psychological support
- review for diagnostic reappraisal (examine at least every 4 months)
- avoid telling patients they are depressed
- treat symptomatically—pain relief, consider NSAIDs and antidepressants if significant depression
- refer to counselling and support groups
- provide a realistic, regular, graduated exercise program
- reduce relevant stress factors (map a realistic living program)
- psychiatric referral if appropriate
- ask the patient to keep a diary of exercise/stress and symptom severity, in particular
- avoid long-distance travel, which is poorly tolerated

Cognitive behaviour therapy appears to help some patients, as do relaxation therapy, meditation, stress management and psychotherapy, where indicated.

The emphasis should be placed on caring, rather than curing, until a scientific solution is found.

A systematic review has found that cognitive behaviour therapy administered by skilled therapists and exercise are beneficial. There is insufficient data or evidence to support the use of antidepressants, corticosteroids, complementary therapies and dietary supplements, including vitamins B12 and C and co-enzyme Q<sub>10</sub>.<sup>5</sup> Prolonged rest and immunotherapy was unlikely to be beneficial.<sup>13</sup>

## Fibromyalgia

The fibromyalgia syndrome (see CHAPTER 37) bears a clinical resemblance to CFS. Musculoskeletal pain

is more prominent although tiredness (fatigue) and sleep disturbance are features. According to Schwenk,<sup>14</sup> fibromyalgia affects 5% of the American population with a peak age of 35 years (range 20–60) and a female:male ratio of 10:1. The management is similar to CFS but the prognosis less optimistic.

### Practice tips

- Always consider underlying psychological distress, especially a depressive disorder.
- Do not overlook a sleep disorder.
- Believe the patient's symptoms.
- Ask the patient what he or she believes may be the cause of the tiredness.
- Be careful of labelling a patient as having CFS.
- Restrict investigations to those which are more likely to be relevant, therapeutic and reassuring.

*In whatever disease sleep is laborious, it is a deadly symptom; but if sleep does good, it is not deadly.*

Hippocrates

The state of arousal is determined by the function of the central reticular formation, which extends from the brain stem to the thalamus. Coma occurs when this centre is damaged by a metabolic abnormality or by an invasive lesion that compresses this centre. Coma is also caused by damage to the cerebral cortex.<sup>1</sup>

The word 'coma' is derived from the Greek *koma*, which is deep sleep. The deeply unconscious patient is not in deep sleep. Coma is best defined as 'lack of self-awareness'.<sup>2</sup>

The various levels of consciousness are summarised in [TABLE 75.1](#); the levels vary from consciousness, which means awareness of oneself and the surroundings in a state of wakefulness,<sup>3</sup> to coma, which is a state of unrousable unresponsiveness. Rather than using these broad terms in clinical practice it is preferable to describe the actual state of the patient in a sentence.

### Key facts and checkpoints

- Always consider hypoglycaemia or opioid overdose in any unconscious patient, especially of unknown background.

- If a patient is unconscious and cyanosed consider upper airway obstruction until proved otherwise.
- The commonest causes of unconsciousness encountered in general practice are reflex syncope, especially postural hypotension, concussion and cerebrovascular accidents (CVAs). The main causes are presented in [TABLE 75.2](#).
- Do not allow the person who accompanies the unconscious patient to leave until all relevant details have been obtained.
- Record the degree of coma as a baseline to determine improvement or deterioration.

### Urgent attention

The initial contact with the unconscious patient is invariably sudden and dramatic and demands immediate action, which should take only seconds to minutes. The primary objective is to keep the patient alive until the cause is determined and possible remedial action taken.<sup>3</sup>

**Table 75.1** The five conscious levels

	State	Clinical features	Simplified classification
↑ Degree of consciousness ↓	1 Consciousness	Aware and wakeful	Awake
	2 Clouded consciousness	Reduced awareness and wakefulness 'Alcohol effect' Confusion Drowsiness	Confused
	3 Stupor	Unconscious Deep-sleep-like state Arousal with vigorous stimuli	Responds to shake and shout
	4 Semicomatose	Unconscious (deeper) Responds only to painful stimuli (sternal rubbing with knuckles) without arousing	Responds to pain
	5 Coma	Deeply unconscious Unrousable and unresponsive	Unresponsive coma

**Table 75.2** Main causes of loss of consciousness

Episodic causes—blackouts
Epilepsy
Orthostatic intolerance and syncope
Drop attacks
Cardiac arrhythmias (e.g. Stokes–Adams attacks)
Vertebrobasilar insufficiency
Psychogenic disorders, including hyperventilation
Breath-holding (children)
Silent myocardial infarction
Hypoxia
Coma
(COMA provides a useful mnemonic for four major groups <sup>1</sup> of causes of unconsciousness)
C = CO <sub>2</sub> narcosis: respiratory failure
O = Overdose of drugs: <ul style="list-style-type: none"> <li>• alcohol</li> <li>• opioids</li> <li>• tranquillisers and antidepressants</li> <li>• carbon monoxide</li> <li>• analgesics</li> <li>• others</li> </ul>

Other: <ul style="list-style-type: none"> <li>• encephalitis</li> <li>• overwhelming infection</li> </ul>
Trauma

## History

A history can be obtained from relatives, friends, witnesses, ambulance officers or others. The setting in which the patient is found is important. Evidence of discs or cards identifying an illness such as diabetes or epilepsy should be searched for. Is there a known history of hypertension, heart disease, respiratory disease or psychiatric illness?

## Questions to be considered<sup>4</sup>

- Is the patient diabetic?  
Does the patient have insulin injections?  
Has the patient had an infection?  
Has the patient been eating properly?
- Is drug overdose possible?  
Has the patient been depressed?  
Has the patient experienced recent stress or personal ‘mishaps’?  
Has the patient been on any medications?
- Is opioid usage possible in this patient?  
Are the presenting circumstances unusual?
- Is epilepsy possible?  
Was twitching in the limbs observed?  
Did the patient pass urine or faeces?
- Is head injury possible?  
Has the patient been in a recent accident?  
Has the patient complained of headache?
- Has a stroke or subarachnoid haemorrhage occurred?  
Has the patient a history of hypertension?  
Did the patient complain of a severe headache?  
Has the patient complained of weakness of the limbs?

## Examination

General features requiring assessment:

- breathing pattern:
  - Cheyne–Stokes respiration (periodic respiration) = cerebral dysfunction
  - ataxic respiration: shallow irregular respiration = brain-stem lesion
  - Kussmaul respiration: deep rapid hyperventilation = metabolic acidosis
- breath: characteristic odours may be a feature of alcohol, diabetes, uraemia and hepatic coma
- level of consciousness: degree of coma (see TABLE 75.1); the Glasgow coma scale (see

TABLE 75.3) is frequently used as a guide to the conscious state

- skin features: look for evidence of injection sites (drug addicts, diabetics) and snake bite marks, colour (cyanosis, purpura, jaundice, rashes, hyperpigmentation) and texture
- circulation
- pulse oximetry
- temperature: consider infection such as meningitis and hyperpyrexia if raised and hypothermia (e.g. hypothyroidism) if low
- hydration: dehydration may signify conditions such as a high fever with infections, uraemia, hyperglycaemic coma

Examination	Action
Is the patient breathing?	If not, clear airway and ventilate.
Note chest wall movement.	
Check pulse and pupils.	Perform cardiopulmonary resuscitation if necessary. Consider naloxone.
Is there evidence of trauma?	Consider extradural haematoma.
Is the patient hypoglycaemic?	Consider glucometer estimation of blood sugar.
Evidence of diabetes (discs, etc.)	
Are vital functions present yet immediate correctable causes eliminated?	Place in coma position.

## Examination of the head and neck<sup>3,4</sup>

The following should be considered:

- facial asymmetry
- the skull and neck: palpate for evidence of trauma and neck rigidity
- eyes, pupils and ocular fundi: look for constricted pupils in opioid overdose
- tongue
- nostrils and ears
- auscultation of the skull

## Examination of the limbs

Consider:

- injection marks (drug addicts, diabetics)
- tone of the limbs by lifting and dropping (e.g. flaccid limbs with early hemiplegia)
- reaction of limbs to painful stimuli
- reflexes—tendon reflexes and plantar response

Table 75.3 Glasgow coma scale

	Score
Eye opening (E)	
Spontaneous opening	4
To verbal command	3
To pain	2
No response	1
Verbal response (V)	
Orientated and converses	5
Disorientated and converses	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1
Motor response (M)	
Obeys verbal command	6
Response to painful stimuli	5
Localises pain	4
Withdraws from pain stimuli	3
Abnormal flexion	2
Extensor response	1
No response	
Coma score = E + V + M	
Minimum 3	
Maximum 15	
If 8–10: take care—monitor the airway	

## General examination of the body

This should include assessment of the pulses and blood pressure.

## Urine examination

Catheterisation of the bladder may be necessary to obtain urine. Check the urine for protein, sugar and ketones.

## Diagnosing the hysterical 'unconscious' patient

One of the most puzzling problems in emergency medicine is how to diagnose the unconscious patient caused by a conversion reaction (hysteria). These patients really experience their symptoms (as opposed to the pretending patient) and resist most normal stimuli, including painful stimuli.

## Method

- Hold the patient's eye or eyes open with your fingers and note the reaction to light.

- Now hold a mirror over the eye and watch closely for pupillary reaction. The pupil should constrict with accommodation from the patient looking at his or her own image.

## Investigations

Appropriate investigations depend on the clinical assessment. The following is a checklist.

- Blood tests:
  - All patients: blood sugar  
urea and electrolytes
  - Selected patients: FBE  
blood gases  
liver function tests  
blood alcohol  
serum cortisol  
thyroid function tests  
serum digoxin
- Pulse oximetry
- Urine tests:
  - a urine specimen is obtained by catheterisation
  - test for glucose and albumin
  - keep the specimen for drug screening
- Stomach contents: aspiration of stomach contents for analysis
- Radiology: CT or MRI scan are the investigations of choice (if available). If unavailable, X-ray of the skull may be helpful.
- Cerebrospinal fluid: lumbar puncture, necessary with neck stiffness, has risks in the comatose patient. A preliminary CT scan is necessary to search for coning of the cerebellum. If clear, the lumbar puncture should be safe and will help to diagnose subarachnoid haemorrhage and meningitis.
- Electroencephalograph
- ECG; look for ↑ QT interval, etc.

## Blackouts — episodic loss of consciousness

Episodic or transient loss of consciousness is a common problem. The important causes of blackout are presented in [TABLE 75.4](#). The history is important to determine whether the patient is describing a true blackout or episodes of dizziness, weakness or some other sensation.

The clinical features of various types of blackouts are summarised in [TABLE 75.4](#).

### § Epilepsy

Epilepsy is the commonest cause of blackouts. There are various types, the most dramatic being the tonic-clonic seizure in which patients have sudden loss of consciousness without warning. See [CHAPTERS 54](#) and [84](#).

The typical features (in order) of a tonic-clonic convulsion are:

- aura (sensory or psychological feelings)
- initial rigid tonic phase (up to 60 seconds)
- convulsion (clonic phase) (seconds to minutes)
- mild coma or drowsiness (15 minutes to several hours)—postictal confusion

Associated features:

- cyanosis, then heavy ‘snoring’ breathing
- eyes rolling ‘back into head’
- ± tongue biting
- ± incontinence of urine or faeces

It should be noted that sphincter incontinence is not firmly diagnostic of epilepsy. In less severe episodes the patient may fall without observable twitching of the limbs.<sup>5</sup>

In atonic epilepsy, which occurs in those with tonic-clonic epilepsy, the patient falls to the ground and is unconscious for only a brief period.

### § Orthostatic intolerance and syncope

In syncope there is a transient loss of consciousness but with warning symptoms and rapid return of alertness following a brief period of unconsciousness (seconds to 3 minutes). The three main syndromes that are outlined in [CHAPTER 54](#) are reflex syncope, postural orthostatic tachycardia syndrome and autonomic failure.

### § Reflex syncope

Relevant features of reflex syncope or vasovagal or common faint (see [TABLE 75.4](#)):

- occurs with standing or, less commonly, sitting
- warning feelings of dizziness, faintness or true vertigo
- nausea, hot and cold skin sensations
- fading hearing or blurred vision
- sliding to ground (rather than heavy full-length fall)

Table 75.4 Clinical features of blackouts

Cause	Precipitants	Subjective onset	Observation	Recovery
<b>Reflex syncope</b>	Posture Stress Haemorrhage Micturition	Warning of feeling 'faint', 'distant', 'clammy, sweaty'	Very pale Sweating	Gradual Feels 'terrible' Fatigue Nausea
<b>Cardiac syncope including POTS syndrome</b>	Various	May be palpitations	Pale	Rapid May be flushing
<b>Autonomic syncope</b>	Postural change orthostasis, food alcohol	Warning (feels faint)	Pale	Rapid
<b>Respiratory syncope</b>	Cough Weight-lifting 'Trumpet playing'	Warning (feels faint)	Pale	Rapid
<b>Carotid sinus syncope</b>	Carotid pressure (e.g. tight collar + turning neck) Postendarterectomy	Warning (feels faint)	Pale	Rapid
<b>Migrainous syncope</b>	Foods Stress Sleep deprivation	Scotomas	Pale	Nausea and vomiting Throbbing headache
<b>Epilepsy</b>	Stress Sleep deprivation Alcohol withdrawal Infection Menstruation Drug non-compliance	Aura with complex partial seizures (CPS)	Automatism (e.g. fidgeting, lip smacking) with CPS	Slow Confused

- rapid return of consciousness
- pallor and sweating and bradycardia
- often trigger factors (e.g. emotional upset, pain)

The patient invariably remembers the onset of fainting. Most syncope is of the benign vasomotor type and tends to occur in young people, especially when standing still (e.g. choir boys). It is the main cause of repeated fainting attacks.

The treatment is to avoid precipitating causes (e.g. prolonged standing, especially in the sun) and bend forwards with the head down or lie down with premonitory signs. 'Smelling salts' (ammonium carbonate) can be carried and used in these circumstances.

## Other forms of syncope

### Micturition syncope

This uncommon event may occur after micturition in older men, especially during the night when they leave a warm bed and stand to void. The cause appears to be peripheral vasodilatation associated with reduction of venous return from straining.

### Cough syncope

Severe coughing can result in obstruction of venous return with subsequent blackout. This is also the mechanism of blackouts with breath-holding attacks.

### Carotid sinus syncope

This problem is caused by pressure on a hypersensitive carotid sinus (e.g. in some elderly patients who lose consciousness when their neck is touched).

### Effort syncope

Syncope on exertion is due to obstructive cardiac disorders, such as aortic stenosis and hypertrophic obstructive cardiomyopathy.

### Choking

Sudden collapse can follow choking. Examples include the so-called 'café coronary' or 'barbecue coronary' when the patient, while eating meat, suddenly becomes cyanosed, is speechless and grasps the throat. This is caused by inhaling a large bolus of meat that obstructs the larynx. To avoid death, immediate relief of obstruction is necessary. An emergency treatment is the Heimlich manoeuvre, whereby the patient is grasped from behind around the abdomen and a forceful squeeze applied to try to eject the food. If this fails, the foreign body may have to be manually removed from the throat.

### § Drop attacks

Drop attacks are episodes of 'blackouts' in which the patient suddenly falls to the ground and then immediately gets up again. They involve sudden attacks of weakness in the legs. Although there is some doubt about whether loss of consciousness has occurred, most patients cannot remember the process of falling. Drop attacks occur typically in middle-aged women and are considered to be brain-stem disturbances producing sudden changes in tone in the lower limbs. Other causes of drop attacks include vertebrobasilar insufficiency, Parkinson disease and epilepsy.<sup>5</sup>

### Cardiac arrhythmias

Stokes–Adams attacks (see CHAPTER 70) and cardiac syncope are manifestations of recurrent episodes of loss of consciousness, especially in the elderly, caused by cardiac arrhythmias. These arrhythmias include complete heart block, sick sinus syndrome and ventricular tachycardia. The blackout is sudden with the patient falling straight to the ground without warning and without convulsive movements. The patient goes pale at first and then flushed.

Twenty-four-hour ambulatory cardiac monitoring may be necessary to confirm the diagnosis.

Patients with aortic stenosis are prone to have exercise-induced blackouts. Consider the prolonged QT interval syndrome in all age groups when the person presents with dizziness or blackouts.

### Vertebrobasilar insufficiency

Loss of consciousness can occur rarely with vertebrobasilar insufficiency (VBI) transient ischaemic attack. Typical preceding symptoms of VBI include dyspnoea, vertigo, vomiting, hemisensory loss, ataxia and transient global amnesia.

### § Hypoglycaemia

Hypoglycaemia can be difficult to recognise but must be considered as it can vary from a feeling of malaise and lightheadedness to loss of consciousness, sometimes with a convulsion. There are usually preliminary symptoms of hunger, sweating, shaking or altered behaviour. Hypoglycaemic attacks are usually related to diabetes and can occur with oral hypoglycaemics as well as insulin. Causes of hypoglycaemia are presented in TABLE 75.5. Refer to CHAPTER 130.

Table 75.5 Causes of hypoglycaemia (adults)

Diabetes-related including insulin and oral hypoglycaemics
Drugs (e.g. quinine, salicylates, pentamidine)
Alcohol
Fasting
Tumours (e.g. insulinomas)
Addison disease
Hypopituitarism
Liver disease
Post-gastrectomy
Gastric 'dumping' syndrome
Autoimmune: antibodies to insulin or insulin receptors

### Head injuries and unconsciousness

Some non-life-threatening head injuries are sufficiently serious to cause significant loss of consciousness and retrograde amnesia. The clinical terms used to describe brain injury of concussion, contusion and laceration simply indicate minor to major degrees of a similar injury. Severe individual cases of the above can certainly result in fatal outcomes.

## § Concussion<sup>6</sup>

Concussion is a transient disturbance of neurological function induced by head injury and resulting in no persistent abnormal neurological signs. There may or may not be brief loss of consciousness. The old definition of loss of consciousness with eventual recovery applies only to more severe forms of concussion. The features of the various grades of concussion are shown in TABLE 75.6.

*Note:* There is no such thing as delayed concussion or progressive deterioration due to concussion.

**Table 75.6** Classification of concussion

Grade	Clinical features
Mild (grade 1)	Stunned or dazed Sensorium clears in <60 seconds No post-traumatic amnesia ± Loss of consciousness
Moderate (grade 2)	Stunned or dazed Sensorium cloudy >60 seconds Headache Amnesia <60 minutes ± Loss of consciousness
Severe (grade 3)	Sensorium cloudy >60 seconds Irritable Persistent headache Unsteady gait ± Loss of consciousness

### Post-concussion syndrome

Occasionally a person who has an episode of concussion has persistence of headaches and dizziness for a number of weeks. Poor memory and concentration and sluggish decision-making indicate impaired mental capacity. Patients with this problem should be investigated with neuropsychological testing and CT scanning or MRI of the brain.

### Extradural haematoma

This life-threatening head injury is caused by arterial bleeding between the skull bone and dura mater (see FIG. 75.1). Following injury there may be a short lucid interval followed by loss of consciousness. The patient is restless, confused, irritable (see FIG. 75.2), has severe headaches and develops neurological signs such as seizures, ipsilateral pupil dilatation and facial weakness. A skull X-ray and CT scan should demonstrate the haematoma. Lumbar puncture is contraindicated. Urgent decompression of the haematoma is required.

**FIGURE 75.1** Illustration of sites of subdural and extradural haematomas in relation to the dura, skull and brain

**FIGURE 75.2** Classic conscious states leading to extradural haematoma after injury

### Subdural haematoma

This is due to a venous bleed between the dura and the arachnoid. It follows injury, which may be seemingly trivial, especially in the elderly, and may be acute, subacute and chronic. Consider it in a person with personality change, slowness and unsteadiness of movement, headache, irritability and fluctuating conscious level. A CT scan or MRI should reveal the haematoma and/or a midline shift. Neurological referral is urgent.

## Psychogenic factors

Psychogenic factors leading to blackouts represent a diagnostic dilemma, especially if occurring in patients with tonic-clonic epilepsy. If the attacks are witnessed by the practitioner then the possibility of functional origin can be determined.

Hysterical blackouts or fits are not uncommon and have to be differentiated from hyperventilation. It is unusual for hyperventilation to cause unconsciousness but it is possible to get clouding of consciousness, especially if the patient is administered oxygen.

Other features that suggest psychogenic rather than organic factors are:

- labile affect
- rapidly changing levels of consciousness
- well-articulated speech
- bizarre thought control

## The patient found unconscious<sup>7</sup>

### Most likely causes to consider

- drug overdose, including alcohol
- head injury
- postictal state (epilepsy or CVA)
- hypoglycaemia or ketoacidosis
- subarachnoid haemorrhage
- respiratory failure
- hypotension, including cardiac arrhythmias or myocardial infarction
- infection e.g. meningitis
- psychogenic

### Basic investigations

- oxygen saturation
- blood glucose
- urine or blood drug profile
- brain CT scan
- lumbar puncture (CT scan permitting)
- routine blood chemistry
- ECG

## Initial management of the unconscious patient

The first principle of management of a person found unconscious is to keep the patient alive by maintaining the airway and the circulation. The basic management essentials are summarised in **TABLE 75.7**.

**Table 75.7** Basic management essentials

Keep patient alive (maintain airway and circulation)
Get history from witnesses
Examine patient
Give 'coma cocktail' (TONG)
Take blood (for investigations)
CT scan (if diagnosis doubtful)

Before embarking on a secondary survey always consider giving the 'coma cocktail' (also called TONG<sup>2</sup>), which refers to the combination of:

<b>T</b> = Thiamine	100 mg IM or IV
<b>O</b> = Oxygenation	
<b>N</b> = Naloxone	0.1–0.2 mg IV
<b>G</b> = Glucose	i.e. 50 mL, 50% dextrose

The rapid administration of these agents should be considered for any patient<sup>3,8</sup> with an altered level of consciousness because they may lessen or reverse metabolic insult to the brain. Some emergency physicians recommend adding flumazenil to the cocktail.

In the presence of hypoventilation, constricted pupils<sup>9</sup> or circumstantial evidence of opioid use, naloxone (the specific opiate antagonist) should be given intravenously. If there is no response the patient should be intubated before further naloxone is given. Use a nasogastric tube to prevent acute gastric dilatation.

Catheterise to relieve urinary distension, send a urine sample for micro and culture, pregnancy test and drug screen.

### Use of flumazenil

Flumazenil is a specific benzodiazepine antagonist and may have an important use in the assessment of the unconscious patient. It can have a dramatic effect on benzodiazepine overdosage. After an initial dose of 0.2 mg IV, 0.3–0.5 mg boluses should be given every 1–2 minutes with caution until a response is observed.<sup>9</sup>

### Opioid (heroin) overdose

A known overdose patient should be treated initially with both IV and IM naloxone:

- naloxone 0.4 mg IV (repeat in 3 minutes if necessary)
- naloxone 0.4 mg IM (to maintain cover)

## Practice tips<sup>2</sup>

- The hypotensive patient is bleeding until proved otherwise.
- The presence of a head injury should not prevent rigorous resuscitation of the hypotensive patient.
- Always suspect cervical injury in the presence of patients who are victims of time-critical trauma.
- Tachypnoea is a sign of inadequate oxygenation and not a sign of central nerve damage.
- Always suspect opioid overdosage in the 'unknown' patient brought in with an altered conscious state.
- Consider administration of TONG—the 'coma cocktail'.

Disturbances of micturition are a common problem in general practice, with an annual incidence of about 20 per 1000 patients at risk.<sup>1</sup> Such disturbances include dysuria, frequency of micturition, difficulty or inability to initiate micturition, stress incontinence and haematuria. These symptoms are three times as common in women as in men.<sup>1</sup> The combination of dysuria and frequency is the most common of the symptoms with an incidence of about 14 per 1000 patients and a female:male ratio of 5:1.<sup>1</sup>

Among children and the elderly, the patient may complain of urinary incontinence unassociated with stress. However, with the exception of enuresis (CHAPTER 91), disturbances of micturition are uncommon in children.

## Dysuria and frequency

Dysuria, or difficult and/or painful micturition, which is characterised mainly by urethral and suprapubic discomfort, indicates mucosal inflammation of the lower genitourinary tract (i.e. the urethra, bladder or prostate). The passage of urine across inflamed mucosa causes pain. Frequency can vary from being negligible to extreme. It can be 'habit frequency' or associated with anxiety, which is typically long term and worse with stress and cold weather. In these conditions urinalysis is normal. Sometimes haematuria and systemic symptoms can accompany dysuria and frequency.

A summary of the diagnostic strategy model for dysuria is presented in TABLE 76.1.

### Key facts and checkpoints<sup>1,2</sup>

- Strangury = difficult and painful micturition with associated spasm.
- Inflammation usually results in the frequent passage of small amounts of urine and a sense of urgency.

- Urethritis usually causes pain at the onset of micturition.
- Cystitis usually causes pain at the end of micturition.
- Suprapubic discomfort is a feature of bladder infection (cystitis).
- Vesicocolonic fistulas (e.g. prostatic cancer) cause severe dysuria, pneumaturia and foul-smelling urine.
- Dysuria and frequency are most common in women aged 15 to 44 years.
- They are four times more common in sexually active women.
- Vaginitis is an important cause and must be considered.
- Dysuria and discomfort is a common feature of postmenopausal syndrome, due to atrophic urethritis. The urethra and lower bladder are oestrogen-dependent.
- Unexplained dysuria could be a pointer to *Chlamydia* urethritis.
- Urinary infection and other disorders can be quite asymptomatic.

## Is it really a urinary tract infection?

Although UTIs account for the majority of cases of dysuria in women it must be remembered that vaginitis and postmenopausal atrophic vaginitis can cause dysuria (see FIG. 76.1). Vaginitis is the most common cause of dysuria in the adolescent age group and is a relatively common cause of dysuria in family practice, estimated at around 15%. Postmenopausal oestrogen deficiency is estimated at 5–10%.<sup>3</sup> In the latter it is worthwhile prescribing oestrogen, either topically or systemically. Acute bacterial cystitis accounts for about 40% of causes of dysuria.

The dysuria associated with vaginitis may be described as burning 'on the outside' with the discomfort usually felt at the beginning or end of micturition. If

A. Depression
Diabetes
Drugs
UTI
Q. Is the patient trying to tell me something?
A. Consider psychosexual problems, anxiety and hypochondriasis.

vaginitis is suspected, a pelvic examination should be carried out to inspect the genitalia and obtain swabs.<sup>3</sup>

## Urethral syndrome

Also known as chronic sterile inflammatory disorder and abacterial cystitis, it presents with lower urinary tract symptoms (LUTS) or symptoms of urethritis. Others refer to it as 'painful bladder syndrome' or interstitial cystitis. It affects 20–30% of adults, mainly female. Management, which is difficult, is supportive.

**FIGURE 76.1** Relative causes of dysuria in women

## The clinical approach

### History

It is important to determine whether dysuria is really genitourinary in origin and not attributable to functional disorders, such as psychosexual problems. Disturbances of micturition are uncommon in the young male and if present suggest venereal infection.

### Key questions

- Could you describe the discomfort?
- What colour is your urine?
- Does it have a particular odour?
- Have you noticed a discharge?
- If so, could it be sexually acquired?
- Do you find intercourse painful or uncomfortable (women)?
- Have you any fever, sweats or chills?

### Examination

The general inspection and examination should include measurement of the basic parameters of pulse, temperature and blood pressure. The possibility of underlying kidney disease, especially in the presence of an obstructive component, should be kept in mind.

Abdominal palpation is important with a focus on the loins and suprapubic areas. The possibility of sexually transmitted diseases should also be considered and vaginal examination of the female and rectal and genital examination in the male may be appropriate. In the menopausal female, a dry atrophic urethral opening, a urethral caruncle or

urethral prolapse may give the clue to this important and neglected cause of dysuria.

### Investigations

Basic investigations include:

- dipstick testing of urine
- microscopy and culture (midstream specimen of urine, or suprapubic puncture in children), and possibly urethral swabs or first pass urine for sexually transmitted infections

Further investigations depend on initial findings and referral for detailed investigation will be necessary if the primary cause cannot be found.

### Haematuria

Haematuria is the presence of blood in the urine and can vary from frank bleeding (macroscopic) to the microscopic detection of red cells. Haematuria can occur in a wide variety of disorders but a careful history and examination can often lead to the source of the bleeding and help with the selection of investigations. It is often a sign of a serious underlying disorder.

#### Key facts and checkpoints

- Macroscopic haematuria is the presence of blood visible to the naked eye. It is always abnormal except in menstruating women.
- Small amounts of blood (1 mL/1000 mL urine) can produce macroscopic haematuria.
- Microscopic haematuria is the presence of blood in the urine that can only be detected by microscopic or chemical methods.
- Microscopic haematuria includes the presence of red blood cells (RBC) >8000 per mL of urine (phase contrast microscopy) or >2000 per mL of urine (light microscopy) representing the occasional RBC on microscopic examination.
- Joggers and athletes engaged in very vigorous exercise can develop transient microscopic haematuria.
- Microscopic (asymptomatic haematuria) can be classified as either:
  - glomerular (from kidney parenchyma): common causes are IgA nephropathy and thin membrane disease<sup>4</sup>
  - or
  - non-glomerular (urological): the common causes are bladder cancer, benign prostate hyperplasia and urinary calculi

- Common sources of macroscopic haematuria are the bladder, urethra, prostate and kidney.<sup>5</sup>
- Macroscopic haematuria occurs in 70% of people with bladder cancer and 40% with kidney cancer.<sup>5</sup>
- Common urological cancers that cause haematuria are the bladder (70%), kidney (17%), kidney pelvis or ureter (7%) and prostate (5%).<sup>6</sup>
- It is important to exclude kidney damage, so patients should have blood pressure, urinary protein and plasma creatinine levels measured as a baseline.
- All patients presenting with macroscopic haematuria or recurrent microscopic haematuria require judicious investigation, which may involve both radiological investigation of the upper urinary system and visualisation of the lower urinary system to detect or exclude pathology.
- The key radiological investigation is the intravenous urogram (pyelogram), unless there is a history of iodine allergy, severe asthma or other contraindications, when ultrasound is the next choice.

### The clinical approach

#### History

Is it really haematuria? In many patients the underlying disorder may be suspected from a detailed enquiry about associated urinary symptoms. The presence of blood can be verified rapidly by microscopy so that red discolouration due to haemolysis or red food dye can be discounted.

The time relationship of bleeding is useful because, as a general rule, haematuria occurring in the first part of the stream suggests a urethral or prostatic lesion, while terminal haematuria suggests bleeding from the bladder. Uniform haematuria has no localising features.

The possibility of sexually acquired urethritis should be kept in mind. It is most unusual for haematuria to cause anaemia unless it is massive. Massive haematuria is a feature of radiation cystitis.

Painful haematuria is suggestive of infection, urethral caruncle, calculi or kidney infarction, while painless haematuria is commonly associated with infection, trauma, tumours or polycystic kidneys. Loin pain can occur as a manifestation of nephritis and may be a feature of bleeding in cancer of the kidney or polycystic kidney.

A drug history is relevant, especially with anticoagulants and cyclophosphamide. A diet history should also be considered.

It is worth noting that large prostatic veins, secondary to prostatic enlargement located at the bladder neck, may rupture when a man strains to urinate.

A summary of the diagnostic strategy model for haematuria is presented in **TABLE 76.2**.

### Key questions

- Have you had an injury such as a blow to the loin, pelvis or genital area?
- Have you noticed whether the redness is at the start or end of your stream or throughout the stream?
- Have you noticed any bleeding elsewhere, such as bruising of the skin or nose bleed?
- Have you experienced any pain in the loin or abdomen?
- Have you noticed any burning or frequency of your urine?
- Have you had any problems with the flow of your urine?
- Have you been having large amounts of beetroot, red lollies or berries in your diet?
- Could your problem have been sexually acquired?
- Have you been overseas recently?
- What is your general health like?
- Have you been aware of any other symptoms?
- Do you engage in strenuous sports such as jogging?
- Have you had any kidney problems in the past?

### Examination

The general examination should include looking for signs of a bleeding tendency and anaemia, and recording the parameters of temperature, blood pressure and the pulse (see **FIG. 76.2**). The heart should be assessed to exclude atrial fibrillation or infective endocarditis with emboli to the kidney, and the chest should be examined for a possible pleural effusion associated with perinephric or kidney infections.

The abdomen should be examined for evidence of a palpable enlarged kidney or spleen. The different clinical findings for an enlarged left kidney and spleen are shown in **TABLE 76.3**. Kidney enlargement may be due to kidney tumour, hydronephrosis, or polycystic disease. Splenomegaly suggests the possibility of a bleeding disorder.

The suprapubic region should be examined for evidence of bladder tenderness or enlargement. In men the prostate should be examined rectally to detect benign or malignant enlargement or tenderness from prostatitis.

**Table 76.2** Haematuria: diagnostic strategy model

<b>Friction rub</b>	Possible	Not possible

urethral caruncle ('raspberry tumour') or urethral prolapse.

## Investigations

It is important to identify the cause, especially if a possible sequel is impaired kidney function.

- Urinalysis by dipstick testing (e.g. Hemastix-affected derivatives—affected by vitamin C intake).
- Urine microscopy:
  - formed RBCs in true haematuria
  - red cell casts indicate glomerular bleeding
  - deformed (dysmorphic) red cells indicate glomerular bleeding
- Urinary culture: early culture is important because of the common association with infection and consideration of early treatment with antibiotics. If tuberculosis is suspected, three early morning urines should be cultured for tubercle bacilli.
- Urinary cytology: this test, performed on a urine sample, may be useful to detect malignancies of the bladder and lower tract but is usually negative with kidney cancer.
- Blood tests: appropriate screening tests include a full blood count, ESR and basic kidney function tests (urea and creatinine). If glomerulonephritis is suspected, antistreptolysin O titres and serum complement levels should be measured.
- Radiological techniques—available tests include:
  - intravenous urography (IVU); intravenous pyelogram (IVP)—the key investigation
  - ultrasound (less sensitive at detecting LUT abnormalities)
  - CT scanning

- kidney angiography
- retrograde pyelography
- Direct imaging techniques: these include urethroscopy, cystoscopy and ureteroscopy. In all patients, regardless of the IVU findings, cystoscopy is advisable.
- Kidney biopsy: indicated if glomerular disease is suspected, especially in the presence of dysmorphic red cells on microscopic examination.

## Pseudohaematuria

Pseudohaematuria is red urine caused by pigments other than red blood cells that simply stain the culture red.

Causes include:

- anthocyanins in food (e.g. beetroot, berries)
- red-coloured confectionery
- porphyrins
- free haemoglobin (e.g. haemoglobinuria)
- myoglobin (red-black colour)
- drugs (e.g. pyridium, phenolphthalein—alkaline urine)

## Exercise haematuria

Exercise or sports haematuria is the passage of a significant number of red cells in the urine during or immediately after heavy exercise. It has been recorded in a wide variety of athletes, including swimmers and rowers. Dipstick testing is usually positive in these athletes. Despite the theory that it is largely caused by the posterior wall of the bladder impacting repetitively on the base of the bladder during running, there are other possible factors and glomerular disease must be excluded in the athlete with regular haematuria, especially if dysmorphic red cells are found on microscopy.

## Artefactual haematuria

Macroscopic haematuria is a common presenting ploy of people with Munchausen syndrome and pethidine addicts simulating kidney colic. If suspected, it is wise to get these people to pass urine in the presence of an appropriate witness before examining the urine.

## Urethral caruncle

This is a benign granulomatous tumour about the size of a pea in the distal urethra. Almost exclusive to post-menopausal women, it is very tender and bleeds easily. The main symptom is haematuria. It may require cystoscopy and biopsy for diagnosis.

Treatment includes warm salt baths and oestrogen creams. Otherwise obliteration by laser vaporisation, cryotherapy or cautery or even surgical excision is used.

## § Bladder cancer<sup>7</sup>

Bladder cancer is the seventh most common malignancy, with 90% being transitional cell carcinomas. Other forms include squamous cell carcinoma and adenocarcinoma. Smoking is the most common association.

### Clinical features

- Haematuria/microhaematuria
- Irritative symptoms: frequency, urgency, nocturia
- Dysuria

### Diagnosis

- Urine cytology: three specimens
- Cystoscopy and biopsy
- Imaging of upper tracts: IVU, ultrasound, but CT IVU is the gold standard
- Differential diagnosis is haemorrhagic cystitis

### Management

- Cease smoking (if applicable)
- Lifestyle attention
- Drink ample purified (no chlorine) water

Treatment depends on the staging and grading.

- The common carcinoma in situ is treated with intravesical BCG immunotherapy. This 6-week course and follow-up if necessary leads to 60–75% remission
- Other intravesical agents used include various cytotoxics (e.g. mitomycin C)
- Other treatments include surgery such as tumour resection plus intravesical agents, bladder resection (partial or total) and radio-chemotherapy.

Regular patient surveillance, which may be lifelong, is essential.

## Glomerulonephritis<sup>8</sup>

Glomerulonephritis means kidney inflammation involving the glomeruli. It can be simply classified into:

- nephritic syndrome: oedema + hypertension + haematuria
- nephrotic syndrome: oedema + hypoalbuminaemia + proteinuria
- asymptomatic kidney disease

The main causes of glomerulonephritis–nephritic syndrome are:

- IgA nephropathy (commonest)
- thin glomerular basement membrane disease (has an AD genetic link)
- post-streptococcal glomerulonephritis
- systemic vasculitis
- others

## IgA nephropathy

Typically presents as haematuria in a young male adult at the time of or within 1–2 days of a mucosal infection (usually throat, influenza or URTI) and persists for several days. Other presentations are as incidentally found microscopic haematuria or as previously unsuspected chronic kidney failure.

Due to deposition of IgA antibody complexes in the glomeruli, it runs a variable course. There is no specific treatment to date but immune suppression may be used. Refer suspected cases immediately. Diagnosis is by biopsy.

## Acute post-streptococcal glomerulonephritis

Typically seen in children (>5 years), especially in Indigenous communities following GABHS throat infection or impetigo. Presents after a gap of 7–10 days or so.

### Clinical features

- Irritable, lethargic, sick child
- Haematuria: discoloured urine ('Coke' urine)
- Peri-orbital oedema (may be legs, scrotum)
- Rapid weight gain (from oedema)
- Scanty urine output (oliguria)
- Hypertension → may be complications

### Usual course

- Oliguria 2 days
- Oedema and hypertension 2–4 days
- Invariably resolves
- Good long-term prognosis

### Diagnosis

- GABHS antigens
- Blood urea, creatinine,  $C_{3\&4}$  (complement), ASOT, DNase B

### Treatment

- Hospital admission
- Bed rest

- Strict fluid balance chart
- Daily weighing
- Penicillin (if GABHS +ve)
- Fluid restriction
- Low protein, high carbohydrate, low salt diet
- Antihypertensives and diuretics (as necessary)

Follow-up: monitor BP and kidney function. Regular urinalysis (microscopic haematuria may last for years).

**DxT** discoloured urine + peri-orbital oedema + oliguria → post-streptococcal glomerulonephritis

## Proteinuria

Proteinuria is an important and common sign of kidney disease. The protein can originate from the glomeruli, the tubules or the LUT. Healthy people, however, do excrete some protein in the urine, which can vary from day to day and hour to hour; hence the value of collecting it over 24 hours. While proteinuria can be benign, it always requires further investigation. Important causes of proteinuria are presented in **TABLE 76.4**.

### Key facts and checkpoints<sup>9</sup>

- The amount of protein in the urine is normally less than 100 mg/24 hours.
- Greater than 150 mg protein/24 hours is abnormal in adults.
- Greater than 300 mg/24 hours is abnormal for children and adults.
- Proteinuria >1 g/24 hours indicates a serious underlying disorder.
- If accompanied by dysmorphic haematuria or red cell casts, this tends to confirm glomerular origin.
- Routine dipstick testing will only detect levels greater than 300 mg/24 hours and thus has limitations.
- In diabetics, microalbuminuria is predictive of nephropathy and an indication for early blood pressure treatment.

### Predictive levels

- **Proteinuria** >150–300 mg/day
- **Microalbuminuria** 30–300 mg/day
- **Macroalbuminuria** >300 mg/day

**Table 76.4** Important causes of proteinuria

## Transient

Contamination from vaginal secretions  
 Urinary tract infection  
 Pre-eclampsia  
 These all require exclusion and follow-up.

## Kidney disease

Glomerulonephritis  
 Nephrotic syndrome  
 Congenital tubular disease, e.g.  
 • polycystic kidney  
 • kidney dysplasia  
 Acute tubular damage  
 Kidney papillary necrosis, e.g.  
 • analgesic nephropathy  
 • diabetic papillary necrosis  
 Overflow proteinuria, e.g.  
 • multiple myeloma  
 Systemic diseases affecting the glomeruli:  
 • diabetes mellitus  
 • hypertension  
 • SLE  
 • malignancy  
 • drugs (e.g. penicillamine, gold salts)  
 • amyloid  
 • vasculitides

## No kidney disease

Orthostatic proteinuria  
 Exercise  
 Emotional stress  
 Fever  
 Cold exposure  
 Postoperative  
 Acute medical illness (e.g. heart failure)

If proteinuria is confirmed on repeated dipstick testing it should be measured more accurately by measuring daily albumin excretion with a 24-hour urine or the albumin creatinine ratio (ACR), which is preferred. High values require referral for investigation. The minimum investigations are microurine and assessment of kidney function (eGFR). Nephrotic range proteinuria (>3 g/24 hours) is due to one or other form of glomerulonephritis in over 90% of patients.<sup>8</sup> Possible contamination from vaginal secretions or from a low UTI needs to be excluded.

**Orthostatic proteinuria**

Orthostatic proteinuria is the presence of significant proteinuria after the patient has been standing but is absent from specimens obtained following

recumbency for several hours, such as an early morning specimen.

It occurs in 5–10% of people,<sup>6</sup> especially during their adolescent years. In the majority it is of no significance and eventually disappears without the development of significant kidney disease. However, in a small number the proteinuria can foreshadow serious kidney disease.

**Diabetic microalbuminuria**

The presence of protein in the urine is a sensitive marker of diabetic nephropathy, so regular screening for microalbuminuria in diabetics is regarded as an important predictor of nephropathy and other possible complications of diabetes. Dipstick testing for microalbuminuria is now available but more accurate measurement can be performed with radioimmunoassay techniques. The use of ACE inhibitors at the microalbuminuria stage may slow the development of overt nephropathy. The gold standard is a 24-hour collection.

**Consequences of proteinuria**

While proteinuria is usually simply a marker of kidney disease, heavy proteinuria in excess of 3 g/24 hours may have severe clinical consequences, including oedema, intravascular volume depletion, venous thromboembolism, hyperlipidaemia and malnutrition.

Minimal change glomerulonephritis is the commonest cause of the nephrotic syndrome in childhood and accounts for about 30% of adult nephrotic syndrome.<sup>7</sup> It is steroid responsive.

**§ Nephrotic syndrome<sup>8,9</sup>**

**DxT** proteinuria + generalised oedema  
 + hypoalbuminaemia → nephrotic syndrome

**Clinical features**

- Proteinuria >3 g/day (3–4<sup>1</sup> on dipstick)
- Swelling of eyelids and face
- Generalised oedema, especially peripheral oedema
- Hypoalbuminaemia <30 g/L
- Hypercholesterolaemia >4.5 mmol/L
- Waxy pallor
- Normal BP
- Dyspnoea
- Frothy urine

Predisposes to sepsis (e.g. peritonitis, pyelonephritis, thromboembolism).

### Causes

- 1 in 3 (approx.):
  - systemic kidney disease (e.g. diabetes, SLE, amyloid)
- 2 in 3 (approx.):
  - idiopathic nephrotic syndrome (based on kidney biopsy)
  - minimal change disease (commonest)
  - focal glomerular sclerosis
  - membranous nephropathy
  - membranoproliferative glomerulonephritis
- Others: drugs, malignancy, infection e.g. malaria

### Treatment

- Referral to renal physician or unit
- Bed rest
- Diet: low fluid, high protein, low salt
- Diuretics
- Prednisolone
- Phenoxyethylpenicillin
- Aspirin

## URINARY INCONTINENCE

### Definitions

**Functional incontinence** Loss of urine secondary to factors extrinsic to the urinary tract.

**Nocturnal enuresis** (or bed-wetting) Involuntary urine loss during sleep.

**Overactive bladder (detrusor instability)** The commonest cause of urge incontinence; synonymous with an irritable or unstable bladder; characterised by involuntary bladder contractions, resulting in a sudden urge to urinate.

**Overflow incontinence** Escape of urine following poor bladder emptying.

**Stress incontinence** The involuntary loss of urine on coughing, sneezing, straining or lifting, or any factor that suddenly increases intra-abdominal pressure.

**Urge incontinence** An urgent desire to void followed by involuntary loss of urine.

**Urinary incontinence** The involuntary loss of urine during the day or night.

**Voiding dysfunction** Includes urinary difficulties, detrusor instability and overflow incontinence.

A summary of the types of incontinence and their causes is presented in **TABLE 76.5**.

**Table 76.5** Types of incontinence and their implied causes

Type of incontinence	Likely cause
Simple stress incontinence (with cough/sneeze)	Sphincter incompetence
Urge incontinence Giggle incontinence Stress and urge incontinence Enuresis Complex stress incontinence (with exercise)	Unstable bladder, with or without sphincter weakness
Quiet dribble incontinence	Sphincter incompetence and unstable bladder or overflow
Continuous leakage	Fistula, ectopic ureter, patulous urethra
Reflex incontinence	Neuropathic bladder

The basic requirements for continence are:

- adequate central and peripheral nervous function
- an intact urinary tract
- a compliant stable bladder
- a competent urethral sphincter
- efficient bladder emptying

### Female urinary incontinence

Urinary leakage affects at least 37% of women in Australia.<sup>11</sup> Successful treatment depends on accurate assessment of the LUT storage and emptying functions. The most common contributing factor is weakness of the pelvic floor muscles.

### Assessment

The basic assessment of the incontinent patient requires a careful history and examination, exclusion of infection and keeping of a micturition or bladder chart. Use of a severity index questionnaire is very helpful. Drugs that adversely affect urinary function are presented in **TABLE 76.6**. Investigations may be required to dispel doubt about the diagnosis or to exclude intravesical or kidney disorders: these include cystometry, uroflowmetry, cystourethroscopy, micturating cystourethrogram, IVU and also residual volume (>100 mL is abnormal).

**Table 76.6** Drugs that can cause or aggravate incontinence

- ACE inhibitors
- phenoxybenzamine (Dibenyline)
- prazosin
- labetalol

Bladder relaxants → overflow incontinence:

- anticholinergic agents
- tricyclic antidepressants

Bladder stimulants → urge incontinence:

- cholinergic agents
- caffeine

Sedatives → urge incontinence:

- antidepressants
- antihistamines
- antipsychotics
- hypnotics
- tranquillisers

Others → urge incontinence:

- alcohol
- loop diuretics (e.g. frusemide), other diuretics
- lithium

#### Causes of incontinence (a mnemonic)<sup>10,11</sup>

- D** = Delirium  
**I** = Infection of urinary tract  
**A** = Atrophic urethritis  
**P** = Pharmacological (e.g. diuretics)  
**P** = Psychological (e.g. acute distress)  
**E** = Endocrine (e.g. hypercalcaemia)  
**E** = Environmental (e.g. unfamiliar surrounds)  
**R** = Restricted mobility  
**S** = Stool impaction  
**S** = Sphincter damage or weakness

#### The severity index questionnaire

- How often do you experience urine leakage?  
 0 = never  
 1 = less than once a month  
 2 = one or several times a month  
 3 = one or several times a week  
 4 = every day and/or night
- How much urine do you lose each time?  
 1 = drops or little  
 2 = more

The total score is the score for the first question multiplied by the score for the second question.

0 = dry, 1–2 = slight, 3–4 = moderate, 6–8 = severe

## Management

- 1 Exclude UTI and drug causes.
- 2 Is it stress incontinence?
  - key symptoms: involuntary loss with coughing, jumping, etc.
  - demonstrable (e.g. patient coughs when standing with full bladder—check for leakage)

Treatment

- Weak pelvic floor—exercises
- Obesity—weight reduction
- Menopause—HRT/vaginal oestrogen creams
- Chronic cough—physiotherapy

If urodynamic studies of LUT function show genuine stress incontinence (GSI) due to urethral sphincter weakness, consider surgery (e.g. suprapubic urethral suspension—better than vaginal repair)

- 3 Is it urge incontinence?

- urge symptoms prominent
- no residual urine
- urodynamic studies to confirm GSI

Treatment

- neurological signs → neurologist
- abnormal voiding pattern → bladder retraining (e.g. void more urine less frequently)
- surgery (e.g. Burch procedure)

- 4 Is it voiding dysfunction?

- symptoms of voiding difficulty (e.g. frequency, urgency, nocturia, incomplete emptying)
- large residual urine

Treatment

- Neurological signs → neurologist
- Gynaecological cause (e.g. pelvic mass) → gynaecologist
- If bladder atony → anticholinergic drugs
- Intravesical treatment:
  - oxybutynin
  - botulinum toxin
  - others, e.g. capsaicin
- May require catheterisation

## Anticholinergic/antispasmodic drugs<sup>12</sup>

These may be worth a trial for bladder instability or voiding dysfunction:

- solifenacin 5–10 mg (o) daily
- propantheline 15 mg (o) bd or tds
- oxybutynin 2.5–5 mg (o) bd or tds
- tolterodine 2 mg (o) bd
- imipramine 10–75 mg (o) nocte

The future:

- neuromodulation (e.g. sacral nerve)

### Pelvic floor muscle training<sup>13</sup>

- The mainstay of treatment of most problems, especially GSI (e.g. 40 'squeezes' daily).
- 75% improved and 25% cured.
- Best in motivated young women with bladder GSI.
- At least 3 months trial with supervision (physiotherapist or continence nurse adviser).

Basic techniques:

- Advise the patient to pull up her pelvic muscles to imagine herself stopping passing urine (or controlling diarrhoea) and hold the 'squeeze' for a count of 10. Repeat many times daily. Refer to *Patient Education*.
- Bladder retraining includes getting the patient to delay micturition for 10–15 minutes whenever she wishes to void.

### Bladder dysfunction (in women during night)

Women with urethral syndrome constantly wake at night with urge to micturate but produce only a small dribble of urine.

- Instruct patient to perform a pelvic tilt exercise by balancing on upper back, lifting her pelvis with knees flexed and holding position for 30 seconds
- Squeeze pelvic floor inwards (as though holding back urine or faeces)
- Repeat a few times

### § Uterovaginal prolapse<sup>14</sup>

Uterovaginal prolapse is very common, affecting 50% of parous women. The main complaint is of 'heaviness' in the vagina and a sensation of 'something coming down'. Relevant symptoms that are of considerable distress for the patient and, depending on the type of prolapse, include voiding difficulties, urinary stress incontinence, faecal incontinence, incomplete rectal emptying and recurrent cystitis. Backache is a common associated symptom, usually relieved by lying down.

### Classification of prolapse

See FIGURE 76.3.

- Cystocele—bladder descends into vagina
- Urethrocele—urethra bulges into vagina
- Rectocele—rectum protrudes into vagina
- Enterocele—loop of small intestine bulges into vagina (usually posterior wall)

FIGURE 76.3 Uterovaginal prolapse

- Uterine—uterus and cervix descend toward vaginal introitus:
  - first degree—cervix remains in vagina
  - second degree—cervix protrudes on coughing/straining
  - third degree (procidentia)—uterus lies outside vagina

### Examination

This is best performed with women in the left lateral position using a Sims speculum or posterior blade of the Graves speculum. Ask the patient to cough or bear down (several times)—observe anterior, posterior and lateral vaginal walls and descent of cervix.

### Management

As a rule asymptomatic prolapse does not need invasive treatment, just basic reassurance and education, including pelvic floor exercises (see earlier in this chapter). Consider referral to a physiotherapist. Lifestyle measures include optimal nutrition, weight loss if obese, smoking cessation and exercise. Aggravating comorbidities such as constipation, menopause/atrophic vaginitis and COPD require optimal treatment. Consider topical oestrogens.

### Prevention

Promote optimal obstetric management, especially postpartum exercises, lifelong pelvic floor exercises, ideal weight and sensible bladder and bowel function.

### Ring pessaries

Pessaries are an option for those who are poor anaesthetic risks, too frail for surgery, don't want surgery, are young and have not completed their family or are awaiting surgery. Each patient needs

to be fitted individually with the correct-sized pessary. Topical oestrogens will improve comfort. The pessary needs to be cleaned or changed every 4–6 months.

## Surgery

Refer to a gynaecological surgeon if the patient who is fit for surgery has symptomatic prolapse that warrants surgery especially with associated incontinence and recurrent UTIs. The principles of reconstructive pelvic surgery are to:

- reposition pelvic structures to normal anatomical relationships
- restore and maintain urinary and/or faecal continence
- maintain coital function
- correct coexisting pelvic pathology

Options include repair procedures (vaginally, sometimes abdominally, per laparoscopy), colpo/vaginal suspension, hysteroscopy and hysterectomy (vaginal or abdominal).

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Incontinence of urine

*All those, therefore, who have cataract see the light more or less, and by this we distinguish cataract from amaurosis and glaucoma, for persons affected with these complaints do not perceive the light at all.*

Paul of Aegina (615–690)

The commonest cause of visual dysfunction is a simple refractive error. However, there are many causes of visual failure, including the emergency of sudden blindness, a problem that requires a sound management strategy. Apart from migraine, virtually all cases of sudden loss of vision require urgent treatment.

The ‘white’ eye or uninflamed eye presents a different clinical problem from the red or inflamed eye.<sup>1</sup> The ‘white’ eye is painless and usually presents with visual symptoms and it is in the ‘white’ eye that the majority of blinding conditions occur.

## Criteria for blindness and driving

This varies from country to country. The WHO defines blindness as ‘best visual acuity less than 3/60’, while in Australia eligibility for the blind pension is ‘bilateral corrected visual acuity less than 6/60 or significant visual field loss’ (e.g. a patient can have 6/6 vision but severely restricted fields caused by chronic open-angle glaucoma). The minimum standard for driving is 6/12 (Snellen system).

### Key facts and checkpoints

- The commonest cause of blindness in the world is trachoma. The other major causes of gradual blindness are cataracts, onchocerciasis and vitamin A deficiency.<sup>2</sup>
- In Western countries the commonest causes are senile cataract, glaucoma, age-related macular degeneration, trauma and the retinopathy of diabetes mellitus.<sup>2</sup>
- The commonest causes of sudden visual loss are transient occlusion of the retinal artery (amaurosis fugax) and migraine.<sup>3</sup>
- ‘Flashing lights’ are caused by traction on the retina and may have a serious connotation: the commonest cause is vitreoretinal traction, which is a classic cause of retinal detachment.

- The presence of floaters or ‘blobs’ in the visual fields indicates pigment in the vitreous: causes include vitreous haemorrhage and vitreous detachment.
- Posterior vitreous detachment is the commonest cause of the acute onset of floaters, especially with advancing age.
- Retinal detachment has a tendency to occur in short-sighted (myopic) people.
- Suspect a macular abnormality where objects look smaller or straight lines are bent or distorted.

## The clinical approach

### History

The history should carefully define the onset, progress, duration, offset and the extent of visual loss. An accurate history is important because a longstanding visual defect may only just have been noticed by the patient, especially if it is unilateral. Two questions need to be answered:

- Is the loss unilateral or bilateral?
- Is the onset acute, or gradual and progressive?

The distinction between central and peripheral visual loss is useful. Central visual loss presents as impairment of visual acuity and implies defective retinal image formation (through refractive error or opacity in the ocular media) or macular or optic nerve dysfunction. Peripheral field loss is more subtle, especially when the onset is gradual, and implies extramacular retinal disease or a defect in the visual pathway.

It is important to differentiate the central field loss of macular degeneration from the hemianopia of a CVA.

A drug history is very important (see TABLE 77.1). Treatment for tuberculosis with ethambutol or

**Table 77.1** Visual disorders associated with drugs

Disorder	Drug
Corneal opacities	Amiodarone Hydroxychloroquine Chlorpromazine Vitamin D Indomethacin Chlorpropamide
Precipitating of acute narrow angle glaucoma	Mydriatic drops Tricyclics Antihistamines
Refractive changes	Thiazides
Lens opacities	Corticosteroids Phenothiazines
Retinopathy	Hydroxychloroquine Chloroquine Thioridazine (other phenothiazines less commonly) Tamoxifen
Papilloedema (secondary to benign intracranial hypertension)	Oral contraceptives Corticosteroids Tetracyclines Nalidixic acid Vitamin A
Optic neuropathy	Ethanol Tobacco Ethambutol Disulfiram

Source: Reprinted from *Central Nervous System: Clinical Algorithms*, published by the BMJ, with permission

treatment with quinine/chloroquine has to be considered as these drugs are oculotoxic. The family history is relevant for diabetes, migraine, Leber hereditary optic atrophy, Tay–Sachs disease and retinitis pigmentosa.

### Questions directed to specific symptoms

- Presence of floaters → normal ageing (especially ≥55 years) with posterior vitreous detachment or may indicate haemorrhages or choroiditis
- Flashing lights → normal ageing with posterior vitreous detachment or indicates traction on the retina (? retinal detachment)
- Coloured haloes around lights → glaucoma, cataract
- Zigzag lines → migraine
- Vision worse at night or in dim light → retinitis pigmentosa, hysteria, syphilitic retinitis
- Headache → temporal arteritis, migraine, benign intracranial hypertension

- Central scotomata → macular disease, optic neuritis
- Pain on moving eye → retrobulbar neuritis
- Distortion, micropsia (smaller), macropsia (larger) → macular degeneration
- Visual field loss:
  - central loss—macular disorder
  - total loss—arterial occlusion
  - peripheral loss

It is worth noting that if a patient repeatedly knocks into people and objects on a particular side (including traffic accidents), a bitemporal or homonymous hemianopia should be suspected.

### Diseases/disorders to exclude or consider

- Diabetes mellitus
- Giant cell (temporal) arteritis
- Hypopituitarism (pituitary adenoma)
- Cerebrovascular ischaemia/carotid artery stenosis (emboli)
- Multiple sclerosis
- Cardiac disease (e.g. arrhythmias, and SBE—emboli)
- Anaemia (if severe can cause retinal haemorrhage and exudate)
- Marfan syndrome (subluxated lenses)
- Malignancy (the commonest cause of eye malignancy is melanoma of the choroid)

### Examination

The same principles of examination should apply as for the red eye. Testing should include:

- visual acuity (Snellen chart)—with pinhole testing
- pupil reactions, to test afferent (sensory) responses to light
- confrontation fields (using a red pin)
- colour vision
- Amsler grid (or graph paper)
- fundus examination with dilated pupil (ophthalmoscope), noting:
  - the red reflex
  - appearance of the retina, macula and optic nerve
- tonometry

### General examination

General examination should focus on the general features of the patient, the nervous system, endocrine system and cardiovascular system.

**FIGURE 77.1** Diagrammatic representation of important causes of sudden painless loss of vision (right side) and typical defects in the visual fields (left side)

## Perimetry

Various defects in the visual fields are depicted in **FIGURE 77.1**.

## Investigations

Depending on the clinical examination the following tests can be selected to confirm the diagnosis:

- blood tests:
  - full blood (? anaemia, lead poisoning, leukaemia)
  - ESR (? temporal arteritis)
  - blood sugar (? diabetes mellitus)
- temporal artery biopsy (? temporal arteritis)
- CT/MRI scan (? CVA, optic nerve lesions, space-occupying lesions)
- formal perimetry and Bjerrum screen
- fluorescein angiography (? retinal vascular obstruction, diabetic retinopathy)
- visual evoked responses (? demyelinating disorders)
- carotid Doppler ultrasound

## Visual failure in children

There are long lists of causes for visual failure or blindness in children. An approximate order of frequency of causes of blindness in children is cortical blindness, optic atrophy, choroidoretinal degeneration, cataract and retinopathy of prematurity. Almost half the causes of blindness are genetically determined, in contrast to the nutritional and infective causes that predominate in third world countries.<sup>4</sup> About 3% of children will fail to develop proper vision in at least one eye.

The eyes of all babies should be examined at birth and at 6 weeks.

## Amblyopia

Amblyopia is defined as a reduction in visual acuity due to abnormal visual experience in early childhood. It is the main reason for poor unilateral eyesight until middle age and is usually caused by interference with visual development during the early months and years of life.

The common causes are:

- strabismus
- large refractive defect, especially hypermetropia
- congenital cataract

### Principles of management<sup>5</sup>

- Most cases are treatable.
- Early diagnosis and intervention is fundamental to achieving useful vision.
- No child is too young to have the visual system assessed.
- The good eye should be patched in order to utilise the affected eye.
- Remove a remedial cause such as strabismus.
- Correct any refractive error, usually by prescription of glasses.

## Some important guidelines in children

### Referral

Refer if any of the following are present in infants:

- nystagmus
- a wandering eye
- a lack of fixation or following of movements
- photophobia
- opacities (seen with ophthalmoscope set on +3, held 30 cm from baby's eye)
- delayed development

### Strabismus

- The two serious squints are the constant and alternating ones, which require early referral. Transient squint and latent squint (occurs under stress e.g. fatigue) usually are not a problem.
- Always refer children with strabismus (squint) when first seen to exclude ocular pathology such as retinoblastoma, congenital cataract and glaucoma, which would require emergency surgery.
- Children with strabismus (even if the ocular examination is normal) need specialist management because the deviating eye will become amblyopic (a lazy eye with reduced vision i.e. 'blind' if not functioning by 7 years of age). The younger the child, the easier it is to treat amblyopia; it may be irreversible if first detected later than school age. Surgical correction of a true squint is preferred at 1–2 years of age. (See also CHAPTER 92.)

### Cataracts

Children with suspected cataracts must be referred immediately; the problem is very serious as the

development of vision may be permanently impaired (amblyopia).<sup>2</sup> Cataracts are diagnosed by looking at the red reflex and this should be a routine part of the examination of a young child. Common conditions causing cataracts are genetic disorders and rubella but most causes are unknown. Rarer conditions, such as galactosaemia, need to be considered.

### Refractive errors

Refractive errors, with the error greater in one eye, can cause amblyopia. Detection of refractive errors is an important objective of screening.

### Retinoblastoma

Retinoblastoma, although rare, is the commonest intraocular tumour in childhood. It must be excluded in any child presenting with a white pupil. Such children also have the so-called 'cat's eye reflex'. In 30% of patients the condition is bilateral with an autosomal dominant gene being responsible.

## Visual failure in the elderly

Most patients with visual complaints are elderly and their failing vision affects their perception of the environment and their ability to communicate effectively. Typical problems are cataracts, vascular disease, macular degeneration, chronic simple glaucoma and retinal detachment. Retinal detachment and diabetic retinopathy can occur at any age, although they are more likely with increasing age. Macular degeneration in its various forms is the commonest cause of visual deterioration in the elderly. For the elderly with cataracts the decision to operate depends on the patients' vision and their ability to cope. Most patients with a vision of 6/18 or worse in both eyes usually benefit from cataract extraction, but some can cope with this level of vision and rely on a good, well-placed (above and behind) reading light.<sup>6</sup>

Sudden loss of vision in the elderly is suggestive of temporal arteritis or vascular embolism, so this problem should be checked.

## Floaters and flashes

When the vitreous gel shrinks as part of the normal ageing process, it tugs on the retina (rods and cones), causing flashing lights. When the gel separates from the retina, floaters (which may appear as dots, spots or cobwebs) are seen. Floaters are more commonly seen with age, but are also more common in people

who are myopic or who have had eye surgery such as removal of cataracts. It is important to consider retinal detachment but if floaters remain constant there is little cause for concern. The appearance of a fresh onset of flashes or floaters is of concern.

## § Refractive errors

Indistinct or blurred vision is most commonly caused by errors of refraction.

In the normal eye (emmetropia) light rays from infinity are brought to a focus on the retina by the cornea (contributing about two-thirds of the eye's refractive power) and the lens (one-third). Thus, the cornea is very important in refraction and abnormalities such as keratoconus may cause severe refractive problems.<sup>6</sup>

The process of accommodation is required for focusing closer objects. This process, which relies on the action of ciliary muscles and lens elasticity, is usually affected by ageing, so that from the age of 45 close work becomes gradually more difficult (presbyopia).<sup>6</sup>

The important clinical feature is that the use of a simple 'pinhole' in a card will usually improve blurred vision or reduced acuity where there is a refractive error only.<sup>1</sup>

## Myopia (short-sightedness)

This is usually progressive in the teens. Highly myopic eyes may develop retinal detachment or macular degeneration.

### Management

- Glasses with a concave lens
- Contact lenses
- Consider radial keratotomy or excimer laser surgery

## Hypermetropia (long-sightedness)

This condition is more susceptible to closed angle glaucoma. In early childhood it may be associated with convergent strabismus (squint). The spectacle correction alone may straighten the eyes. It is mostly overcome by the accommodative power of the eye, though it may cause reading difficulty. Typically, the long-sighted person needs reading glasses at about 30 years.

## Presbyopia

There is a need for near correction with loss of accommodative power of the eye in the 40s.

## Astigmatism

This creates the need for a corrective lens that is more curved in one meridian than another because the cornea does not have even curvature. If uncorrected, this may cause headaches of ocular origin. Conical cornea is one cause of astigmatism.

## Pinhole test

The pinhole reduces the size of the blur circle on the retina in the uncorrected eye. A pinhole acts as a universal correcting lens. If visual acuity is not normalised by looking through a card with a 1 mm pinhole, then the defective vision is not solely due to a refractive error. The pinhole test may actually help to improve visual acuity with some cataracts. Further investigation is mandatory.

## § Cataract

The term 'cataract' describes any lens opacity. The symptoms depend on the degree and the site of opacity. Cataract causes gradual visual loss with normal direct pupillary light reflex.

The prevalence of cataracts increases with age: 65% at age 50 to 59, and all people aged over 80 have opacities.<sup>3</sup> Significant causes of cataracts are presented in [TABLE 77.2](#) and causes of progressive visual loss in [TABLE 77.3](#).

Typical symptoms:

- reading difficulty
- difficulty in recognising faces
- problems with driving, especially at night
- difficulty with television viewing
- reduced ability to see in bright light
- may see haloes around lights

**Table 77.2** Causes of cataracts

Advancing age
Diabetes mellitus
Steroids (topical or oral)
Radiation: long exposure to UV light
TORCH organisms → congenital cataracts
Trauma
Uveitis
Dystrophia myotonica
Galactosaemia

**Table 77.3** Progressive bilateral visual loss

<b>Globe</b>	Chronic glaucoma Senile cataracts
<b>Retina</b>	Macular degeneration  Retinal disease: <ul style="list-style-type: none"> <li>• diabetic retinopathy</li> <li>• retinitis pigmentosa</li> <li>• choroidoretinitis</li> </ul>
<b>Optic nerve</b>	Optic neuropathies  Optic nerve compression (e.g. aneurysm, glioma)  Toxic damage to optic nerves
<b>Optic chiasma</b>	Chiasmal compression: pituitary adenoma, craniopharyngioma, etc.
<b>Occipital cortex</b>	Tumours  Degenerative conditions

*Note:* Unilateral causes (e.g. cataract, refractive errors, uveitis, glaucoma, progressive optic atrophy and tumours) can affect the second eye.

**FIGURE 77.2** Blurred vision: appearance of a subject through the eyes of a person with cataracts.

Photo courtesy Allergan Pharmaceuticals

The type of visual distortion seen by patients is illustrated in **FIGURE 77.2**.

### Examination

- Reduced visual acuity (sometimes improved with pinhole)
- Diminished red reflex on ophthalmoscopy
- A change in the appearance of the lens

### The red reflex and ophthalmoscopy

The 'red reflex' is a reflection of the fundus when the eye is viewed from a distance of about 60 cm (2 feet) with the ophthalmoscope using a zero lens. This reflex is easier to see if the pupil is dilated. Commencing with the plus 15 or 20 lens, reduce the power gradually and, at plus 12, lens opacities will be seen against the red reflex, which may be totally obscured by a very dense cataract. The setting up of the ophthalmoscope to examine intraocular structures is illustrated in **FIGURE 77.3**.

**FIGURE 77.3** Settings of the ophthalmoscope used to examine intraocular structures

### Management

Advise extraction when the patient cannot cope. Contraindications for extraction include intraocular inflammation and severe diabetic retinopathy. There is no effective medical treatment for established cataracts. The removal of the cataractous lens requires optical correction to restore vision and this is usually performed with an intraocular lens implant. Full visual recovery may take 2–3 months. Complications are uncommon yet many patients may require YAG laser capsulotomy to clear any opacities that may develop behind the lens implant.

### Postoperative advice to the patient

- Avoid bending for a few weeks.
- Avoid strenuous exercise.
- The following drops may be prescribed:
  - steroids (to reduce inflammation)
  - antibiotics (to avoid infection)
  - dilators (to prevent adhesions)

### Prevention

Sunglasses, particularly those that wrap around and filter UV light, may offer protection against cataract formation.

**FIGURE 77.4** Typical visual field loss for chronic simple glaucoma; a similar pattern occurs with retinitis pigmentosa and hysteria

## § Glaucoma

Chronic simple glaucoma is the commonest cause of irreversible blindness in middle age.<sup>1</sup> At a very late stage it presents as difficulty in seeing because of loss of the outer fields of vision due to optic atrophy (see FIG. 77.4). Acute glaucoma, on the other hand, has a relatively rapid onset over a few days.

### Clinical features (chronic glaucoma)

- Familial tendency
- No early signs or symptoms
- Central vision usually normal
- Progressive restriction of visual field

### Investigations

#### Tonometry

- Upper limit of normal is 22 mmHg

#### Ophthalmoscopy

- Optic disc cupping >30% of total disc area

### Screening

- Adults 40 years and over: 2–5 yearly (at least 2 yearly over 60)
- Start about 30 years, then 2 yearly if family history

### Management

- Treatment can prevent visual field loss

- Medication (for life) usually selected from:
  - timolol or betaxolol drops bd*Note:* These beta blockers can cause systemic complications, e.g. asthma
  - latanoprost drops, once daily
  - pilocarpine drops qid
  - dipivefrine drops bd
  - acetazolamide (oral diuretics)
- Surgery or laser therapy for failed medication

## § Retinitis pigmentosa

Primary degeneration of the retina is a hereditary condition characterised by a degeneration of rods and cones associated with displacement of melanin-containing cells from the pigment epithelium into the more superficial parts of the retina.

### Typical features

- Begins as night blindness in childhood
- Visual fields become concentrically narrowed (periphery to centre)
- Blind by adolescence (sometimes up to middle age)
- Irreversible course—may be delayed by vitamin A

### Examination (ophthalmoscopic)

- Irregular patches of dark pigment, especially at periphery
- Optic atrophy

## Trauma

Trauma to the eye may cause only a little discomfort so it is important to keep this in mind.

### Intraocular foreign body

A small metal chip may penetrate the eye with minimal pain and the patient may not present with an ocular problem until the history of injury is long forgotten.

If infection does not supervene, presentation may be delayed for months or years until vision deteriorates due to metal degradation. The iris becomes rust-brown. It is important to X-ray the eye if it has been struck by a hammered fragment or if in any doubt at all about the mechanism of the injury.<sup>1</sup>

## Chronic uveitis

Pain and redness may be minimal with this chronic inflammation. If untreated, visual loss often develops from secondary glaucoma and cataract. The pupil is bound to the lens by synechiae and is distorted.

## HIV infection

AIDS may have serious ocular complications, including Kaposi sarcoma of the conjunctivae, retinal haemorrhage and vasculitis.<sup>3</sup> Another problem is ocular cytomegalovirus infection, which presents as areas of opacification with haemorrhage and exudates.

## Sudden loss of vision

It is important to remember that the problem is alarming and distressing to the patient; considerable empathy is needed and care must be taken not to diagnose seemingly inappropriate behaviour as of psychogenic origin.

A comparison of bilateral and unilateral causes of sudden loss of vision is presented in TABLE 77.4, and the diagnostic strategy model in TABLE 77.5. A simplified classification is:

- unilateral: retinal detachment
  - retinal artery occlusion
  - retinal vein thrombosis
  - temporal arteritis
  - optic neuritis
  - migraine
- bilateral: bilateral optic nerve lesion
  - hysteria

A flow chart for the diagnosis of painless loss of vision is presented in FIGURE 77.5.

## § Amaurosis fugax

Amaurosis fugax is transient loss of vision (partial or complete) in one eye due to transient occlusion of a retinal artery. It is painless and lasts less than 60 minutes. It is usually caused by an embolus from an atheromatous carotid artery in the neck. The most common emboli are cholesterol emboli, which usually arise from an ulcerated plaque.<sup>7</sup> Other causes include emboli from the heart, temporal arteritis and benign intracranial hypertension. Other symptoms or signs of cerebral ischaemia, such as transient hemiparesis, may accompany the symptom. The source of the problem should be investigated. The risk of stroke after an episode of amaurosis fugax appears to be about 2% per year.<sup>7</sup>

## Transient ocular ischaemia

Unilateral loss of vision provoked by activities such as walking, bending or looking upwards is suggestive of ocular ischaemia.<sup>7</sup> It occurs in the presence of severe extracranial vascular disease and may be triggered by postural hypotension and stealing blood from the retinal circulation.

## § Retinal detachment<sup>8</sup>

Retinal detachment may be caused by trauma, thin retina (myopic people), previous surgery (e.g. cataract operation), choroidal tumours, vitreous degeneration or diabetic retinopathy.

Table 77.4 Causes of sudden loss of vision<sup>7</sup>

	Bilateral	Unilateral	
		Transient	Permanent
<b>Vascular causes</b>	Occipital cortex ischaemia Pituitary apoplexy Homonymous hemianopia—vascular	Amaurosis fugax Transient ocular ischaemia Retinal emboli Malignant hypertension	Central retinal artery occlusion Central retinal vein occlusion Vitreous haemorrhage Ischaemic optic neuropathy
<b>Other causes</b>	Bilateral optic neuritis Toxic damage to optic nerve: <ul style="list-style-type: none"> <li>• methanol</li> <li>• ethanol</li> <li>• tobacco</li> <li>• lead</li> </ul> Leber optic atrophy Quinine poisoning of retina Cerebral oedema Occipital lobe trauma Craniopharyngioma Hysteria	Acute angle closure glaucoma Uhthoff phenomenon Papilloedema Posterior vitreous detachment	Optic neuritis Retinal detachment Optic nerve compression Carcinomatous optic neuropathy Intraocular tumour

**Table 77.5** Acute or subacute painless loss of vision: diagnostic strategy model

Q.	Probability diagnosis
A.	Amaurosis fugax Migraine Retinal detachment
Q.	Serious disorders not to be missed
A.	Cardiovascular: <ul style="list-style-type: none"> <li>• central retinal artery occlusion</li> <li>• central retinal vein occlusion</li> <li>• hypertension (complications)</li> <li>• CVA</li> </ul> Neoplasia: <ul style="list-style-type: none"> <li>• intracranial tumour</li> <li>• intraocular tumour:               <ul style="list-style-type: none"> <li>— primary melanoma</li> <li>— retinoblastoma</li> <li>— metastases</li> </ul> </li> </ul> Vitreous haemorrhage AIDS Temporal arteritis Acute glaucoma Benign intracranial hypertension
Q.	Pitfalls (often missed)
A.	Acute glaucoma Papilloedema Optic neuritis Intraocular foreign body Posterior uveitis
Q.	Seven masquerades checklist
A.	Diabetes (diabetic retinopathy) Drugs (quinine) Thyroid disorder (hyperthyroidism)
Q.	Is this patient trying to tell me something?
A.	Consider 'hysterical' blindness, although it is uncommon.

### Clinical features

- Sudden onset of floaters or flashes or black spots
- Blurred vision in one eye becoming worse
- 'A curtain came down over the eye', grey cloud or black spot
- Partial or total loss of visual field (total if macula detached)

Ophthalmoscopy may show detached retinal fold as large grey shadow in vitreous cavity.

### Management

- Immediate referral for sealing of retinal tears
- Small holes treated with laser or freezing probe

- Pneumatic retinopexy is an option
- True detachments usually require surgery

## § Vitreous haemorrhage

Haemorrhage may occur from spontaneous rupture of vessels, avulsion of vessels during retinal traction or bleeding from abnormal new vessels.<sup>6</sup> Associations include ocular trauma, diabetic retinopathy, tumour and retinal detachment.

### Clinical features

- Sudden onset of floaters or 'blobs' in vision
- May be sudden loss of vision
- Visual acuity depends on the extent of the haemorrhage; if small, visual acuity may be normal

Ophthalmoscopy may show reduced light reflex: there may be clots of blood that move with the vitreous (a black swirling cloud).

### Management

- Urgent referral to exclude retinal detachment
- Exclude underlying causes such as diabetes
- Ultrasound helps diagnosis
- May resolve spontaneously
- Bed rest encourages resolution
- Surgical vitrectomy for persistent haemorrhage

## § Central retinal artery occlusion

The cause is usually arterial obstruction by atherosclerosis, thrombi or emboli. There may be a history of TIAs. Exclude temporal arteritis (perform immediate ESR).

### Clinical features

- Sudden loss of vision like a 'curtain descending' in one eye
- Vision not improved with 1 mm pinhole
- Usually no light perception

### Ophthalmoscopy

- Initially normal
- May see retinal emboli
- Classic 'red cherry spot' at macula

### Management

If seen early, use this procedure within 30 minutes:

- massage globe digitally through closed eyelids (use rhythmic direct digital pressure)—may dislodge embolus

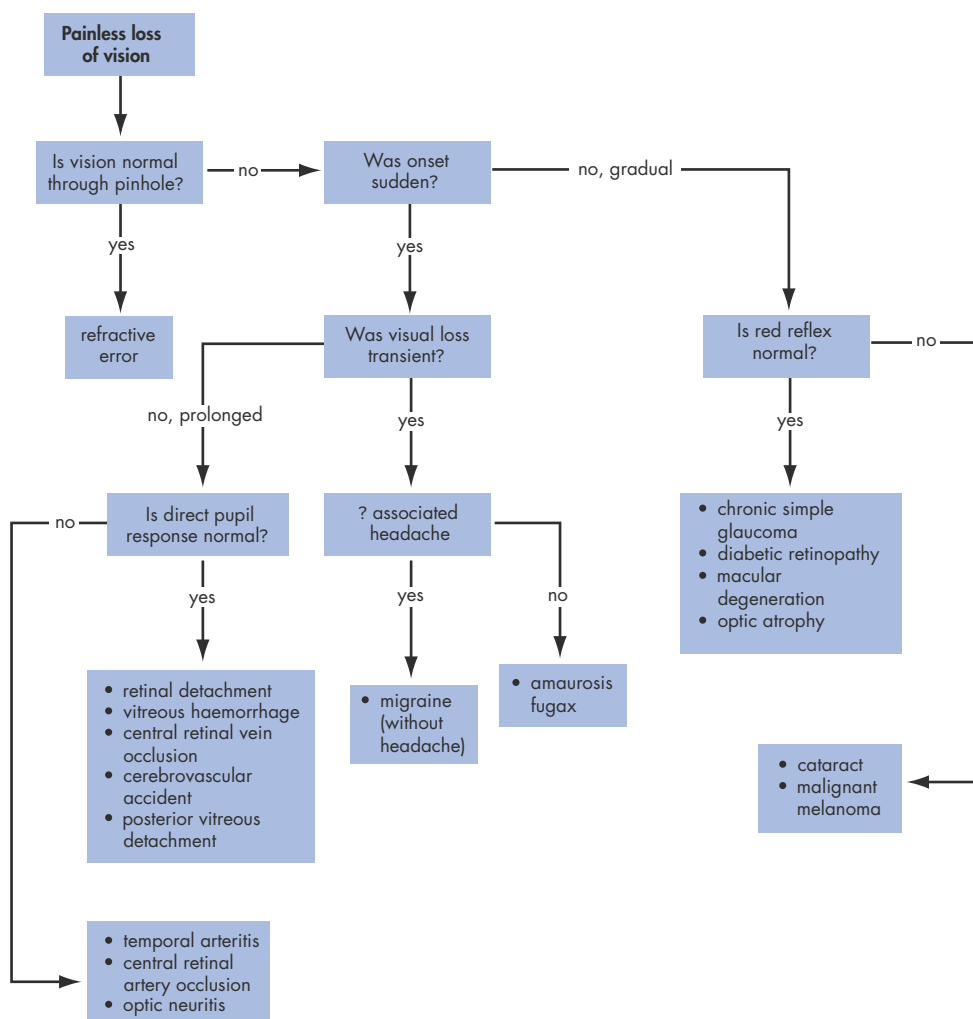

FIGURE 77.5 Diagnosis of painless loss of vision

Source: Reproduced with permission of Dr J Reich and Dr J Colvin

- rebreathe carbon dioxide (paper bag) or inhale special CO<sub>2</sub> mixture (carbogen)
- intravenous acetazolamide (Diamox) 500 mg
- refer urgently (less than 6 hours)—exclude temporal arteritis

Prognosis is poor. Significant recovery is unlikely unless treated immediately (within 30 minutes).

### § Central retinal vein thrombosis

Thrombosis is associated with several possible factors, such as hypertension, diabetes, anaemia, glaucoma and hyperlipidaemia. It usually occurs in elderly patients.

### Clinical features

- Sudden loss of central vision in one eye (if macula involved): can be gradual over days
- Vision not improved with 1 mm pinhole

Ophthalmoscopy shows swollen disc and multiple retinal haemorrhages, 'stormy sunset' appearance.

### Management

No immediate treatment is effective. The cause needs to be found first and treated accordingly. Some cases respond to fibrinolytic treatment. Laser photocoagulation may be necessary in later stages if neovascularisation develops to prevent thrombotic glaucoma.

## § Macular degeneration

There are two types: exudative or 'wet' (acute), and pigmentary or 'dry' (slow onset).

- 'Wet' MD is caused by choroidal neovascular membranes that develop under the retina of the macular area and leak fluid or bleed. It is a serious disorder.
- 'Dry' MD (9 out of 10 cases of MD) develops slowly and is always painless.
- More common with increasing age (usually over 60), when it is termed 'age-related MD', and in those with myopia (relatively common).
- May be familial.

### Clinical features

- Sudden fading of central vision (see FIG 77.6)
- Distortion of vision
- Straight lines may seem wavy and objects distorted
- Use a grid pattern (Amsler chart): shows distorted lines
- Central vision eventually completely lost
- Peripheral fields normal

**FIGURE 77.6** Appearance of a subject through the eyes of a person with age-related macular degeneration.

Photo courtesy Allergan Pharmaceuticals

### Ophthalmoscopy

- White exudates, haemorrhage in retina
- Macula may look normal or raised

### Management

No treatment is available to stop or reverse MD. For 'wet' MD refer urgently for treatment, which is currently based on injection of antivascular endothelial growth factor drugs (ranibizumab or bevacizumab) into the vitreous humour.<sup>9</sup> The

Age-Related Eye Disease Study provided confirmatory evidence that the chronic pigmentation type responds to free-radical treatment with the antioxidants vitamins A, C, E, and zinc using beta-carotene, 15 mg; vitamin C, 500 mg; vitamin E, 400 IU; and 80 mg zinc oxide.<sup>10</sup> Advise patient to cease smoking if applicable.

## § Temporal arteritis

With temporal arteritis (giant cell arteritis) there is a risk of sudden and often bilateral occlusion of the short ciliary arteries supplying the optic nerves, with or without central retinal artery involvement.<sup>11</sup>

### Clinical features

- Usually older person: over 65 years
- Sudden loss of central vision in one eye (central scotoma)
- Can rapidly become bilateral
- Associated temporal headache (not invariable)
- Temporal arteries tender, thickened and non-pulsatile (but often normal)
- Visual acuity severely impaired
- Afferent pupil defect on affected side
- Usually elevated ESR >40 mm

Ophthalmoscopy shows optic disc swollen at first, then atrophic. The disc may appear quite normal.

### Management

- Other eye must be tested
- Immediate corticosteroids (60–100 mg prednisolone daily for at least 1 week)
- Biopsy temporal artery (if there is a localised tender area)

## Retinal migraine

Migraine may present with symptoms of visual loss. Associated headache and nausea may not be present.

### Clinical features

- Zigzag lines or lights
- Multicoloured flashing lights
- Unilateral or bilateral field deficit
- Resolution within a few hours

## § Posterior vitreous detachment

The vitreous body collapses and detaches from the retina. It may lead to retinal detachment.

### Clinical features

- Sudden onset of floaters

- Visual acuity usually normal
- Flashing lights indicate traction on the retina

### Management

- Refer to an ophthalmologist urgently.
- An associated retinal hole or detachment needs exclusion.

### § Optic (retrobulbar) neuritis

Causes include multiple sclerosis, neurosyphilis and toxins. A significant number of cases eventually develop multiple sclerosis.

### Clinical features

- Usually a woman 20–40 years
- Loss of vision in one eye over a few days
- Retro-ocular discomfort with eye movements
- Variable visual acuity
- Usually a central field loss (central scotoma)
- Afferent pupil defect on affected side

### Ophthalmoscopy

- Optic disc swollen if 'inflammation' anterior in nerve
- Optic atrophy appears later
- Disc pallor is an invariable sequel

### Management

- Test visual field of other eye
- Consider MRI
- Most patients recover spontaneously but are left with diminished acuity
- Intravenous steroids hasten recovery and have a protective effect against the development of further demyelinating episodes

### Corneal disorders

Patients with corneal conditions typically suffer from ocular pain or discomfort and reduced vision. The common condition of dry eye may involve the cornea while contact lens disorders, abrasions/ulcers and infections are common serious problems that threaten eye sight. Inflammation of the cornea—keratitis—is caused by factors such as ultraviolet light e.g. 'arc eye', herpes simplex, herpes zoster ophthalmicus and the dangerous 'microbial keratitis'. Bacterial keratitis is an ophthalmological emergency that should be considered in the contact lens wearer presenting with pain and reduced vision. Topical corticosteroids should be avoided in the undiagnosed red eye.

Refer to **CHAPTER 51** for corneal lesions.

### Pitfalls

- Mistaking the coloured haloes of glaucoma for migraine.
- Failing to appreciate the presence of retinal detachment in the presence of minimal visual impairment.
- Omitting to consider temporal arteritis as a cause of sudden visual failure in the elderly.
- Using eyedrops to dilate the pupil (for fundal examination) in the presence of glaucoma.

### When to refer

- Most problems outlined need urgent referral to an ophthalmologist.
- Acute visual disturbance of unknown cause requires urgent referral.
- Any blurred vision—sudden or gradual, painful or painless—especially if 1 mm pinhole fails to alter visual acuity.
- Refer all suspicious optic discs.

### Practice tips

- Tonometry is advised routinely for all people over 40 years; those over 60 years should have tests every 2 years.
- Any family history of glaucoma requires tonometry at earliest age.
- Sudden loss of vision in the elderly suggests temporal arteritis (check the ESR and temporal arteries). It requires immediate institution of high-dose steroids to prevent blindness in the other eye. A time-scale guide showing the rate of visual loss is presented in **TABLE 77.6**.
- Temporal arteritis is an important cause of retinal artery occlusion.
- Suspect field defect due to chiasmal compression if people are misjudging when driving.
- Pupillary reactions are normal in cortical blindness.
- Central retinal artery occlusion may be overcome by early rapid lowering of intraocular pressure.
- Retinal detachment and vitreous haemorrhage may require early surgical repair.
- Keep in mind antioxidant therapy (vitamins and minerals) for chronic macular degeneration.
- Consider multiple sclerosis foremost if there is a past history of transient visual failure, especially with eye pain.
- If the patient has been using a hammer, always X-ray if a fragment of metal has hit the eye but nothing can be seen.

**Table 77.6** Time-scale guide for rate of visual loss<sup>3,7</sup>

Sudden: less than 1 hour

Amaurosis fugax

Central retinal artery occlusion

Hemianopias from ischaemia (emboli)

Migraine

Vitreous haemorrhage

Acute angle glaucoma

Papilloedema

Within 24 hours

Central retinal vein occlusion

Hysteria

Less than 7 days

Retinal detachment

Optic neuritis

Acute macular problems

Up to several weeks (variable)

Choroiditis

Malignant hypertension

Gradual

Compression of visual pathways

Chronic glaucoma

Cataracts

Diabetic maculopathy

Retinitis pigmentosa

Hippocrates

Obesity is the most common nutrition-related disorder in the Western world; as Tunnessen puts it, 'Obesity is the most common form of malnutrition in the United States'.<sup>1</sup> Most overweight adults and children who are obese have exogenous obesity, which tends to imply that 'they ate too much', but the problem is more complex than relative food input. Physical activity and environmental and genetic influences must also be taken into account. However, only a small percentage (4–6%) of human obesity is thought to be due to a single gene mutation.<sup>2</sup> There is still a persisting tendency of affected families to blame 'glandular' problems as a cause of obesity. It is now considered that there is a strong genetic basis to obesity and that attributing it to overeating and lack of exercise is an overly simplistic viewpoint.

### Key facts and figures

- Two-thirds of the Australian population are overweight or obese and only 2–4% underweight.<sup>3</sup>
- Abdominal obesity gives a higher cardiovascular risk at any weight.
- The onset of obesity can occur at any age.
- Secondary or pathologic causes are rare.
- Less than 1% of obese patients have an identifiable secondary cause of obesity.<sup>2</sup>
- Two conditions causing unexplained weight gain that can be diagnosed by the physical examination are Cushing syndrome and hypothyroidism.
- After pregnancy, obesity may result from a failure to return to prepartum energy requirements.
- Even small weight losses are effective in preventing diabetes and improving the cardiovascular risk profile.<sup>4</sup>

### A diagnostic approach

A summary of the diagnostic strategy model is presented in **TABLE 78.1**.

**Table 78.1** Weight gain: diagnostic strategy model

- |   |
|---|
| Q. Probability diagnosis                            |
| A. Exogenous obesity                                |
| Alcohol excess                                      |
| Drugs   |
| Q. Serious disorders not to be missed               |
| A. Cardiovascular:                                  |
| • cardiac failure                                   |
| Hypothalamic disorders (hyperphagia):               |
| • craniopharyngiomas                                |
| • optic gliomas                                     |
| Liver failure                                       |
| Nephrotic syndrome                                  |
| Q. Pitfalls (often missed)                          |

| Congenital disorders:                               |
| • Prader–Willi syndrome                             |
| • Laurence–Moon–Biedl syndrome                      |
| Q. Seven masquerades checklist                      |
| A. Depression                                       |
| Drugs   |
| Thyroid disorder (hypothyroidism)                   |
| Q. Is the patient trying to tell me something?      |
| A. Yes: the reasons for obesity should be explored. |

## Probability diagnosis

The outstanding cause of weight gain in exogenous obesity is excessive calorie intake coupled with lack of exercise. This is determined largely by environmental influences. Overweight people often deny overeating but the true situation can be determined by recording actual food intake and energy expenditure, and by interviewing reliable witnesses.

## Serious causes not to be missed

It is important not to misdiagnose hypothalamic disorders, which may result in hyperphagia and obesity. Injury to the hypothalamus may occur following trauma and encephalitis and with a variety of tumours, including craniopharyngiomas, optic gliomas and pituitary neoplasms. Some of these tumours may cause headaches and visual disturbances.

It is also important not to overlook major organ failure and kidney disorders as a cause of increased body weight, especially cardiac failure, liver failure and the nephrotic syndrome. The associated increase in body water needs to be distinguished from increased body fat.

## Pitfalls

### Endocrine disorders

The endocrine disorders that cause obesity include Cushing syndrome, hypothyroidism, insulin-secreting tumours and hypogonadism. They should not represent difficult diagnostic problems.

An insulin-secreting tumour (insulinoma) is a very rare adenoma of the B cells of the islets of Langerhans. The main features are symptoms of hypoglycaemia and obesity.

### Congenital disorders

The rare congenital disorders that cause obesity, such as Prader–Willi and Laurence–Moon–Biedl syndromes, should be easy to recognise in children (see CHAPTER 18 and later in this chapter).

### Chromosomal abnormalities

An important abnormality to bear in mind is Klinefelter syndrome (XXY karyotype), which affects one out of every 400–500 males. The boys show excessive growth of long bones and are tall and slim. Without testosterone treatment they become obese as adults.

Some girls with Turner syndrome (XO karyotype) may be short and overweight.

## Some gender pointers

Consider polycystic ovarian syndrome in women and obstructive sleep apnoea in obese men.

## Seven masquerades checklist

The important masquerades include hypothyroidism and drug ingestion. Hypothyroidism is usually not associated with marked obesity. Drugs that can be an important contributing factor include tricyclic antidepressants, mirtazapine, corticosteroids, pizotifen, thioridazine, haloperidol, Depo-Provera and the contraceptive pill. Obesity (overeating) may be a feature of depression, especially in the early stages. Prescribed tricyclic antidepressants may compound the problem.

## Psychogenic considerations

An underlying emotional crisis may be the reason for the overweight patient to seek medical advice. It is important to explore diplomatically any hidden agenda and help the patient to resolve any conflict.

## The clinical approach

A careful history is very valuable in ascertaining food and beverage intake and perhaps giving patients insight into their calorie intake, since some deny overeating or will underestimate their food intake.<sup>4</sup> Enquire about gynaecological and family history e.g. diabetes, cardiac disease.

## Relevant questions

- Do you feel that you have an excessive appetite?
- Tell me in detail what you ate yesterday.
- Give me an outline of a typical daily meal.
- Tell me about snacks, soft drink and alcohol that you have.
- What exercise do you get?
- Do you have any special problems, such as getting bored, tense and upset or depressed?
- What drugs are you taking?

## Examination

In the physical examination it is very important to measure body weight and height and calculate the BMI, and assess the degree and distribution of body fat and the overall nutritional status. Record the blood pressure and test the urine with dipsticks. Keep in mind that a standard blood pressure cuff on a large arm may give falsely elevated values. Remember the rare possibilities of Cushing syndrome, acromegaly and hypothyroidism. Search for evidence of atherosclerosis and diabetes and for signs of alcohol abuse.

An extensive working up of the CNS is not indicated in obesity without the presence of suspicious symptoms such as visual difficulties.

## Investigations

It is essential to perform two measurements:

- weight and height (to calculate BMI)
- waist circumference

## Important investigations

- Cholesterol/triglycerides
- Glucose (fasting)
- Liver function tests
- Electrolytes and urea

## Investigations to consider

- Thyroid function tests
- Cortisol (if hypertensive)
- Testosterone (suspected sleep apnoea)
- ECG and chest X-ray (older than 40)

## Anthropometric measurements<sup>5</sup>

Useful measuring instruments include:

- BMI: 'healthy' range is between 20 and 25
- Waist circumference: increased risk of comorbidities
  - in men >94 cm (>102—high risk)
  - in women >80 cm (>88—high risk)

Measure waist halfway between inferior margin of last rib and crest of ilium in mid-axillary line over bare skin.

- waist-hip circumference ratio (W/H ratio): healthy range <0.9—a better predictor of cardiovascular risk than BMI
- single skinfold thickness (>25 mm suggests increased body fat)
- upper arm circumference
- 4 skinfold thickness (sum of suprailiac, subscapular, triceps and biceps skinfolds)—for calculation of percentage body fat

Abdominal fatness, which is defined as a W/H ratio of >0.85 in women and >0.95 in men, is a more accurate indicator of the complications of diabetes.

## Body mass index

The easiest and possibly most accurate assessment of obesity is the BMI (refer to Appendix V):

$$\text{BMI} = \frac{\text{weight (kg)}}{\text{height (m}^2\text{)}}$$

**Table 78.2** Classification of obesity (based on WHO guidelines)<sup>6</sup>

BMI	Grading	Suggested therapy
<18.5	Underweight	Diet and counselling
18.5–25	Healthy weight	
25–30	Overweight	More exercise Diet: less alcohol
30–35	Grade I: mildly obese	Combined program: <ul style="list-style-type: none"> <li>• behaviour modification</li> <li>• diet</li> <li>• exercise</li> </ul>
35–40	Grade II: moderately obese	Consider medical therapy if >35
≥40	Grade III: severely obese	Combined program plus medical therapy Consider gastric surgery

Garrow<sup>6</sup> has produced a simple classification of the BMI associated with the relative degree of risk increase and suggested therapy (see **TABLE 78.2**).

The BMI has limitations. It doesn't distinguish between men and women or between body types and it doesn't work for children.

## Weight gain in children

Various studies have found that approximately 10% of prepubertal and 15% of adolescent age groups are obese.<sup>1</sup>

Obesity in children is a BMI for age >95th percentile while overweight is >85th percentile. There is a risk of obesity associated diseases and carrying the problem into adulthood. Raising the issue with parents and child requires sensitivity and discretion.

Parents often blame obesity in children on their 'glands', but endocrine or metabolic causes are rare and can be readily differentiated from exogenous obesity by a simple physical examination and an assessment of linear growth. Children with exogenous obesity tend to have an accelerated linear growth whereas children with secondary causes are usually short.

## Congenital or inherited disorders associated with obesity

### Prader-Willi syndrome

The characteristic features are bizarre eating habits (e.g. binge eating), obesity, hypotonia, hypogonadism, intellectual disability, small hands and feet and a

characteristic facial appearance (narrow bifrontal diameter, 'almond-shaped' eyes and a 'tented' upper lip). Progressive obesity results from excessive intake in addition to decreased caloric requirements (see CHAPTER 18).

### Laurence-Moon-Biedl syndrome

The characteristic features are obesity, intellectual disability, polydactyly and syndactyly, retinitis pigmentosa and hypogonadism.

### Beckwith-Wiedemann syndrome

Characteristics include excessive growth, macrosomia, macroglossia, umbilical hernia and neonatal hypoglycaemia. Children appear obese as they are above the 95th percentile by 18 months of age. Intelligence is usually in the normal range.

## Endocrine disorders

Endocrine disorders in children that can rarely cause obesity include hypothyroidism (often blamed as the cause but seldom is), Cushing syndrome, insulinomas, hypothalamic lesions, Fröhlich syndrome (adiposogenital dystrophy) and Stein-Leventhal syndrome (PCOS) in girls.

## Managing obesity in children

Childhood obesity usually reflects an underlying problem in the family system. It can be a very difficult emotional problem in adolescents, who develop a poor body image. An important strategy is to meet with family members, determine whether they perceive the child's obesity as a problem and whether they are prepared to solve the problem. The family dynamics will have to be assessed and strategies outlined. This may involve referral for expert counselling. It is worth pointing out that children eat between one-third and two-thirds of their meals at school so schools should be approached to promote special programs for children who need weight reduction.

Conventional therapy by dietary modification, increasing energy expenditure by increasing activity, reducing sedentary behaviour, behaviour modification and family involvement is recommended. Some authorities emphasise that weight maintenance rather than weight loss is appropriate since many children will 'grow into their weight'.<sup>7</sup>

## § Cushing syndrome

Cushing syndrome is the term used to describe the chemical features of increased free circulating glucocorticoid. The most common cause is iatrogenic with the prescribing of synthetic

corticosteroids. The spontaneous primary forms such as Cushing disease (pituitary dependent hyperadrenalism) are rare. As the disorder progresses the body contour tends to assume the often quoted configuration of a lemon with matchsticks (see CHAPTER 23).

## Clinical features

- Change in appearance
- Central weight gain (truncal obesity)
- Hair growth and acne in females
- Muscle weakness
- Amenorrhoea/oligomenorrhoea (females)
- Thin skin/spontaneous bruising
- Polymyalgia/polydipsia (diabetes mellitus)
- Insomnia
- Depression

## Signs

- Moon face
- 'Buffalo hump'
- Purple striae
- Large trunk and thin limbs: the 'lemon with matchsticks' sign

The patient should be referred for diagnostic evaluation, including plasma cortisol and overnight dexamethasone suppression tests.

Untreated Cushing syndrome has a very poor prognosis, with premature death from myocardial infarction, cardiac failure and infection; hence early diagnosis and referral is essential.

## § Obesity

Obesity and overweight are the most common pathological conditions in our society and are caused by an accumulation of adipose tissue (see TABLE 78.3). It is not the extra weight per se that causes problems but excess fat. The calculation of the BMI gives a better estimate of adiposity and it is convenient and preferable to use this index when assessing the overweight and obese. However, recent data suggest that the distribution of body fat is as important a risk factor as its total amount. Abdominal fat (upper body segment obesity, or 'apple' obesity) is considered a greater health hazard than fat in the thighs and buttocks (lower body segment obesity, or 'pear' obesity) (see FIG. 78.1).

Obese patients with high waist-hip ratios (>1.0 in men and >0.9 in women) have a significantly greater risk of diabetes mellitus, stroke, coronary artery disease and early death than equally obese people with lower waist-hip ratios.<sup>2</sup>

**Table 78.3** Factors predisposing to primary obesity

<b>Genetic</b>	Familial tendency
<b>Sex</b>	Women more susceptible
<b>Activity</b>	Lack of physical activity
<b>Psychogenic</b>	Emotional deprivation, depression
<b>Socioeconomic status</b>	Lower
<b>Alcohol</b>	Problem drinking
<b>Smoking</b>	Cessation of smoking
<b>Prescribed drugs</b>	Tricyclic derivatives

**FIGURE 78.1** Comparison of two types of obesity according to distribution of body fat

In regard to the BMI reference scale it is worth noting that the risks follow a J-shaped curve (see FIG. 78.2) and are only slightly increased in the overweight range but increase with obesity so that a BMI of  $>40$  carries a threefold increase in mortality.

The consequences of obesity include:

- cardiovascular:
  - increased mortality (stroke, ischaemic heart disease, etc.)
  - hypertension
  - varicose veins
- metabolic:
  - dyslipidaemia
  - type 2 diabetes
  - insulin resistance
  - hyperuricaemia/gout
  - infertility
  - PCOS
- mechanical:
  - osteoarthritis
  - obstructive sleep apnoea
  - restrictive pulmonary disease
  - spinal dysfunction
  - low back pain

**FIGURE 78.2** Body mass index (BMI) reference scale

- other:
  - hiatus hernia
  - gall bladder disease
  - fatty liver
  - cancer (various)
  - kidney disease (check microalbuminuria)
  - excessive daytime sleepiness
  - erectile dysfunction
  - psychological problems/depression

### Management

An imperative of treatment is to address the serious comorbidities of type 2 diabetes and insulin resistance.

Treatment is based on four major interventions, the choice of which depends on the degree of obesity, the associated health problems and the health risk posed:

- 1 reduction in energy intake
- 2 change in diet composition
- 3 increased physical activity
- 4 behavioural therapy

Pharmacological agents are not used for first-line therapy although they may have a place in management, especially at grade III level of obesity. Surgery is an option for the treatment of morbid obesity.

There is no single effective method for the treatment of obesity, which is a difficult and frustrating problem. A continuing close therapist/patient contact has a better chance of success than any single treatment regimen.

## Goals

- 1 no further weight gain
- 2 loss of 5–10% initial body weight
- 3 improve activity

Most successful programs involve a multidisciplinary approach to weight loss, embracing the four major interventions. The first goal should be no further weight gain. Emphasis must be on maintenance of weight loss. Behaviour modification is important and the most valuable strategy is to emphasise planning and record keeping with a continuous weekly diary of menus, exercise and actual behaviour.

Social support is essential for a successful weight loss program. A better result is likely if close family members, especially the chief cook, are involved in the program, preferably striving for the same goals.<sup>2</sup>

## A doctor–patient strategy

A close therapeutic supportive relationship with a patient can be effective using the following methods:<sup>8</sup>

- 1 *Promote realistic goals.* Lose weight at the same rate that it was gained (i.e. slowly)—for example, 5–10 kg a year. A graph can be used for this purpose with an ‘exaggerated’ scale on the vertical axis so that small variations appear highly significant and encouraging (see FIG. 78.3).

Promote the equation:

Energy In = Energy Out + Energy Stored

The appropriate way to reduce the stored energy (fat) is either to reduce energy in (eat less) or increase energy out (exercise).

- 2 *Dietary advice.* It is important to be realistic and allow patients to eat their normal foods but advise them about quantity and frequency. Give advice on simple substitutions (e.g. fortified skim milk in place of whole milk, high-fibre wholemeal bread instead of white bread, and fruit and vegetables instead of biscuits and cakes as in-between snacks).<sup>8</sup> A strategy that seems to work effectively is to advise patients, especially those who are overweight (and grade I obesity), to eat one-third less than they usually do and discipline themselves not to ‘pick’ and to avoid second helpings.
- 3 *Counselling* is simple and commonsense. It involves being supportive, interested and encouraging. A list of tips on coping is provided (see below ‘A practical plan’ for grade II and III obesity) and the patient advised to keep a food, exercise and behaviour diary.

FIGURE 78.3 Weight loss chart to encourage patient

Source: After Kaczmarczyk<sup>8</sup>

- 4 *Review.* ‘Review is the most vital part of the weight loss programme as it stimulates and revitalises motivation and enables assessment of progress.’<sup>8</sup> It should be frequent initially (e.g. fortnightly), then monthly until the goal weight has been achieved and then 3-monthly. It is important never to be judgmental or critical if progress is unsatisfactory.

## A practical plan

The following patient education sheet to be handed to patients represents useful advice to offer the obese patient.<sup>8</sup> The emphasis is on a healthy lifestyle program.

### Physical activity

- A brisk walk for at least 20–30 minutes each day is the most practical exercise.
- Other activities such as tennis, swimming, golf and cycling are a bonus.

### Dietary advice

Provide patients with a glycaemic index guide (see TABLE 10.1 in CHAPTER 10).

Breakfast:

- oatmeal (soaked overnight in water); after cooking, add fresh or dried fruit; serve with fat-reduced milk or yoghurt
- or
- muesli (homemade or from a health food store)—medium serve with fat-reduced milk, perhaps add extra fruit (fresh or dried)

- slice of wholemeal toast with a thin scraping of margarine, spread with Vegemite, Marmite or sugar-free marmalade
- fresh orange juice or herbal tea or black tea/coffee

Morning and afternoon tea:

- piece of fruit or vegetable (e.g. carrot or celery)
- freshly squeezed juice or chilled water with fresh lemon

Midday meal:

- salad sandwich with wholemeal or multigrain bread and thin scraping of margarine (for variety use egg, salmon, chicken or cheese fillings)
- drink as for breakfast

Evening meal:

- Summer (cold)—lean meat cuts (grilled, hot or cold), poultry (skin removed) or fish; fresh garden salad; slices of fresh fruit
- Winter (hot)—lean meat cuts (grilled), poultry (skin removed) or fish; plenty of green, red and yellow vegetables and small potato; fruit for sweets

### Weight-losing tips<sup>9</sup>

- Have sensible goals; do not 'crash' diet but have a 6–12 month plan to achieve your ideal weight.
- Go for natural foods; avoid junk foods.
- Select fish, poultry and lean meats.
- Trim excess fat from meat and skin from poultry.
- Eat more breads (wholemeal), cereals, fruit and vegetables.
- Increase intake of complex carbohydrates that contain starch and fibre.
- Plant food is good for you; have it as part of breakfast.
- Eat less sugar; avoid lollies and syrups.
- Avoid alcohol, sugary soft drinks and high-calorie fruit juices.
- Strict dieting without exercise fails.
- If you are mildly overweight, eat one-third less than you usually do.
- Do not eat biscuits, cakes, buns, etc. between meals (preferably at no time).
- Limit the intake of full-cream products, fried foods and fatty take-away meals.
- Limit the amount of butter or margarine on vegetables and bread.
- Reduce calorie intake; reduce fat intake to <30% of total calorie intake.

- Use high-fibre foods to munch on.
- Drink copious water—at least 2 L a day.
- A small treat once a week may add variety.
- Avoid seconds and do not eat leftovers.
- Avoid non-hungry eating.
- Eat slowly—spin out your meal.

### Pharmacological agents

A variety of these are available or imminent but they have limitations and need to be used with caution, if at all. Adverse effects can be problematic. Consider for those with a BMI >30 and failed well-supervised lifestyle measures.

The agents are:<sup>4,5,9,10</sup>

- Local, acting on GIT:
  - bulking agents (e.g. methylcellulose)
  - lipase inhibitor—orlistat (Xenical) 120 mg (o) tds ac (used with a low-fat eating program)
- Centrally acting agents:
  - amphetamine derivatives (reduce hunger):
  - phentermine 15–40 mg (o) daily (limited use)
  - serotonin analogues (enhance satiety):
  - fluoxetine 20–40 mg (o) daily
  - sibutramine 10–15 mg (o) daily (monitor BP)
  - sertraline

A summary of systemic reviews to date indicates that the effectiveness of serotonin analogues is unknown or, with sibutramine and phentermine, of some benefit, which has to be weighed against adverse effects, including the potentially fatal serotonin syndrome. The same applies to orlistat, which, together with a low-fat eating program, does produce extra weight loss over placebo.<sup>11</sup> Drugs should not be expected to have a continuing effect after therapy ceases.

### Meal replacements

Food replacement agents such as Optifast have been promoted but there is insufficient evidence so far to evaluate their effectiveness and the reduced intake of key vitamins.

### Surgery (bariatric surgery)<sup>5,7</sup>

Surgery is the most effective treatment for obesity but is associated with risks such as malabsorption.<sup>4</sup> In those with morbid obesity (about 2% of the population) unresponsive to behaviour modification therapy and a course of pharmacological agents for 3 months or so, gastric banding has a place. It is recommended in those with a BMI >40 or >35

with severe comorbidities such as poorly controlled diabetes or severe OSA. One example is Lap-Band, which is inserted laparoscopically and can be adjusted and eventually removed with minimal significant residual adverse defect left in the stomach. It appears to be effective for 10 years.<sup>5,12</sup> Sleeve gastrectomy gastric bypass such as Roux-en-Y bypass and other techniques to consider.

## Oedema

Oedema (dropsy) is an excessive accumulation of fluid in tissue spaces. It may be generalised or localised—periorbital, peripheral or an arm (lymphoedema, refer CHAPTER 69).

## Generalised oedema

The site of generalised oedema is largely determined by gravity. It is due to an abnormal excess of sodium in the body, which leads to accumulation of water. The causes can be generally divided into two groups—oedema associated with a decreased plasma volume and oedema associated with an increased plasma volume (see TABLE 78.4).

**Table 78.4** Causes of generalised oedema

Decreased plasma volume

Hypoalbuminaemia (e.g. nephrotic syndrome, chronic liver disease, malnutrition)

Increased plasma volume

Congestive cardiac failure

Chronic kidney failure

Drugs (e.g. corticosteroids, NSAIDs, certain antihypertensives, oestrogens, lithium, others)

Idiopathic oedema

## Diagnosis

Clinical examination, including urinalysis, is usually sufficient to establish the cause of the oedema. In other cases, investigation of kidney or liver function may be required.

## Treatment

- Treat the cause where known
- Salt (sodium) restriction
- Diuretics:
  - a loop diuretic (e.g. frusemide)
  - a potassium-sparing diuretic (e.g. spironolactone)

## Idiopathic oedema

Idiopathic oedema, also known as cyclical or periodic oedema, is a common problem and the diagnosis is made on a characteristic history:

- exclusive to women
- may be cyclical or persistent
- usually unrelated to menstrual cycle
- excessive diurnal weight gain (worse on prolonged standing)
- abdominal bloating
- may affect hands and face as well as feet
- often made worse by diuretics
- may be associated with headache, depression, tension

Treatment of this condition is difficult. Most diuretics can aggravate the problem. Supportive stockings and a nutritious diet (with restricted sodium intake) is recommended as first-line treatment. A trial of spironolactone is often recommended.

## Swelling (puffiness) of the face and eyelids

The causes are similar to those for generalised oedema. Important specific causes to consider are:

- kidney disease (e.g. nephrotic syndrome, acute nephritis)
- hypothyroidism
- Cushing syndrome and corticosteroid treatment
- mediastinal obstruction
- angio-oedema
- skin sensitivity (e.g. drugs, cosmetics, hair dryers)

## Swelling of the legs

Refer to CHAPTER 69.

## § 'Cellulite'

'Cellulite' refers to a characteristic form of dimpling seen in the subcutaneous tissues of hips, buttocks and thighs of females. The dimpling pattern is related to the manner of attachment of fibrous septae that contain the fat. Many patients seek advice about 'cellulite' in the buttocks and thighs in particular. Explain that the best way to overcome it is to maintain an ideal weight. If overweight, lose it slowly and exercise to improve the muscle tone in the buttocks and thighs.

## When to refer

- Patients with grade II or III obesity (BMI >35) who are resistant to simple weight control measures.<sup>5</sup>
- Patients with associated medical problems such as angina or severe osteoarthritis who require relatively rapid weight reduction.
- Possibility of endocrine cause of obesity.
- Suspicion of congenital or inherited disorder in children.

### Practice tips

- Avoid a critical or judgmental attitude to the overweight patient.
- Diplomatically seek independent information from a spouse or parent about food and beverage intake.
- Obtain a chronological history of the patient's weight from infancy onwards and attempt to correlate any significant changes to stressful life events.
- Central or visceral obesity carries a large risk factor for medical complications. People are advised to keep the waist circumference to less than 100 cm, and ideally less than 80 cm in women and 94 cm in men.
- The best approach is to focus on fitness, with dietary advice on fresh vegetables and fewer 'empty' calories (soft drinks, snack foods). It is much better to be overweight and fit than normal weight and unfit.<sup>3</sup>

*Among young women dieters in modern society about 1 in 20 will become preoccupied with their appearance and progress to the eating disorders of anorexia nervosa and bulimia.*

Professor Doris Young 1988

In family practice complaints of loss of weight are more frequent than complaints about being too thin. Of great significance is the problem of recent loss of weight. A very analytical history is required to determine the patient's perception of weight loss. The equivalent problem in children is failure to gain weight or thrive.

Weight loss is an important symptom because it usually implies a serious underlying disorder, either organic or functional. It may or may not be associated with anorexia and thus diminished food intake.

## Key facts and checkpoints

- Any loss of more than 5% of normal body weight is significant.
- The most common cause in adults of recent weight loss is stress and anxiety.<sup>1</sup>
- Serious organic diseases to consider are:
  - malignant disease
  - diabetes mellitus
  - chronic infections (e.g. tuberculosis)
  - thyrotoxicosis
- The most important variable to consider in evaluating weight loss is appetite. Eating and weight go hand in glove.
- Two conditions commonly associated with weight loss are anaemia and fever; they must be excluded.
- Early detection of eating disorders improves outcome.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in **TABLE 79.1**.

## Probability diagnosis

Excluding planned dietary restriction, psychological factors are the most common cause, particularly

recent stress and anxiety.<sup>1</sup> Elderly people with adverse psychological factors, neglect and possibly drug effects can present with wasting.

## Serious disorders not to be missed

Many of the problems causing weight loss are very serious, especially malignant disease.

### Malignant disease

Weight loss may be a manifestation of any malignancy. With cancer of the stomach, pancreas and caecum, malignant lymphomas and myeloma, weight loss may be the only symptom. Occult malignancy must be regarded as the most common cause of weight loss in the absence of major symptoms and signs. The mechanisms may be multiple, with anorexia and increased metabolism being important factors.

### Chronic infections

These are now less common but tuberculosis must be considered, especially in people from less developed countries. Some cases of infective endocarditis may progress only very slowly with general debility, weight loss and fever as major features.<sup>2</sup>

Other infections to consider are brucellosis, and protozoal and systemic fungal infection. Infection with HIV virus must be considered, especially in high-risk groups.

## Pitfalls

Drug dependency, including alcohol and narcotic drugs, must be considered, especially when the problem may result in inappropriate nutrition. Apart from malignant disease there is a whole variety of gastrointestinal disorders that require consideration—these include malabsorption states, gastric ulceration, and intestinal infestations that should be considered, especially in people returning from a significant stay in tropical and under-developed countries.

Addison disease (**CHAPTER 23**) can be very difficult to diagnose. Symptoms include excessive

**Table 79.1** Weight loss: diagnostic strategy model (other than deliberate dieting or malnutrition)

Q.	Probability diagnosis
A.	Stress and anxiety (e.g. redundancy, divorce) Depressive illness Non-coping elderly/dementia Eating disorders: anorexia nervosa/bulimia

A.	Depression Diabetes Drugs Anaemia Thyroid disorder (hyperthyroidism) UTI
Q.	Is the patient trying to tell me something?
A.	A possibility. Consider stress, anxiety and depression. Anorexia nervosa and bulimia are special considerations.

fatigue, anorexia, nausea and postural dizziness. Hyperpigmentation is a late sign.

## Seven masquerades checklist

Depression and the endocrine disorders, diabetes mellitus and hyperthyroidism, are important causes.

## Diabetes

The diabetic who presents with weight loss will be young and insulin-dependent. The initial presentation may be ketoacidosis. The triad of symptoms is thirst + polyuria + weight loss.

## Hyperthyroidism

This is usually associated with weight loss although in some, such as an elderly male, it may not be obvious. An important clue will be weight loss in the presence of an excellent appetite and this helps to distinguish it from a psychoneurotic disturbance.

## Depression

Weight loss is a common feature of depression and is usually proportional to the severity of the disease. In the early stages of depression, weight gain may be present but when the classic loss of the four basic drives (appetite, energy, sleep and sex) becomes manifest, weight loss is a feature.

## Drugs

Any prescribed drugs causing anorexia can cause weight loss. Important drugs include digoxin, narcotics, cytotoxics, NSAIDs, some antihypertensives and theophylline.

## Red flag pointers for weight loss

- Weight loss per se is a big red flag
- Rapid weight loss with malaise
- Acid dental erosion on surfaces of upper teeth: think bulimia
- Weakness and malaise in young females: consider eating disorder and hypokalaemia
- Evidence of abuse in a child

## Psychogenic considerations

Weight loss is a feature of anxiety as well as depression. Some patients with psychotic disturbances, including schizophrenia and mania, may present with weight loss.

Anorexia nervosa is quite common and is almost entirely confined to females between the ages of 12 and 20 years. The main differential diagnosis is hypopituitarism, although anorexia nervosa can cause endocrine disturbances through the hypothalamic pituitary axis.

## The clinical approach

### History

It is important to document the weight loss carefully and evaluate the patient's recordings. The same set of scales should be used. It is also important to determine the food intake. However, in the absence of an independent witness such as a spouse or parent, this can be difficult. Food intake may be diminished with psychogenic disorders and cancer but increased or steady with endocrine disorders, such as diabetes and hyperthyroidism, and with steatorrhoea.

FIGURE 79.1 shows the possible causes of weight loss.

### General questions

- Exactly how much weight have you lost and over how long?
- Have you changed your diet in any way?
- Has your appetite changed? Do you feel like eating?
- Have your clothes become looser?
- What is your general health like?
- How do you feel in yourself?
- Do you feel uptight (tense), worried or anxious?
- Do you get very irritable or tremulous?
- Do you feel depressed?
- Do you ever force yourself to vomit?
- Are you thirsty?
- Do you pass a lot of urine?
- Do you have excessive sweating?
- Do you experience a lot of night sweats?
- What are your motions like?
- Are they difficult to flush down the toilet?
- Do you have a cough or bring up sputum?

FIGURE 79.1 Weight loss: causes to consider

- Do you get short of breath?
- Do you have any abdominal pain?
- Are your periods normal (for females)?
- What drugs are you taking?
- How many cigarettes do you smoke?

## Examination

A careful general examination is essential with special attention to:

- vital parameters e.g. BMI, temperature, BP
- the thyroid and signs of hyperthyroidism
- the abdomen (check liver, any masses and tenderness)
- rectal examination (test stool for occult blood)
- reflexes
- look for acid dental erosion on surface of upper teeth (bulimia)

## Investigations

Basic investigations include:

- haemoglobin, red cell indices and film
- white cell count
- ESR/CRP
- thyroid function test
- random blood sugar
- urea and electrolytes
- chest X-ray
- urine analysis
- faecal occult blood

Others to consider:

- upper GIT (endoscopy or barium meal)
- HIV serology
- ultrasound of abdomen (or CT if suspected abnormality not found)
- colonoscopy
- LFTs
- tumour markers e.g. CA-125, CEA

## Weight loss in children

Weight loss in children can be considered as:

- 1 failure to thrive (FTT): the child up to 2 years below 3rd percentile (refer to [CHAPTER 91](#))
- 2 weight loss in a child after normal development

## Loss of weight in the older child

Acute or chronic infections are the most common causes of weight loss in children beyond infancy.<sup>3</sup> In acute infections the weight loss is transient, and

once the infection clears the child generally regains the lost weight. In chronic infections signs may be more difficult to detect (e.g. urinary tract infection, pulmonary infection, osteomyelitis, chronic hepatitis). In common with the younger child who fails to thrive, the older child may be suffering from malabsorption syndrome, chronic infection of the urinary tract or a rare chromosomal or metabolic disorder.<sup>4</sup> Tuberculosis, diabetes and malignant disease may present as weight loss and it is necessary to exclude organic disease before considering the more common emotional disorders.

## Eating disorders in the adolescent

Concerns about body image and dieting are very common among young women in modern society. Among these dieters 5–10% become abnormally preoccupied with dieting and slimness and progress to the eating disorders of anorexia nervosa and bulimia. Sufferers often have extremely low self-esteem and feel ineffective. They tend to be perfectionists with obsessive-compulsive traits. A history of childhood sexual abuse may be relevant. Media images alone do not cause eating disorders but have a role—genetic vulnerability, temperament, psychological and environmental factors also mediate these illnesses: ‘Genes load the gun—the environment pulls the trigger’.<sup>5</sup>

The DSM-5 criteria for diagnosing these disorders, which have serious physical and psychological consequences, are presented in [TABLE 79.2](#). The differential diagnosis of anorexia nervosa includes most of the problems listed in [TABLE 79.1](#).

## Anorexia nervosa

See [FIGURE 79.2](#).

Anorexia nervosa is a syndrome characterised by the obsessive pursuit of thinness through dieting with extreme weight loss and disturbance of body image.<sup>6</sup> The main symptoms are anorexia and weight loss. The mortality rate may be as high as 18%. It has the highest mortality and suicide rate of any psychiatric disorder.<sup>5</sup>

## Typical features

- Adolescent and young adult females
- Up to 1% incidence among schoolgirls aged 16<sup>7</sup>
- Bimodal age of onset: 13–14 and 17–18 years<sup>6</sup>
- Unknown cause
- Poor insight
- Severe emaciation

**Table 79.2** DSM-5 criteria for diagnosing anorexia nervosa and bulimia

#### Anorexia nervosa

- A** Restriction of energy intake relative to requirements leading to significantly low body weight in context of age, sex and physical health. That weight is less than minimally normal or expected
- B** Intense fear of gaining weight or becoming fat, despite current underweight status
- C** Disturbance of body image (body size or shape) or persistent lack of recognition of seriousness of low body weight
- Types** restricting type—no binge eating or purging  
binge eating/purging type

#### Bulimia nervosa

- A** Recurrent episodes of binge eating, that is:
- 1 eating in a discrete period of time an abnormal quantity of food compared with the average person
  - 2 a sense of lack of control during the binge
- B** Recurrent inappropriate compensatory behaviour to prevent weight gain (e.g. self-induced vomiting; misuse of laxatives, diuretics, enemas etc.); fasting or excessive exercise
- C** A and B both occur, on average, at least twice a week for 3 months
- D** Self-evaluation is unduly influenced by body shape and weight
- E** Does not occur exclusively during periods of anorexia nervosa
- Types** purging non-purging (e.g. fasting, excessive exercise)

- Amenorrhoea
- Loss of body fat
- Sallow, dry and scaly skin, hair loss
- Increased lanugo body hair
- BMI <17.5
- Continuing behaviour directed at weight loss

### **Bulimia nervosa**

Bulimia is episodic secretive binge eating followed by self-induced vomiting, fasting or the use of laxatives or diuretics. This binge–purge syndrome is also referred to as bulimarexia. It is more difficult to detect than anorexia nervosa but has a higher incidence. There are two types—the purging type and the non-purging type where fasting or excessive exercise are

**FIGURE 79.2** 18-year-old adolescent with severe anorexia nervosa (BMI 8.7). This patient survived after care by her GP. Photo and history courtesy Dr MM O'Brien

the compensatory behaviours. The purging type is the most life-threatening behaviour because of the danger of hypokalaemia.

### **Typical features**

- Young females (F:M ratio 10:1)
- Begins at later age, usually 17–25 years
- Associated psychoneurotic disorders
- Family history
- Fluctuations in body weight without extreme loss or gain
- Menstrual history usually normal but periods may be irregular—amenorrhoea rare
- Physical complications of frequent vomiting (e.g. dental decay, effects of hypokalaemia)
- Recurrent laxative, stimulant or enema abuse

- Preoccupation with food
- Exaggerated weight/body shape concern
- Impulse control disorders (e.g. gambling, substance abuse)
- Depressed mood with guilt after a binge

Laboratory evaluation should include electrolytes, FBE, iron studies, TFTs, kidney function tests, coeliac disease screening and LFTs, ESR.

*Note:* The other main eating disorder is 'binge eating disorder', which is defined as recurrent episodes of binge eating in the absence of regular use of inappropriate compensatory behaviours characteristic of bulimia nervosa. However, most of these patients are obese.

## Management of eating disorders

Early detection and intervention are essential to reduce the risk of chronicity. Treatment can be conducted on an outpatient basis but if there are marked trends, such as severe weight loss, a family crisis, severe depression and a suicide risk, the patient requires hospital admission. The burden on caregivers of people with eating disorders is high. There are often problematic family interrelationships that require exploration.

Important goals are:

- establish a good and caring relationship with the patient
- resolve underlying psychological difficulties
- restore weight to a level between ideal and the patient's concept of optimal weight
- provide a balanced diet of at least 3000 calories per day (anorexia nervosa)

Structured behavioural therapy, intensive psychotherapy and family therapy may be tried but supportive care by physicians and allied health staff appears to be the most important feature of therapy.<sup>8</sup> Psychotherapy may be arranged by referral to a psychologist or psychiatrist. The patient may need admission to hospital, especially if dehydration and hypokalaemia (from purging) and also suicide are concerns. Rapid weight loss, vomiting, especially with poor insight, are also 'red flags' for hospital admission. Antidepressants, especially of the SSRI group, may be helpful for selected patients with a comorbid depressive illness. Fluoxetine is the preferred agent for bulimia. It is important to provide ongoing support for both patient and family.

## Weight loss in the elderly

General weight loss is a relatively common physiological feature of many elderly people. However, abnormal weight loss is commonly encountered in the socially disadvantaged elderly, especially those who live alone and lack drive and interest in adequate food preparation. Other factors include relative poverty and poor dentition, including ill-fitting and painful false teeth. An important cause that should always be considered is malignant disease. Consider depression, dementia and drug interactions as potential causes of weight loss. Depression is the most common reversible cause of weight loss in elderly people, occurring in up to 30% of all medical outpatients presenting with undernutrition.<sup>9</sup> Weight loss of more than 5% body weight in 6 months is significant and suggests undernutrition.<sup>9</sup>

Congestive cardiac failure, especially secondary to ischaemic heart disease, is a common cause of weight loss. This is due to visceral congestion.

## Gastrointestinal causes of weight loss

The following conditions may lead to weight loss:

- coeliac disease
- poor oral hygiene
- chronic vomiting or diarrhoea (e.g. pyloric stenosis)
- gastric ulcer
- cancer of the stomach, oesophagus, large bowel
- problem alcohol drinking
- partial or total gastrectomy
- other GIT surgery
- inflammatory bowel disease (e.g. Crohn disease, ulcerative colitis)
- steatorrhoea
- lymphoma of the gut
- parasitic infestation
- cirrhosis of the liver

The mechanisms of weight loss include anorexia, malabsorption, obstruction with vomiting and inflammation.

## When to refer

- Any unexplained weight loss, especially if an endocrine cause or malignancy is suspected
- Weight loss related to a serious psychological illness
- A serious eating disorder

## Practice tips

- Ask patients what they really believe is the cause of their weight loss.
- An anxiety state and hyperthyroidism can be difficult to differentiate. Consider the latter and perform thyroid function tests.
- Laboratory tests are rarely needed to establish the diagnosis of an eating disorder. Hormonal levels return to normal following weight gain.
- A high index of suspicion by the family doctor is required to diagnose eating disorders. Think of it in a mid-teen female; weight loss through dieting; wide fluctuation in weight; amenorrhoea and hyperactivity.

## Part 4

# Chronic disorders: continuing management

---

*The nostril membrane is so irritable that light dust, contradiction, an absurd remark—anything—sets me sneezing and I can be heard in Taunton with a favourable wind, a distance of six miles. Turn your mind to this little curse. If consumption is too powerful for physicians, at least they should not suffer themselves to be outwitted by such little upstart disorders as the hay fever.*

Sydney Smith, letter to Dr Holl and, 1835

Allergic disorders affect approximately 20% of the population. The most common allergies are those associated with IgE-mediated (immediate, or type 1) hypersensitivity, such as allergic rhinoconjunctivitis (hay fever), atopic dermatitis (eczema) and allergic asthma.<sup>1</sup>

Less commonly encountered but of increasing clinical importance in the community are IgE-mediated allergies to foods such as peanuts and/or other nuts and seafoods (crustaceans or molluscs), which may cause urticaria, angioedema, anaphylaxis and even death. Peanuts are one of the most common causes of food-induced anaphylaxis in adults. A clinically significant cross-reactivity between peanuts and other legumes is uncommon, but allergy to tree nuts such as almonds and walnuts may occur in up to 50% of those with peanut allergy.<sup>2</sup> Another special case is the oral allergy syndrome, in which people with some degree of seasonal allergy to grass pollens or birch pollen suffer oral itch and swelling when they come into contact with certain fruits. This problem may be alleviated by desensitisation to pollens.<sup>2</sup>

Natural rubber latex allergy, associated with the introduction of universal precautions to decrease transmissible infections, is an increasingly important cause of type 1 hypersensitivity, affecting particularly medical and paramedical personnel. Patients who have had multiple operations or procedures are another high-risk group. Diagnosis is suggested by history and confirmed by specific skin tests or the detection of serum specific IgE. The development of urticaria on contact with latex is highly suggestive of underlying type 1 hypersensitivity. An interesting association between latex allergy and sensitivity to fruit is recognised, most commonly banana, kiwifruit or avocado.<sup>2</sup>

## Atopy

Atopy refers to those 40% of people who have an inherited tendency for an exaggerated IgE antibody response to common environmental antigens.<sup>1</sup>

There will be a positive response to one or more allergen skin-prick tests, and usually a family history of allergic disorders. Of those who are atopic, one-half to one-third manifest an allergic disorder, most commonly allergic rhinitis, asthma, atopic dermatitis or allergic gastroenteropathy.

## Common allergens causing immediate hypersensitivity

It is helpful to consider important allergen exposure during history taking. TABLE 80.1 lists sources of common allergens.

**Table 80.1** Sources of common allergens<sup>1</sup>

### Inhalants

Pollens, domestic animals, house dust mites, mould spores, cockroaches

### Foods

Peanuts, fish, shellfish, milk, eggs, wheat

### Other

Drugs, latex, insect venoms, occupational

## Inhalant allergies

Allergic rhinoconjunctivitis and asthma are the main manifestations. The history provides a strong pointer to the causative allergen. If symptoms are seasonal, pollen allergy is most likely; perennial symptoms indicate an allergy to dust mites, household pets or moulds. Certain activities that precipitate symptoms may also provide a clue—these include mowing lawns, dusting and vacuuming.

## FOOD ALLERGY AND INTOLERANCE<sup>3</sup>

Food allergy usually manifests in infancy and childhood, with symptoms ranging from severe urticarial-type reactions to gastrointestinal symptoms

such as anorexia, nausea, vomiting and spitting up of food, colic, diarrhoea and failure to thrive.

Foods that commonly cause allergic reactions include milk and other dairy products, eggs and peanuts. Other foods implicated include oranges, soy beans, nuts, chocolate, fish, shellfish and wheat.

The allergic reactions are not to be confused with non-immunological food intolerance such as lactose intolerance.

A food intolerance is an adverse reaction to a specific food or food ingredient. It is regarded as a food allergy if the reaction is immune based. Food allergies can be simply classified as:

- immediate reactions—occurring within 2 hours
- delayed reactions—occur up to 24 hours after ingestion

### § IgE-mediated food reactions<sup>3</sup>

These are immediate immune-mediated responses to a foreign protein that are relatively easy to diagnose.

#### Clinical features

- Typically in infants and toddlers
- Usually occurs within 30–60 minutes
- Due to release of mast cell mediators
- Produce flushing or blotchiness/pallor (if severe)
- Itchy oropharynx
- Itchy, runny nose and eyes
- Wheeze
- Dizziness and confusion
- Urticaria—facial or generalised (see FIG. 80.1)
- Feeling of intense fear (angor animi)
- Angioedema of face and airway
- Vomiting, diarrhoea and abdominal colic (immediate or soon after)
- ± Anaphylaxis with wheezing, etc.
- Death can occur (especially if asthma history)
- Big three foods—cow's milk, egg, peanuts
- Also: soy beans; fish, especially shellfish; wheat; tree nuts; various fruits and vegetables
- Cow's milk can cross-react with goat's milk and soy protein
- Frequently resolves by 3–5 years

#### Management

- Document diet, symptoms, past history, family history
- Refer for specialist allergy advice
- Provide patient education sheet
- Advise avoidance of suspected food
- IgE reactions investigated with skin testing
- Consider provision of an EpiPen

### § Non-IgE-mediated food reactions<sup>3</sup>

These are less common and are usually delayed, occurring within 24–48 hours of food ingestion—but some reactions may be immediate. The real explanation is not clear. This includes cow's milk protein intolerance with both breast milk- and formula-fed infants. It affects 2% of infants under 2 years with most resolving by 2–3 years.

#### Clinical features

- Gastrointestinal symptoms (e.g. vomiting, diarrhoea, abdominal colic)
- May be malabsorption, weight loss, failure to thrive (rare)
- Aggravation of atopic dermatitis
- Severe reactions possible
- Main foods—cow's milk, soy proteins
- Uncommon after 3 years of age—50% resolve in 1–2 years

FIGURE 80.1 Acute urticaria in a child caused by a sensitivity to aspirin

## Management

- Elimination of suspected food, then formal food challenge
- For milk protein intolerance first-line treatment is a formula containing cow's milk protein hydrolysate. Don't use soy-based formulas under 6 months since many are also soy protein intolerant.
- Skin testing usually not helpful and may be risky

## Food protein induced enterocolitis syndrome (FPIES)

This is seen in young infants usually <6 months and it is usually due to cow's milk, soy or cereals. It can be seen in breastfed infants and older children. A typical reaction is delayed onset of projectile vomiting and protracted diarrhoea. The stool contains blood and eosinophils. Treatment is with substance elimination.

## § Food intolerances<sup>4</sup>

In general practice it is common to see a variety of food intolerances that are not immune (allergic) or psychologically based. The food constituents represent an important group. The intolerances can be grouped as:

- fructose intolerance from excessive ingestion of fruit juices and soft drinks
- lactase deficiency from milk
- histamine-related reactions from strawberries, tomatoes
- chemical triggers:
  - aspirin, tartrazine, sodium metabisulphite—triggering rhinitis and asthma
  - aspirin, tartrazine, benzoic acid—triggering chronic urticaria
- others—salicylates (manufactured or natural), amines, preservatives and colourings

*Note:*

- foods with high-content natural salicylate—dried fruits, pineapple, apricots, oranges, cucumbers, grapes, honey, olives, tomato sauce, wines, tea, herbs
- foods likely to contain tartrazine (food colouring)—bottled sauces, cakes (from shops), coloured fizzy drinks, fruit cordial, custard, coloured sweets, ice-cream and lollies, jam

## Symptoms

There can be a variety of symptoms:

- irritability, behavioural problems

- gastrointestinal (e.g. infant colic, diarrhoea, irritable bowel syndrome)
- respiratory—rhinitis, asthma
- headache/migraine

## Management

- Document diet, reactions, past/family history
- Elimination diet and controlled food challenge
- Referral for specialist allergy advice
- Radioallergosorbent (RAST) testing is indicated where skin testing contraindicated

## § Peanut allergy

Peanuts are one of the most common causes of food-induced anaphylaxis in adults. The diagnosis is confirmed by demonstration of peanut-specific IgE by either skin-prick tests with peanut extract or RAST testing. Reaction to peanuts usually begins within minutes of ingestion, the first symptoms being oropharyngeal itching or burning. Flushing, urticaria, wheeze, stridor, angioedema and collapse may follow.<sup>5</sup> The combination of peanut allergy and asthma is dangerous, as evidenced by fatal or near-fatal reactions in young children.<sup>6</sup> The key to management is avoidance of peanut-containing foods. Desensitisation is currently not recommended. Those at risk should carry an anaphylaxis kit (see TABLE 80.2).

**Table 80.2** Adult anaphylaxis kit<sup>2</sup>

Autoinjector 300 mcg adrenaline 1:1000 IM injection
Inject into outer thigh muscle at first sign of swelling of throat or tongue, or other reaction (e.g. breathlessness)
Medihaler-Epi MDI (adrenaline metered aerosol spray)
Spray 10–20 times in milder reactions only (e.g. local lip tingling or swelling)
Oral antihistamines
e.g. 10 mg loratadine tablets (× 2)
Take 1 tablet after adrenaline injection
Prednisolone 25 mg tablets (× 2)
Take immediately after adrenaline
Doses for children: 15–30 kg—150 mcg; 30 kg—300 mcg

## § Egg allergy

Avoid all eggs including cakes and biscuits until 2 years then introduce cautiously (e.g. in cake). Current vaccinations do not include egg; it is present in only minute amounts in the MMR vaccine.

## § Latex allergy

The clinical manifestations of type 1 hypersensitivity reactions to latex protein are wide-ranging, from urticaria to life-threatening anaphylaxis and death. It is believed that some episodes of intra-operative anaphylaxis are due to the patient—who has been sensitised to latex—reacting after mucosal contact with gloves worn by operating staff. Some institutions now provide latex-free operating suites in response to this serious problem.<sup>7</sup>

Latex allergy is thus a significant problem for at-risk people, including health care workers, patients with spina bifida or other spinal cord abnormalities, and those who have had multiple operations. The greatest risk is contact with ‘dipped’ rubber products (e.g. gloves, condoms, balloons). Some hard rubber products may not pose a risk.

### Symptoms

- Contact dermatitis (type 4 hypersensitivity), urticaria, worsening atopic dermatitis, allergic rhinoconjunctivitis, asthma, allergy to multiple fruits and possibly anaphylaxis

### Diagnosis

Skin-prick tests (dangerous and best left to experts) are more sensitive than blood tests at this stage but carry a risk of anaphylaxis. Measurement of serum specific IgE is safe although less sensitive. Contact allergy (type 4) is identified by patch testing.

### Management

Health care workers who are allergic can never again wear latex gloves.<sup>8</sup>

## Tests for specific IgE

### Skin-prick tests

This is the preferred method as results can be read at the first consultation, provided the high-quality allergen preparations are used. A positive test alone may be of no diagnostic significance if the patient is asymptomatic to the specific allergens. A negative test is very useful for excluding IgE-mediated allergy.

### Detection of serum specific IgE

A number of tests, including RAST tests<sup>1</sup> and ELISA tests, measure allergen-specific IgE in the serum. They are no more accurate than skin testing, are expensive and do not provide an immediate result.

Indications include: history and skin tests not matching, extensive eczema, dermatographism, infants

and very young children, immunotherapy work-up, antihistamine use in past 48 hours.

## Management principles<sup>1</sup>

### Allergen avoidance

If relevant from history and skin-prick testing, special attention should be paid to reducing exposure to house dust mites and mould, to pet selection and specific food avoidance. Change of occupation and environment may be necessary for some people.

### Pharmacotherapy

Drugs are used to alleviate symptoms where avoidance methods have failed or are impractical. Examples include antihistamines (H<sub>1</sub>-receptor and H<sub>2</sub>-receptor antagonists), adrenaline (emergency use), sodium cromoglycate, corticosteroids, some anticholinergics and sympathomimetics.

### Immunotherapy (desensitisation)

This involves repeated administration of small, increasing doses of allergen by subcutaneous injection. This is the treatment of choice for severe wasp or bee venom allergy and for resistant allergic rhinoconjunctivitis where a single causative allergen can be identified. Patients should be observed for at least 45 minutes and adequate resuscitation facilities are essential.

## Management of specific allergic disorders

- Asthma—see CHAPTER 82
- Atopic dermatitis—see CHAPTER 123
- Urticaria—see CHAPTER 122
- Anaphylaxis and angioedema—see CHAPTER 130

## Rhinitis

Refer to CHAPTER 59.

The classification of rhinitis can be summarised as:

- seasonal allergic rhinoconjunctivitis = hay fever
- perennial rhinitis:
  - allergic (usually due to house dust mites)
  - non-allergic = vasomotor: eosinophilic, non-eosinophilic

## ALLERGIC RHINITIS<sup>9,10</sup>

### Definition

**Allergic rhinitis** May be seasonal or perennial. It can be classified as either intermittent (lasting for <4 days of the week or <4 weeks) or persistent (lasting >4 days of the week or >4 weeks).

The severity of symptoms is classified as either mild (normal function including sleep and only slightly troublesome symptoms) or moderate/severe (troublesome symptoms with impairment of activities).<sup>9</sup> Its prevalence has increased worldwide, affecting 20% of the adult population and up to 40% in children: 60% have a family history. It varies from 5–20% with a peak prevalence in children and young adults up to 20%.<sup>11</sup> The symptoms are caused by release of powerful chemical mediators such as histamine, serotonin, prostaglandins and leucotrienes from sensitised mast cells.<sup>11</sup>

## § Seasonal allergic rhinoconjunctivitis (hay fever)

This is the most common type of allergic rhinitis and is due to a specific allergic reaction of the nasal mucosa, principally to pollens. The allergens responsible for perennial allergic rhinitis include inhaled dust, dust mite, animal dander and fungal spores.

Most cases of hay fever begin in childhood with one-half having the problem by the age of 15 and 90% of eventual cases by the age of 30.<sup>12</sup> Approximately 20% suffer from attacks of asthma.

While patients with hay fever tend to have widespread itching (nose, throat and eyes), those with perennial rhinitis rarely have eye or throat symptoms but mainly sneezing and watery rhinorrhoea. Nasal polyps are associated with this disorder (refer to CHAPTER 59).

## Management

Management consists of four main areas:

- 1 appropriate explanation and reassurance
- 2 allergen avoidance
- 3 pharmacological treatment
- 4 immunotherapy

## Advice to patients

- Keep healthy, eat a well-balanced diet, avoid 'junk food' and live sensibly with balanced exercise, rest and recreation. If your eyes give you problems, try not to rub them, avoid contact lenses and wear sunglasses.
- Avoid using decongestant nose drops and sprays: although they soothe at first, a worse effect occurs on the rebound.
- Avoidance therapy: avoid the allergen, if you know what it is (consider pets, feather pillows and eiderdowns).
- Sources of the house dust mite are bedding, upholstered furniture, fluffy toys and carpets.

Seek advice about keeping your bedroom or home dust-free, especially if you have perennial rhinitis.

- Pets, especially cats, should be kept outside.
- Avoid chemical irritants such as aspirin, smoke, cosmetics, paints and sprays.

## Allergen avoidance

This is difficult during the spring pollen season, particularly where patients are living in high-pollen (e.g. country farming) areas, or spending considerable time outdoors in the course of work or sporting and recreational activities.

## Treatment (pharmacological)<sup>9</sup>

Therapy can be chosen from:

- 1 antihistamines:
  - oral (not so effective for vasomotor rhinitis)
  - intranasal spray (rapid action)
  - ophthalmic drops
- 2 decongestants (oral or topical)
- 3 sodium cromoglycate
  - intranasal: powder insufflation or spray
  - ophthalmic drops for associated conjunctivitis
- 4 corticosteroids
  - intranasal (not so effective for non-eosinophilic vasomotor rhinitis)
  - oral (very effective if other methods fail)
  - ophthalmic drops for allergic conjunctivitis

## Immunotherapy

Consider hyposensitisation/immunotherapy when specific allergens are known (very important) and conventional response is inadequate. Immunotherapy to grass pollen is generally very effective and should be considered in moderate to severe springtime hay fever. Immunotherapy by injection or oral administration can be intensive, often taking years.

## Antihistamines

Oral antihistamines are the first line of treatment for seasonal hay fever and are generally effective where symptoms are intermittent, or when they can be used prophylactically before periods of high pollen exposure. The newer generation, so-called 'non-sedating' antihistamines that do not cross the blood-brain barrier are used in preference to the first-generation drugs, although some degree of sedation may occur even with these. A list of non-sedating antihistamines is presented in TABLE 80.3. It is claimed by some that the newer topical preparations,

**Table 80.3** Less sedating antihistamines (oral regimens)

Generic name	Onset	Adult dosage
Cetirizine	Rapid	10 mg daily
Desloratadine	Very rapid	5 mg daily
Fexofenadine	Rapid	60 mg bd
Levocetirizine	Rapid	5 mg daily
Loratadine	Very rapid	10 mg daily

levocabastine and azelastine, as intranasal sprays, are rapidly effective for an exacerbation of symptoms. If sedation is desirable (e.g. overnight), a sedating antihistamine can be used.

### Oral decongestants

Oral sympathomimetics, either used alone or in combination with antihistamines (where they may help reduce drowsiness), may be of value, particularly where nasal discharge and stuffiness are major symptoms. Side effects include nervousness and insomnia. They should be used cautiously in patients with hypertension, heart disease, hyperthyroidism, glaucoma and prostatic hypertrophy.

Examples:

pseudoephedrine HCl 60 mg (o) tds (max. 240 mg/day), or 120 mg controlled release (o) bd

### Intranasal therapy<sup>9,10</sup>

*Intranasal decongestants* should be used for limited periods only (i.e. less than a week) or intermittently (3–4 doses per week) because of the potential problems with rebound congestion and rhinitis medicamentosa. They are often of particular value during the first week of treatment with intranasal corticosteroids (where the onset of action is delayed several days), improving nasal patency and allowing more complete insufflation of the corticosteroids. Adverse reactions similar to those of oral decongestants may occur.

*Intranasal sodium cromoglycate* acts by preventing mast cell degranulation and is effective without serious side effects. The capsule variety must be used (the spray form requires 1–2 hourly dosage to be effective); it is useful in perennial allergic rhinitis but is not as effective as intranasal corticosteroids for springtime hay fever.

*Intranasal corticosteroid sprays* are the most effective agents for treating seasonal allergic rhinitis.

Side effects are minimal and adrenal suppression is not a problem with normal usage. Patients should be informed that these medications will not give immediate relief (often taking 10–14 days to have peak effect) and must be used continuously throughout the hay fever season for at least 6–8 weeks. Local side effects include dryness and mild epistaxis.

*Intranasal antihistamines group*—includes azelastine and levocabastine—are effective at relieving itching and sneezing.

TABLE 80.4 lists intranasal preparations for rhinitis.

### Ophthalmic preparations

Sodium cromoglycate eyedrops are usually very effective for springtime conjunctivitis. They can be used as necessary (there is no dosage limit) and are most helpful when used prophylactically before periods of high pollen exposure. Decongestant eyedrops may also be helpful (care with narrow angle glaucoma), while corticosteroid eyedrops are reserved for resistant allergic conjunctivitis and should be used with care to exclude infection and glaucoma. Antihistamine eyedrops antazoline and levocabastine are yet another option.

### Other treatments

#### Corticosteroids (oral)

These can be very effective where other treatments or methods have failed. A 6–10 day short course can be used. An example of a 6-day ‘rescue course’ is prednisolone 25, 25, 20, 15, 10, 5 mg daily doses.

#### Ipratropium bromide (Atrovent)<sup>12</sup>

The nasal preparation of this topical anti-cholinergic is often very effective when rhinorrhoea is the major problem.

#### Leukotriene receptor antagonist

Regarded as equivalent to oral antihistamines, they have a place in the management of children with concurrent asthma and hay fever (e.g. montelukast).

### Surgery

Inferior turbinate reduction aims to reduce the size of turbinates and so reduce nasal obstruction when congested.

TABLE 80.5 summarises recommended steps in management.

**Table 80.4** Intranasal preparations for rhinitis

	Brand name	Dosage	Comments
<b>Sodium cromoglycate</b>	Rynacrom powder (capsules) Rynacrom nasal spray	Insufflate 1 capsule, qid 2% Spray 4–6 times daily 4% Spray 2–4 times daily	Compliance a problem
<b>Beclomethasone dipropionate 50 mcg/spray</b>	Beconase Hayfever	100 mg spray each nostril bd or tds	
<b>Budesonide 64 mcg/spray</b>	Budamax nasal Rhinocort nasal	1–2 sprays each nostril daily	
<b>Ciclesonide 50 mcg/spray</b>	Alvesco, Omnaris	2 sprays each nostril daily	
<b>Fluticasone furoate 27.5 mcg/spray</b>	Avamys	2 sprays each nostril daily, reducing to 1 spray	
<b>Fluticasone propionate 50 mcg /spray</b>	Beconase Allergy 24 hour aqueous	2 sprays each nostril daily reducing to 1 spray	
<b>Mometasone furoate 50 mcg spray</b>	Nasonex	2 sprays per nostril daily	
<b>Triamcinolone 55 mcg spray</b>	Telnase	2 sprays each nostril daily reducing to 1 spray	
<b>Ipratropium bromide</b>	Atrovent	1–2 sprays per nostril tds prn	Useful for vasomotor rhinitis and profuse rhinorrhoea Care needed with elderly
<b>Azelastine</b>	Azep	1 spray each nostril bd	Antihistamine
<b>Levocabastine 0.05%</b>	Livostin	2 sprays each nostril bd	Antihistamine, max. 8 weeks
<b>Various sympathomimetics (e.g. phenylephrine)</b>		2, 3 or 4 times daily (max. 7 days)	Short-term use only Care with elderly, prostatic hypertrophy

**Table 80.5** Summary of recommended treatment steps for allergic rhinitis<sup>9</sup>

- Patient education  
Allergen avoidance (if possible)
- Mild cases:
- less sedating antihistamines including levocabastine nasal spray ±
  - decongestant (e.g. pseudoephedrine)
- Moderate to severe (persistent):
- intranasal corticosteroids (as preventer—the most effective)
  - sodium cromoglycate (Opticrom) eyedrops
  - oral corticosteroids (if topicals ineffective)
  - immunotherapy if applicable

## When to refer

- Where surgical intervention is required, such as with nasal obstruction from polyps, bulky nasal turbinates and deviated septum
- For immunotherapy

## Practice tips

- Avoid long-term use of topical decongestant nasal drops.
- Avoid topical antihistamine preparations.
- Prescribe sodium cromoglycate eyedrops for the hay fever patient with itchy eyes.
- Be careful of severe systemic reactions that can occur with intradermal skin testing and with immunotherapy. Resuscitation facilities should be available.

## Resource

---

ASCIA <[www.allergy.org.au](http://www.allergy.org.au)>

*Anxiety is a thin stream of fear trickling through the mind. If encouraged, it cuts a channel into which all other thoughts are drained.*

Arthur Somers Roche

Anxiety is a normal human physiological response that helps us respond to potential threats or dangers. We cannot get by without it. With an increase in anxiety, our performance should increase accordingly (e.g. preparing for exams). When we have too much anxiety, however, a further increase in anxiety will lead to our performance dropping off, described by the Yerkes–Dodson curve (see FIG. 81.1). The optimal place to be on the curve is to the left of the peak, so we have a positive response in our performance to an increase in stress. Being at the peak or to the right of the peak will make us vulnerable to stress.

FIGURE 81.1 Yerkes–Dodson curve

Anxiety becomes a problem when the stressor overwhelms us, resulting in poor performance, or if the unwanted consequences of the anxiety response give us undesirable physiological consequences. The stressor causes limbic activation, which in turn leads to autonomic and neuro-endocrine activity (down-regulation) that causes various physiological responses, including activation of the hypothalamic–pituitary axis. Blood flows from the gut to the skeletal muscles, there is activation of smooth muscle contraction in the bowels and an increase in nausea, muscle tension increases, the pupils dilate, the heart rate increases and blood pressure rises. The various somatic symptoms commonly seen in anxiety disorders can be explained by this (e.g. tension

headaches, palpitations, eye strain and irritable bowel-like symptoms). In high stress situations, a flight–fright–freeze response can ensue.

The physiological role of anxiety and the way in which excess anxiety can cause these physical symptoms can be explained to patients suffering from anxiety disorders—and the GP is very well placed to conduct such psycho-education. Patients suffering from somatic symptoms are often unaware of the physiological consequences of anxiety and usually find this clarification comforting. It can help motivate patients to pursue strategies to reduce them.

## Prevalence and classification of anxiety

Anxiety disorders affect 14% of the population,<sup>1</sup> with many people fulfilling the criteria for multiple anxiety disorders, also a common co-diagnosis of depression.<sup>2</sup> Specific phobias are the most common anxiety-related diagnosis (1 in 5 women and 1 in 10 men), and PTSD is the most common disorder (over 6%).<sup>1</sup> Anxiety disorders listed in the DSM-5 are:<sup>3</sup>

- separation anxiety disorder
- selective mutism
- specific phobia
- social anxiety disorder (social phobia)
- panic disorder
- panic attack (specifier)
- agoraphobia
- generalised anxiety disorder
- substance/medication-induced anxiety disorder
- anxiety due to another medical condition
- other specified anxiety disorder
- unspecified anxiety disorder

Other conditions discussed in this chapter include:

- obsessive–compulsive disorder
- body dysmorphic disorder (see CHAPTER 45)
- post-traumatic stress disorder
- acute stress disorder
- adjustment disorder with anxious mood
- somatic symptom disorder

## § Generalised anxiety disorder

Generalised anxiety comprises excessive anxiety and worry about various life circumstances and is not related to a specific activity, time or event such as trauma, obsessions or phobias. There is an overlap between generalised anxiety disorder (GAD) and other anxiety disorders.

General features:

- persistent unrealistic and excessive anxiety
- worry about a number of life circumstances for 6 months or longer

### Diagnostic criteria for generalised anxiety disorder

Three or more of:

- restless, 'keyed up' or 'on edge'
- easily fatigued
- difficulty concentrating or 'mind going blank'
- irritability
- muscle tension
- sleep disturbance

## Clinical features

### Psychological

- Apprehension/fearful anticipation
- Irritability
- Exaggerated startle response
- Sleep disturbance and nightmares
- Impatience
- Panic
- Sensitivity to noise
- Difficulty concentrating or 'mind going blank'

### Physical

- Motor tension:
  - muscle tension/aching
  - tension headache
  - trembling/shaky/twitching
  - restlessness
  - tiredness/fatigue
- Autonomic overactivity:
  - dry mouth
  - palpitations/tachycardia
  - sweating/cold, clammy hands
  - flushes/chills
  - difficulty swallowing or 'lump in throat'
  - diarrhoea/abdominal distress
  - frequency of micturition
  - difficulty breathing/smothering feeling
  - dizziness or lightheadedness

## Symptoms and signs according to systems

- *Neurological*: dizziness, headache, trembling, twitching, shaking, paraesthesia
- *Cardiovascular*: palpitations, tachycardia, flushing, chest discomfort
- *Gastrointestinal*: nausea, indigestion, diarrhoea, abdominal distress
- *Respiratory*: hyperventilation, breathing difficulty, air hunger
- *Cognitive*: fear of dying, difficulty concentrating, 'mind going blank', hypervigilance

## Diagnosis of generalised anxiety disorder

The diagnosis is based on:

- history—it is vital to listen carefully to what the patient is saying
- exclusion of organic disorders simulating anxiety by history, examination and appropriate investigation
- exclusion of other psychiatric disorders, especially depression

Main differential diagnoses (note that this conforms to the seven masquerades list):

- depression
- drug and alcohol dependence/withdrawal
- benzodiazepine dependence/withdrawal
- hyperthyroidism
- angina and cardiac arrhythmias
- iatrogenic drugs
- caffeine intoxication

## Important checkpoints

Five self-posed questions should be considered by the family doctor before treating an anxious patient:

- Is this hyperthyroidism?
- Is this depression?
- Is this normal anxiety?
- Is this mild anxiety or simple phobia?
- Is this moderate or severe anxiety?

## Management

The management applies mainly to generalised anxiety, as specific psychotherapy is required in other types of anxiety. Much of the management can be carried out successfully by the family doctor using brief counselling and support. Cognitive behaviour therapy (CBT), in which maladaptive thinking, feelings, perceptions and related behaviours are identified, assessed, challenged and modified, can be

**Table 81.1** Significant differential diagnoses of anxiety

Psychiatric disorders

Depression

Drug and alcohol dependence/withdrawal

Benzodiazepine dependence/withdrawal

Schizophrenia

Acute or chronic organic brain disorder

Early dementia

Organic disorders

Drug-related:

- amphetamines
- bronchodilators
- caffeine excess
- ephedrine
- levodopa
- thyroxine

Cardiovascular:

- angina
- cardiac arrhythmias
- mitral valve prolapse

Endocrine:

- hyperthyroidism
- phaeochromocytoma
- carcinoid syndrome
- hypoglycaemia
- insulinoma

Neurological:

- epilepsy, especially complex partial seizures
- acute brain syndrome

Respiratory:

- asthma
- acute respiratory distress
- pulmonary embolism

of considerable benefit.<sup>4</sup> Hence psychological therapy and non-drug strategies are first-line therapy for most anxiety disorders.<sup>5</sup>

### Principles of management

- Non-pharmacological approaches (e.g. 'life coaching' and CBT) are first line.

- Give careful explanation and reassurance:
  - explain the reasons for the symptoms
  - be aware that patients often 'worry about worrying' (e.g. that anxiety is dangerous, that they are going crazy or 'losing it')<sup>6</sup>
  - reassure the patient about the absence of organic disease (can only be based on a thorough examination and appropriate investigations)
  - direct the patient to appropriate resources to give insight and support (see box: Further information)
- Provide practical advice on ways of dealing with the problems.
- Advise on the avoidance of aggravating substances such as caffeine, nicotine and other drugs.
- Advise on general measures such as stress management techniques, relaxation programs and regular exercise and if possible organise these for the patient (don't leave it to the patient).
- Advise on coping skills, including personal and interpersonal strategies, to manage difficult circumstances and people (in relation to that patient).
- Provide ongoing supportive psychotherapy.

TABLES 81.2 and 81.3 list a number of good sources of reliable information about anxiety.<sup>7</sup>

### Pharmacological treatment<sup>8,9</sup>

The key principles of using medication for anxiety disorders are:

- SSRIs and other antidepressants have shown to benefit some anxiety disorders (see TABLES 81.4 and 81.6), but their benefits are not as long lasting as psychological and behavioural approaches
- assess efficacy of antidepressants after at least 12 weeks (in contrast to 6–8 weeks when treating major depression) and treat for at least 6 months
- propranolol is of benefit in social anxiety disorder, particularly with anticipated stressful events (e.g. public speaking, presenting at work events)
- benzodiazepines have a limited role in anxiety disorders. If used, they should be reserved for people who have not responded to at least 2 therapies (e.g. psychological therapy and antidepressant) and used only in the short term (stop within 6 weeks). They can also be used for specific phobias (e.g. fear of flying, agoraphobia and MRI machines)

*Note:* not every SSRI has Australian TGA approval for use for each anxiety disorder; the TGA

website can provide up-to-date information on this changing landscape. There is insufficient evidence to differentiate between efficacy of the individual SSRIs.

## § Panic attack<sup>8</sup>

A panic attack is defined<sup>3</sup> as a discrete period of intense fear or discomfort in which four (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes:

- shortness of breath or smothering sensations
- dizziness, unsteady feelings, lightheadedness or faintness
- palpitations or accelerated heart rate
- trembling or shaking
- sweating
- feeling of choking
- nausea or abdominal distress
- depersonalisation or derealisation
- numbness or tingling sensations (paraesthesia)
- flushes (hot flashes) or chills
- chest pain or discomfort
- fear of dying
- fear of going crazy or of doing something uncontrolled

Organic disorders that simulate a panic attack are hyperthyroidism, phaeochromocytoma and hypoglycaemia.

*Note:* A single panic attack is not synonymous with panic disorder. Some 40% of young people have had at least one spontaneous panic attack. Panic disorder is when there are recurrent attacks that are followed by at least a month of worrying about future attacks and/or the consequences of them. Panic disorder can occur with or without associated agoraphobia, though >90% of people with agoraphobia develop it as a result of recurrent panic attacks.<sup>10</sup>

## Management

Reassurance, explanation and support (as for generalised anxiety). This is the mainstay of treatment. A patient who is experiencing a panic attack should be taught breathing techniques to help control hyperventilation (e.g. timing breaths, breathing through nose, slow inspiration, measured medium-sized breaths). Relaxation techniques can also be employed, such as progressive muscle relaxation, and patients can teach themselves these techniques via online resources (see TABLES 81.2 and 81.3). Rebreathing into a paper bag is rarely indicated in a general practice setting<sup>9,10</sup> as the hyperventilation has usually settled by the time the patient presents. The above breathing techniques can be used by the patient anywhere and are more socially acceptable than breathing noisily into a paper bag when an attack is feared.

The danger in a panic attack is the danger *to the self by the self*<sup>8</sup> (e.g. fleeing into danger, non-intentional overdose).

## Cognitive behaviour therapy (CBT)

(See CHAPTER 5.)

CBT aims to reduce anxiety by teaching patients how to identify, evaluate, control and modify their negative, fearful thoughts and behaviour. If simple psychotherapy and stress management fail then patients should be referred for CBT.

Patients' fears, especially if irrational, need to be clearly explained by the therapist, examined rationally and challenged, then replaced by positive calming thoughts.

## Pharmacological treatment

Pharmacological treatment is rarely of benefit in the acute attack, as the attacks occur too quickly for their effect to be of use. Antidepressants can be useful in reducing panic attacks and agoraphobia (see TABLE 81.4) with the response rate being 60–90%.<sup>9</sup>

**Table 81.4** Dosage recommendations for SSRIs in anxiety disorders<sup>10</sup>

Drug	Initial dose	Maximum dose
citalopram	10 mg	40 mg
escitalopram	5 mg	20 mg
fluoxetine	10 mg	80 mg
fluvoxamine	50 mg	300 mg (split dose to bd over 150 mg)
paroxetine	10 mg	60 mg
sertraline	25 mg	200 mg

Continual use of benzodiazepines (BDZs, e.g. alprazolam or clonazepam) has previously been utilised in panic and other anxiety disorders but is now no longer recommended.<sup>10</sup> Problems associated with benzodiazepine use include:

- impaired alertness, oversedation
- dependence
- increased risk of accidents
- adverse effects on mood and behaviour
- interaction with alcohol and other drugs
- potential for abuse and overdose
- risks during pregnancy and lactation
- muscle weakness
- sexual dysfunction
- diminished motivation
- lowered sense of competency
- lower self-esteem

Some principles of using BDZs in anxiety disorders<sup>10</sup> are:

- always check for a history of problem alcohol or drug use
- be wary of prescribing to unfamiliar patients, especially if asking for a particular drug by name (may indicate drug-seeking behaviour)
- carefully discuss the potential for addiction with the patient
- avoid using short-acting drugs as they are the most highly addictive
- prescribe only small quantities of medication at a time
- use only as short-term treatment
- ensure regular review of the patient and continuity of care

If already being used, BDZs should be tapered very slowly (this may take 6–12 months or longer). A benzodiazepine withdrawal syndrome, which can include rebound anxiety, depression, confusion, insomnia and seizures, may occur. Specialist drug and alcohol advice should be sought in such situations.

## § Phobic disorders

In phobic states, the anxiety is related to specific situations or objects. Phobic disorders include agoraphobia, social anxiety disorder (otherwise known as social phobia) and specific phobias. Patients avoid these objects or situations, become anxious when they anticipate having to meet them and/or endure them with intense distress. A list of specific phobias is presented in TABLE 81.5.

Common phobias are spiders, people and social situations, flying, open spaces, confined spaces, heights, cancer, thunderstorms, death and heart disease. The problem is seldom encountered in practice and there is usually no call for drug therapy.

## Agoraphobia

Avoidance includes staying away from many situations where there are issues of distance from home, crowding or confinement. Typical examples are travel on public transport, crowded shops and confined places. Patients fear they may lose control, faint and suffer embarrassment.

**Table 81.5** Phobias

Name of phobia	Fear of or aversion to
Acrophobia	Heights
Aerophobia	Draughts
Agoraphobia	Open spaces
Aichmophobia	Sharp objects
Ailurophobia	Cats
Algophobia	Pain
Androphobia	Men
Anthophobia	Flowers
Anthropophobia	People
Apiphobia	Bees
Aquaphobia	Water
Arachnophobia	Spiders
Astraphobia	Lightning
Aviaphobia	Flying
Bacteriophobia	Bacteria
Bathophobia	Depth
Belonephobia	Needles
Brontophobia	Thunder
Cancerophobia	Cancer
Cardiophobia	Heart disease
Claustrophobia	Closed spaces
Cynophobia	Dogs
Demonophobia	Demons
Dromophobia	Crossing streets
Equinophobia	Horses
Genophobia	Sex
Gynophobia	Women
Haptophobia	Being touched
Herpetophobia	Creeping, crawling things
Homophobia	Homosexuals
Hypsophobia	Falling
Hypnophobia	Going to sleep
Iatrophobia	Doctors
Musophobia	Mice
Mysophobia	Dirt, germs, contamination
Necrophobia	Death
Neophobia	Anything new
Noctiphobia	Night
Numerophobia	Numbers
Nyctophobia	Darkness
Ochlophobia	Crowds
Ophidiophobia	Snakes
Pyrophobia	Fire
Scotophobia	Blindness
Sociophobia	Social situations
Taphophobia	Being buried alive
Theophobia	God
Trypanophobia	Injections
Xenophobia	Strangers
Zoophobia	Animals

## Social anxiety disorder

Social anxiety disorder is experienced in anxiety-provoking social situations in which the person feels subject to critical public scrutiny (e.g. canteens, restaurants, staff meetings, speaking engagements). It can either be generalised (fear of numerous social situations, including both performance and interactional situations) or non-generalised (fear of one or just a few situations of performance type). The treatments for the two subtypes are quite different (see TABLE 81.6). The sufferer may be a shy, self-conscious, premorbid personality. Social phobias, including performance anxiety and symptoms, are often related to sympathetic overactivity.

**Table 81.6** First-line medication options for anxiety disorders<sup>10</sup>

Condition	Medication options
Generalised anxiety disorder	SSRI, duloxetine (30–120 mg), venlafaxine controlled release (75–225 mg)
Panic disorder	SSRI, venlafaxine controlled release (75–225 mg)
Obsessive-compulsive disorder	SSRI
Agoraphobia (without panic)	none
Social anxiety disorder (generalised)	SSRI, venlafaxine controlled release (75–225 mg)
Social anxiety disorder (non-generalised)	propranolol 10–40 mg orally, 30–60 minutes before the social event or performance
Specific phobias	none
Post-traumatic stress disorder	SSRI

## Management

The basis of treatment for all phobias is psychotherapy that involves behaviour therapy (e.g. graduated exposure therapy) and cognitive therapy.

## § Obsessive-compulsive disorder (OCD)

Anxiety is associated with obsessive thoughts and compulsive rituals.

The obsessions are recurrent and persistent intrusive ideas, thoughts, impulses or images that are usually resisted by the patient. Compulsions are repetitive, purposeful and intentional behaviours conducted in response to an obsession to prevent a bad outcome for the person (e.g. excessive washing of the genitals).

Mild obsessional or compulsive behaviour can be regarded as normal in response to stress.

### Management

Optimal management is a combination of psychotherapeutic—particularly CBT—and pharmacological treatment, namely:

- cognitive behaviour therapy for obsessions
- exposure and response prevention for compulsions

### § Body dysmorphic disorder

The person with this disorder has an exaggerated preoccupation with an imagined defect in appearance (see CHAPTER 45).

Patients may be helped by counselling and psychotherapy.

### § Acute stress disorder

This is defined as a constellation of abnormal anxiety-related symptoms lasting at least 3 days and occurring within 4 weeks of a traumatic event. The symptoms can include a sense of numbing, altered sense of reality, amnesia of the event, intrusive memories or dreams of the event, dissociative reactions, physiological reactions to triggers, avoidance of reminders, sleep disturbance, hypervigilance, anger and aggression, exaggerated startle response and agitation. It is appropriate to provide people with an acute stress reaction with debriefing and counselling (if agreeable); pharmacological intervention is rarely indicated.

### § Post-traumatic stress disorder (PTSD)

PTSD is defined somewhat differently, in terms of time lapses from the traumatic event. It refers to a similar constellation of symptoms that persist for 1 month after exposure:

- acute PTSD: duration of symptoms < 3 months
- chronic PTSD: duration of symptoms ≥ 3 months
- delayed onset PTSD: onset of symptoms at least 6 months after the stressor

Typical distressing recurrent symptoms:

- intrusive features—recollections, nightmares, flashbacks
- avoidance of events that symbolise or resemble the trauma
- persistent negative alterations in cognitions and mood
- hyperarousal phenomena: exaggerated startle response, irritability, anger, difficulty with sleeping and concentrating, hypervigilance, reckless or self-destructive behaviour

### Treatment

This is difficult and involves counselling, the basis of which is facilitating abreaction of the experience by individual or group therapy. The aim is to allow the patient to face up openly to his or her memories. Persistent symptoms are an indication for referral.

### Pharmacological treatment

SSRIs have limited evidence of some benefit, but response is slower than for their use in depression (trial for 8–12 weeks) and they should be used for at least 12 months.<sup>10</sup>

### § Hyperventilation

Hyperventilation syndrome can be a manifestation of anxiety. The main symptoms are:

- lightheadedness, faintness or dizziness
- breathlessness
- palpitations
- sweating
- dry mouth with aerophagy
- agitation
- fatigue and malaise

Other symptoms include paraesthesia of the extremities, peri-oral paraesthesia and carpopedal spasm (see FIG. 81.2).

### Carpopedal spasm: biochemical explanation

CO<sub>2</sub> loss from hyperventilation

Equation:  $\text{H}^+ + \text{HCO}_3^- \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$

$\text{pCO}_2 \downarrow \rightarrow \text{HCO}_3^- \downarrow$  and  $\text{pH} \uparrow$  (respiratory alkalosis)

H<sup>+</sup> depleted and replenished from plasma proteins

$\text{H}(\text{protein}) \rightleftharpoons \text{H}^+ + \text{Pr}^-$

Protein anions accumulate and take up calcium

$\text{Ca}^{++} + 2 \text{Pr}^- \rightleftharpoons \text{Ca}(\text{Pr})_2$

Thus ionised calcium is depleted causing hypocalcaemic tetany.

**FIGURE 81.2** Carpopedal spasm (showing carpal spasm) in an anxious and agitated 10-year-old girl

### Management

- Reassure.
- Encourage patients to identify the cause and then control their rate and depth of breathing.

### § Adjustment disorder with anxious mood

This term is reserved for patients who present with anxiety symptoms within 3 months of response to an identifiable psychosocial stressor. It is a common presentation of anxiety symptoms and should be regarded as a separate entity to a generalised anxiety disorder.

The symptoms are in excess of the normal expected reaction to the stressor but have persisted for less than 6 months following the removal of the stressor.

The basic treatment is non-pharmacological: counselling, relaxation and stress management. A

short-term course of drug treatment can be used in severe or persisting cases.

### § Somatic symptom disorder

Somatic symptom disorder (SSD) is defined as the tendency to experience, conceptualise and communicate mental states and distress as physical symptoms or altered bodily function. It is associated with excessive illness, worry and abnormal illness behaviour. SSD is persistent with a history of numerous unsubstantiated physical complaints over several years beginning before the age of 30. Previously called somatisation disorder in the DSM-IV-TR, SSD has 2 subtypes: those with predominantly somatic complaints and those with predominantly pain issues (previously known as pain disorder).

Symptoms include:

- gastrointestinal—nausea, vomiting, abdominal pain
- genital/sexual—dysmenorrhoea, dyspareunia, genital pain
- cardiovascular—palpitations, shortness of breath, chest pain
- pseudoneurological—amnesia, loss of voice, dizziness, difficulty walking/talking/swallowing
- pain—diffuse, neck/back ache, joint/limb pain, headaches
- other—fatigue, globus, fainting

None of these symptoms has an adequate physical explanation. SSD is more common in females. There is persistent refusal to be reassured that there is no explanation for the symptoms. There is associated impaired social, occupational and family functioning.

Management involves skilful counselling, explanation for symptoms, searching for and treating comorbid conditions (e.g. depression, anxiety) and CBT. It is preferable to be managed by a single supportive doctor. It is not malingering.

### Anxiety in children

Anxiety disorders can occur in childhood and, if left untreated, may persist into adolescence and adulthood. Panic attacks are not uncommon. Other disorders include GAD, social phobia, obsessive-compulsive disorder, PTSD, selective mutism and separation anxiety disorder. Non-pharmacological approaches are preferred, and may require input from an educational and developmental psychologist. Separation anxiety disorder for real, threatened or imagined separation is the most common anxiety disorder; if severe and

persistent, treatment (under specialist supervision) with one of the SSRIs could be considered.

## When to refer

- If the diagnosis is doubtful
- If drug and alcohol dependence or withdrawal complicate the management
- If depression or a psychosis appears to be involved
- Failure of response to basic treatment

## Practice tips

- Be careful not to confuse depression with anxiety.
- A depressive disorder can be the cause of anxiety symptoms.
- For anxiety, especially with cardiovascular symptoms (palpitations and/or flushing), always consider the possibility of hyperthyroidism and order thyroid function tests.
- Always try non-pharmacological measures to manage anxiety whenever possible.
- Be careful with the use of benzodiazepines: aim for short-term treatment only.

## Tips to beat stress

- Get enough sleep and rest.
- Listen to music.
- Do things that you enjoy.
- Look at positives.
- Develop strategies to laugh.
- Go to the movies or a show weekly.
- Consider getting a pet.
- Remember that your job is what you do (not who you are).
- Have regular chats with close friends.

- Exercise for 30 minutes, 4 or 5 times a week.
- Learn to meditate.
- Avoid interpersonal conflicts.
- Learn to accept what you cannot change.

*After I'd written to you yesterday I had an attack of asthma and an incessantly running nose, which forced me to tramp about, lighting cigarettes at every tobacconist etc. And worse was to come: I went to bed about midnight, feeling all right after spending a long time inhaling smoke, but 3 or 4 hours later came the real attack of the summer.*

Marcel Proust, letter to his mother, 1901

Asthma is defined by the presence of both of the following:<sup>1</sup>

- excessive variation in lung function ('variable airflow limitation' i.e. variation in expiratory airflow that is greater than that seen in healthy people)
- respiratory symptoms (e.g. wheeze, shortness of breath, cough, chest tightness) that vary over time and may be present or absent at any point in time

In young children in whom lung function testing is not feasible, including most preschool children, asthma is defined by the presence of variable respiratory symptoms.

## Key facts and checkpoints

- Asthma continues to be underdiagnosed and undertreated.<sup>3</sup> It is increasing worldwide.
- It has an unacceptable mortality rate of approximately 5 per 100 000 of the population.
- About one child in four or five has asthma (usually in a mild form).
- It tends to develop between the ages of 2 and 7 years, but can develop at any age.
- Most children present with a cough.
- Most children are free from it by puberty.
- At least one in seven adolescents has asthma.
- About one adult in eight has or has had asthma.
- The focus of management should be on prevention; an acute asthmatic attack represents failed treatment.
- Measurement of function is vital as 'objective measurement is superior to subjective measurement'.
- Spirometry is the key investigation.
- The earlier steroid therapy is introduced, the better the outcome.
- Inhaled corticosteroids are the cornerstone of asthma treatment.
- Avoid concomitant medication that may exacerbate asthma (e.g. beta blockers, aspirin, NSAIDs).

- New aerosols, notably hydrofluoroalkanes, have non-CFC propellants leading to increased lung deposition and thus requiring overall lower dosage.

## Pathophysiology<sup>1</sup>

Chronic asthma is an inflammatory disease with the following pathological characteristics:

- infiltration of the mucosa with inflammatory cells (especially eosinophils) and cellular elements
- airway hyper-responsiveness<sup>2</sup>
- intermittent airway narrowing (due to bronchoconstriction, congestion or oedema of bronchial mucosa or a combination of these) (see FIG. 82.1)

## Causes of asthma

No single cause for asthma has been found, but a variety of factors may trigger an attack. These include specific factors such as viruses, allergens and non-specific factors such as temperature or weather changes and exercise. A checklist of *trigger factors* includes:

- A allergens—pollens, animal dander, dust mites, mould
- B bronchial infection
- C cold air, exercise
- D drugs—aspirin, NSAIDs,  $\beta$ -blockers
- E psychosocial problems, emotion—stress, laughter
- F food—sodium metabisulphate, seafood, nuts, monosodium glutamate
- G gastro-oesophageal reflux
- H hormones—pregnancy, menstruation
- I irritants—smoke, perfumes, smells
- J job—wood dust, flour dust, isocyanates, animals

FIGURE 82.1 Airway changes in asthma: (a) normal airway, (b) airway in asthma

### Additional points

- Patients with asthma must never smoke.
- Atopic patients should avoid exposure to furred or feathered domestic animals if they have problems.
- About 90% of children with atopic symptoms and asthma demonstrate positive skin-prick responses to dust mite extract. Total eradication of house dust mite from the home is difficult.

### Clinical features

The classic symptoms are:

- wheezing
- coughing (especially at night)
- tightness in the chest
- breathlessness

Asthma is likely if more than one of the above is present. Other supporting features:

- symptoms recurrent or seasonal
- worse at night or early morning
- history of allergies
- family history of asthma or allergies
- widespread audible wheeze on chest auscultation
- symptoms rapidly relieved by a short-acting  $\beta$ -agonist bronchodilator (SABA)

*Note:* Asthma should be suspected in children with recurrent nocturnal cough and in people with intermittent dyspnoea or chest tightness, especially after exercise.

Severe symptoms and signs are presented in the section on dangerous asthma later in this chapter.

### Examination<sup>4</sup>

Physical signs may be present if the patient has symptoms at the time of examination.

The absence of physical signs does not exclude a diagnosis of asthma as the chest examination may be normal between attacks. During an attack, auscultation usually reveals diffuse, high-pitched wheezes throughout inspiration and most of expiration, which is usually prolonged. If wheeze is not present during normal tidal breathing it may become apparent during a forced expiration. Wheeze does not necessarily indicate asthma.

Absence of wheeze in a breathless person is a serious sign.

### Investigations

- Spirometry: a value of  $<75\%$  for  $FEV_1/VC$  ratio indicates obstruction. It is the more accurate test and recommended for those who can perform it (i.e. most adults and children  $>6$  years).
- Measurement of peak expiratory flow rate (PEFR) or spirometry before and after SABA: has a characteristic improvement  $>15\%$  in  $FEV_1$  and PEFR.
- Inhalation challenge tests: airway reactivity is tested in a respiratory laboratory to inhaled histamine, methacholine or hypertonic saline. Sometimes useful to confirm diagnosis.
- Mannitol inhalation test.

- An exercise challenge may also be helpful.
- Allergy testing may be appropriate.
- Chest X-ray: not routine but useful if complications suspected or symptoms not explained by asthma.

### Significant advances in the management of asthma

- 1 The realisation that asthma is an inflammatory disease. Therefore the appropriate first- or second-line treatment in moderate to severe asthma is inhaled sodium cromoglycate (especially in children) or inhaled corticosteroids (ICS).
- 2 The regular use of spirometry.
- 3 The use of spacers attached to inhalers/puffers.
- 4 Improved and more efficient inhalers.
- 5 Combined long-acting relievers and preventers including combinations of long-acting  $\beta$ -agonists (LA $\beta$ A) and ICS—the fixed-dose inhalers.

Reasons for suboptimal asthma control are presented in TABLE 82.1.

**Table 82.1** Reasons for suboptimal asthma control<sup>2,4</sup>

Poor compliance
Inefficient use of inhaler devices
Procrastination in introducing optimal therapy
Failure to prescribe preventive medications, particularly inhaled corticosteroids for chronic asthma
Using bronchodilators alone and repeating these drugs without proper evaluation
Reliance on inappropriate alternate therapies
Patient fears: <ul style="list-style-type: none"> <li>• inhaled or oral corticosteroids</li> <li>• concern about aerosols and the ozone layer</li> <li>• overdosage</li> <li>• developing tolerance</li> <li>• embarrassment</li> <li>• peer group condemnation</li> </ul>
Doctor's reluctance to: <ul style="list-style-type: none"> <li>• use corticosteroids</li> <li>• recommend obtaining a mini peak flow meter</li> <li>• recommend obtaining a spacer</li> </ul>

### Treating inflammatory airways disease

If inflammatory airways disease is undertreated there is the risk of fixed irreversible airways obstruction from submucosal fibrosis. One of the most common mistakes in medical practice is to fail to introduce

inhaled corticosteroids for the management of patients with moderately severe asthma.

### Measurement of peak expiratory flow rate

Patients with moderate to severe chronic asthma require regular measurement of PEF, which is more useful than subjective symptoms in assessing asthma control. This allows the establishment of a baseline of the 'patient's best', monitors changes, and allows the assessment of asthma severity and response to treatment.

Spirometry including FEV<sub>1</sub> is the gold standard (see CHAPTER 49). Peak flow meters are not a substitute for spirometry. There is considerable variation between users and instruments. However, they have a place in helping patients self-manage their asthma by serially recording their PEF and comparing this with the best peak flow.

### Spacers<sup>3</sup>

#### Large volume spaces

Some people who have trouble using metered dose inhalers (MDIs) can have a special 'spacer' fitted onto the mouthpiece of the inhaler. One puff of the MDI is put in the spacer. The patient breathes in from its mouthpiece, taking one deep inhalation, then 1–2 very deep breaths, or 4–6 normal breaths (especially in children). This method is useful for adults having trouble with the MDI and for younger children (older than 3 years). Spacers are very efficient, overcome poor technique and cause less irritation of the mouth and throat (see FIG. 82.2).

They allow increased airway deposition of inhalant and less oropharyngeal deposition.

**FIGURE 82.2** Using a spacer device. Rules: children—single puff, then 4–5 breaths; adults—single puff, 1–4 breaths

*Note:* It is recommended to dip plastic spacers into ordinary household detergent and dry in sunlight (no rinsing, no wiping) every 10 days or at least monthly.

## Small volume spacers

Children under 5–6 years and/or 20 kg can use an MDI and a small volume valved spacer (AeroChamber, Breath-A-Tech) with a face mask.

## Management principles

### Starting treatment<sup>1</sup>

- Confirm the diagnosis.
- Assess recent asthma control and risk factors (see TABLE 82.2).
- Choose initial treatment appropriate to the above.
- Document evidence—patient's notes.
- Identify management goals in collaboration.
- Provide clear written patient information.
- Educate and review regularly.

Goals of management:

- absent or minimal daytime symptoms and no nocturnal symptoms; restore normal airway function (>80% of predicted)
- maintain best possible lung function at all times—keep asthma under control
- reduce morbidity
- control asthma with the use of regular anti-inflammatory medication and relieving doses of  $\beta_2$ -agonist when necessary

Long-term goals:

- achieve use of the least drugs, least doses and least side effects
- reduce risk of fatal attacks
- reduce risk of developing irreversible abnormal lung function

### Definition of good asthma control

- Minimal symptoms day and night
- No nocturnal waking due to asthma
- No limitation of normal or physical activity
- Minimal need for reliever medication
- No exacerbation
- Normal lung function ( $FEV_1$  and/or  $PEFR$  >80% predicted or best)
- No side effects of medication
- Near or near-normal lung function (i.e. >80% predicted)

## Pharmacological agents to treat asthma

### Simple classification

- Reliever = bronchodilator
- Preventer = anti-inflammatory
- Symptom controller = long-acting  $\beta_2$ -agonist (LA $\beta$ A)

It is useful to teach patients the concept of the 'preventer' and the 'reliever' for their asthma treatment. The pharmacological treatment of asthma is summarised in TABLE 82.3.

### 'Preventer' drugs or anti-inflammatory agents

These medications are directed towards the underlying abnormalities—bronchial hyperreactivity and associated airway inflammation. Treatment with a 'preventer' is recommended if asthma episodes are >3/week or those who use SA $\beta$ A >3 times a week.

### Corticosteroids

#### Inhaled (ICS)

Types:

- beclomethasone
- budesonide
- ciclesonide (single daily dose)
- fluticasone

Dose range:

- 400–1600 mcg (adults); aim to keep below 500 mcg children and 1000 mcg (adults)

Availability:

- MDI
- Turbuhaler
- Autohaler
- Accuhaler

Frequency:

- once or twice daily (helps compliance)

Side effects:

- oropharyngeal candidiasis, dysphonia (hoarse voice)—less risk with once daily ciclesonide
- bronchial irritation: cough
- adrenal suppression (doses of 2000 mcg/daily; sometimes as low as 800 mcg)

*Note:* Rinse mouth out with water and spit out after using inhaled steroids.

**Table 82.2** Asthma severity classification for an untreated newly diagnosed adult asthma patient<sup>5</sup>

Severity/grade	Status before treatment	Lung function FEV <sub>1</sub> or PEFr (% predicted)	Recommended β-agonist	Estimated starting daily dose range of ICS required to achieve good control
Intermittent	Episodic Symptoms <weekly Night symptoms <2 per month Mild occasional symptoms with exercise	≥ 80%	SAβA prn	Regular ICS not required Add preventer if ≥3 SAβA/week
Mild persistent	Symptoms >weekly, not every day Night symptoms >2 per month Symptoms regularly with exercise	≥ 80%	SAβA prn	<250 mcg beclomethasone <400 mcg budesonide <250 mcg fluticasone <160 mcg ciclesonide Increase dose if >2 SAβA 2–3 times daily
Moderate persistent	Symptoms every day Night symptoms >weekly Several known triggers apart from exercise	60–80 %	LAβA + SAβA prn	250–400 mcg beclomethasone 400–800 mcg budesonide 250–500 mcg fluticasone 160–320 mcg ciclesonide
Severe persistent	Symptoms every day Wakes frequently at night with cough/ wheeze Chest tightness on waking Limitation of physical activity	<60%	LAβA + SAβA prn	>400 mcg beclomethasone >800 mcg budesonide >500 mcg fluticasone >320 mcg ciclesonide

ICSs have a flat dose–response curve so it may not be necessary to prescribe above ICS doses considered high—beclomethasone or budesonide 1000 mcg/day or fluticasone 500 mcg/day. For newly diagnosed patients with mild-to-moderate asthma ‘start low and step up prn’ (e.g. 250–400 mcg/day).<sup>4</sup>

## Oral

Prednisolone is used mainly for exacerbations. It is given with the usual inhaled corticosteroids and bronchodilators.

Dose:

- up to 1 mg/kg/day for 1–2 weeks

Side effects:

- these are minimal if drug is used for short periods

- long-term use: osteoporosis, glucose intolerance, adrenal suppression, thinning of skin and easy bruising

Oral corticosteroids can be ceased abruptly.

## Cromolyns

These are sodium cromoglycate (SCG) and nedocromil sodium. SCG is available as dry capsules for inhalation, metered dose aerosols and a nebuliser solution. The availability of the metered aerosol and spacer has helped the use of SCG in the management of asthma in children. Adverse effects are uncommon; local irritation may be caused by the dry powder. Systemic effects do not occur.

**Table 82.3** Pharmacological treatment of bronchial asthma<sup>5</sup>

			Vehicle of administration				
	Generic types	Examples	Nebulising solution	Oral	Aerosol (metered dose inhalation)	Dry powder (inhalation)	Injection
Bronchodilators							
1 $\beta_2$ -adrenoceptor agonists	Salbutamol	Ventolin	✓	✓	✓	✓	✓
	Salmeterol	Serevent			✓	✓	
	Terbutaline	Bricanyl	✓	✓		✓	✓
	Eformoterol	Foradile, Oxis				✓	
	Adrenaline						✓
2 Anticholinergics	Ipratropium bromide	Atrovent	✓		✓		
3 Methylxanthines	Theophylline	Nuelin		✓			
	Aminophylline						✓
Mast cell stabilisers							
	Sodium cromoglycate	Intal Intal Forte	✓		✓ ✓	✓	
	Nedocromil sodium	Tilade			✓		
Corticosteroids—for inhalation							
	Beclomethasone	QVAR (50, 100)			✓	✓	
	Budesonide	Pulmicort	✓		✓	✓	
	Ciclesonide	Alvesco			✓		
	Fluticasone	Flixotide	✓		✓	✓	
Leucotriene antagonists							
Combination reliever (LA $\beta$ A) + preventer (LACS)—fixed combination MDI							
Salmeterol + fluticasone (Seretide)					✓	✓	
Eformoterol + fluticasone (Flutiform)					✓		
Eformoterol + budesonide (Symibort)					✓	✓	
Vilanterol + fluticasone (Breoellipta)							

Nedocromil is used for frequent episodic asthma in children over 2 years of age for the prevention of exercise-induced asthma and the treatment of mild-to-moderate asthma in some adults. The initial dose is 2 inhalations qid. Adverse effects are uncommon.

### Leucotriene antagonists

These drugs, which include montelukast and zafirlukast, are very useful for seasonal asthma and aspirin-sensitive asthma and reduce the need for inhaled steroids or offer an alternative for those

who cannot tolerate ICSs or have trouble using an inhaler. Favourable evidence is based on a small number of trials only, mostly in children but some adults benefit.<sup>6</sup> Montelukast is taken as a 5 or 10 mg chewable tablet once daily.

## Indications for preventive therapy<sup>7</sup>

Guidelines for introducing preventive asthma therapy in adults and children include any of the following:

- requirement of  $\beta_2$ -agonist >3–4 times each week or >1 canister every 3 months (excluding pre-exercise)
- symptoms (non-exercise) >3–4 times per week between attacks
- spirometry showing reversible airflow obstruction during asymptomatic phases
- asthma significantly interfering with physical activity despite appropriate pre-treatment
- asthma attacks >every 6–8 weeks
- infrequent asthma attacks but severe or life-threatening

## 'Reliever' drugs or bronchodilators

The three groups of bronchodilators are:

- the  $\beta_2$ -adrenoceptor agonists ( $\beta_2$ -agonists)—short acting (SA $\beta$ A) and long acting (LA $\beta$ A)
- methylxanthines—theophylline derivatives
- anticholinergics

### $\beta_2$ -agonists

These drugs 'stimulate' the  $\beta_2$  adrenoreceptors and thus relax bronchial smooth muscle. The inhaled route of delivery is the preferred route and the vehicles of administration include metered dose inhalation, a dry powder, and nebulisation where the solution is converted to a mist of small droplets by a flow of oxygen or air through the solution.

Oral administration of  $\beta_2$ -agonists is rarely required. The inhaled drugs produce measurable bronchodilation in 1–2 minutes and peak effects by 10–20 minutes. The traditional agents such as salbutamol and terbutaline are short-acting preparations. The new longer acting agents (LA $\beta$ A) include salmeterol, eformoterol and vilanterol.

These are to be used in combination, not as monotherapy.<sup>8</sup>

### Theophylline derivatives

These oral drugs may have complementary value to the inhaled agents but tend to be limited by side effects and efficacy.

## Omalizumab

This anti-IgE agent is marketed for SC injection in patients >12 years with moderate to severe allergic asthma treated by ICS and who have raised serum IgE levels.

## Starting treatment

Current treatment supports the initial treatment (summarised in TABLE 82.2) of a SA $\beta$ A with low to moderate doses of ICS with estimated equivalent doses shown in the table.

Initiate therapy sufficient to achieve best lung function promptly.

Wean inhaled corticosteroids to the minimum dose needed to maintain adequate asthma control.

## Prophylactic agents

This term is reserved for those medications that are taken prior to known trigger factors, particularly for exercise-induced asthma.

## Exercise-induced asthma (options)

- $\beta_2$ -agonist inhaler (puffer): two puffs 5 minutes immediately before exercise last 1–2 hours. LA $\beta$ A such as salmeterol and eformoterol are more effective.
- SCG or nedocromil, two puffs.
- Combination  $\beta_2$ -agonist + SCG (5–10 minutes beforehand).
- Montelukast 10 mg (less in children  $\geq 2$  years) (o) daily or 1–2 hours beforehand.
- Paediatricians often recommend a non-drug warm-up program as an alternative to medication.

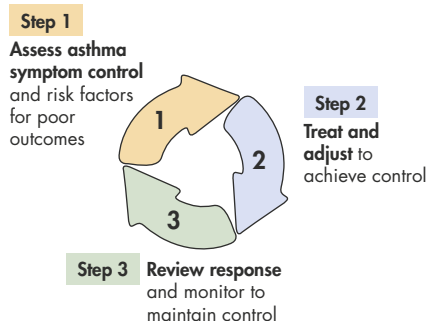

## Ongoing management

### The three-step asthma control plan<sup>9,10</sup>

The National Asthma Council of Australia has developed the following follow-up plan, summarised in FIGURE 82.3.

*Step 1:* Assess asthma symptom control and identify the patient's risk factors.

- Assess asthma symptom control over the previous 4 weeks.
- Assess the patient's risk factors.
- Exclude factors contributing to poor control before intensifying preventer treatment:
  - check adherence
  - check inhaler technique
  - check inhaler device is appropriate
  - consider that symptoms may be due to alternative or comorbid diagnoses

**FIGURE 82.3** Asthma: ongoing management steps  
Source: Reprinted with permission from NPS Medicine Wise

*Step 2: Treat and adjust to achieve good control.*

- All patients should have a reliever inhaler for as-needed use.
- Most patients can achieve well-controlled asthma with low-dose ICS.
- Trial low-dose ICS before ICS/LA $\beta$ A fixed combination therapy<sup>11</sup>
- Reserve ICS/LA $\beta$ A as a later option.
- Where appropriate, step down treatment.
- Schedule follow-up visit.

See **TABLE 82.3**.

*Step 3: Review response and monitor to maintain control.*

- Review diagnosis and treatment regularly.
- Monitor to maintain control.

A general management plan for chronic asthma is summarised in **FIGURE 82.4**.

### Practice tip

- For breakthrough asthma or persistent poorly controlled asthma with poor compliance switch to combined medication (e.g. Seretide MDI Accuhaler, or Symbicort).

## Correct use of the asthma MDI (puffer)

Did you know that:

- faulty inhaler technique occurs in at least one-third of users?
- 90% of the medication sticks to the mouth and does not reach the lungs?
- it is the inhalation effort—not the pressure from the aerosol—that gets the medication to the lungs?
- it is important to instruct patients properly and check their technique regularly?

**FIGURE 82.4** Stepped approach to adjusting asthma medication in adults<sup>10</sup>

Source: Reprinted with permission from NPS Medicine Wise

## The two main techniques

The open-mouth technique and the closed-mouth technique are the main methods, and both are effective but the closed-mouth technique is preferred. Both techniques are suitable for most adults. Most children from the age of 7 can learn to use puffers quite well.

## The closed-mouth technique

See **FIGURE 82.5**.

**FIGURE 82.5** Using the metered dose inhaler: the closed-mouth technique

Instructions for patients:

- 1 Remove the cap. Shake the puffer vigorously for 1–2 seconds. Hold it upright (canister on top) to use it (as shown).
- 2 Place the mouthpiece between your teeth but do not bite it and close your lips around it.
- 3 Breathe out slowly and gently to a comfortable level.
- 4 Tilt your head back slightly with your chin up.
- 5 Just as you then start to breathe in (slowly) through your mouth, press the puffer firmly, once. Breathe in and hold as far as you can over 3–5 seconds. (Do not breathe in through your nose.)
- 6 Remove the puffer from your mouth and hold your breath for about 10 seconds; then breathe out gently.
- 7 Breathe normally for about 1 minute, and then repeat the inhalation if you need to.

### Extra points

- The usual dose of standard MDI is one or two puffs (adult) every 3–4 hours for an attack (four puffs in children).
- If you do not get adequate relief from your normal dose, you should contact your doctor.
- It is quite safe to increase the dose, such as to 4–6 puffs.
- If you are using your inhaler very often, it usually means your other asthma medication is not being used properly. Discuss this with your doctor.

### Autohaler

The Autohaler is a breath-activated MDI which can improve lung deposition in patients with poor inhaler technique.

### The Turbuhaler

The Turbuhaler is a dry powder delivery system that is widely used as an alternative to the MDI. It is a breath-activated device.

Other dry powder devices are the Accuhaler and Diskhaler.

### Spacers versus nebulisers

Both MDIs via a spacer and dry powder inhalers are at least as effective as a nebuliser for treating acute exacerbations in both adults and children.<sup>12</sup>

### Summary of devices

- Breath-activated MDIs: Autohaler

- Breath-activated dry powder inhalers: Accuhaler, Aerolizer, Diskhaler, Rotahaler, Spinhaler, Turbuhaler
- Large-volume spacer: Nebuhaler, Volumatic
- Small-volume spacer: Aerochamber, Breath-A-Tech

## Dangerous asthma

Failure to recognise the development of a severe attack has cost the lives of many asthmatics. The severe attacks can start suddenly (even in mild asthmatics) and catch people by surprise.

### High-risk patients

People who have experienced one or more of the following are more likely to have severe attacks:

- previous severe asthma attack
- previous hospital admission, especially admission to intensive care
- hospital attendance in the past 12 months
- long-term oral steroid treatment
- carelessness with taking medication
- night-time attacks, especially with severe chest tightness
- recent emotional problems
- frequent SABA use

Early warning signs of severe asthma or an asthma attack:

- symptoms persisting or getting worse despite adequate medication
- increased coughing and chest tightness
- poor response to two inhalations
- benefit from inhalations not lasting 2 hours
- increasing medication requirements
- sleep being disturbed by coughing, wheezing or breathlessness
- chest tightness on waking in the morning
- low PEF readings

### Dangerous signs

- Marked breathlessness, especially at rest
- Sleep being greatly disturbed by asthma
- Asthma getting worse quickly rather than slowly, despite medication
- Feeling frightened
- Difficulty in speaking; unable to say more than a few words
- Pulsus paradoxus
- Exhaustion and sleep deprivation

- Drowsiness or confusion
- Chest becoming 'silent' with a quiet wheeze, yet breathing still laboured
- Cyanosis
- Chest retraction
- Respiratory rate greater than 25 (adults) or 50 (children)
- Pulse rate >120 beats/min
- Peak flow <100 L/min or <40% predicted FEV<sub>1</sub>
- Oximetry on presentation (SaO<sub>2</sub>) <90%

## Asthma action plans

Examples of action plans for patients are presented below. Having a written asthma action plan as part of self-management reduces asthma-related mortality and morbidity.<sup>13</sup>

### Action plan

If you are distressed with severe asthma:

- call an ambulance and say 'severe asthma attack' (best option)  
*or*
- call your doctor  
*or*
- if you are having trouble finding medical help, get someone to drive you to the nearest hospital

Follow the '4 × 4 × 4' plan with your reliever medication, but keep using your bronchodilator inhaler continuously if you are distressed.

The following is an example of an asthma action plan that the patient keeps on a card for easy reference.

### Asthma first aid action plan

Name \_\_\_\_\_

Contacts:

Dr \_\_\_\_\_ Tel \_\_\_\_\_

Ambulance tel \_\_\_\_\_

- 1 Sit upright and stay calm.
- 2 Take 4 separate puffs of a reliever puffer (one puff at a time) via a spacer device. Just use the puffer on its own if you don't have a spacer. Take 4 breaths from the spacer after each puff.
- 3 Wait 4 minutes. If there is no improvement, take another 4 puffs. (The 4 × 4 × 4 rule)
- 4 If little or no improvement **CALL AN AMBULANCE IMMEDIATELY** (dial 000 and/or 112 from mobile phone) and state that you are having an asthma

attack. Keep taking 4 puffs every 4 minutes until the ambulance arrives.

**See your doctor immediately after a serious asthma attack.**

## The acute severe asthma attack

Summary (adult dosage):<sup>4,5</sup>

- continuous nebulised salbutamol (or terbutaline) with oxygen flow rate 6–8 L/min if nebuliser available (or 12 puffs of β<sub>2</sub>-agonist inhaler, with spacer, using one loading puff at a time followed by 4–5 normal tidal breaths)

Ipratropium bromide may be mixed with β<sub>2</sub>-agonist for concurrent nebulisation.

- parenteral β<sub>2</sub>-agonist (e.g. salbutamol 500 mcg IM, SC)
- corticosteroids, e.g. prednisolone 50 mg (o) statim then daily until resolved  
*or*
- hydrocortisone 250 mg IV or IM, 6 hourly
- oxygen 8 L/min by face mask to maintain SpO<sub>2</sub> > 92–95% or at least 95% in children
- monitor PEFr

Further deterioration:

- magnesium sulphate 25–100 mg/kg (max 2 gm) IV over 20 min
- adrenaline 0.5 mg 1:1000 SC, IM or 1:10,000 IV

## Guidelines for spacer use in severe asthma<sup>5</sup>

- Frequency—every 20 minutes (first hour)
- One puff actuation at a time
- 4–5 normal breaths each time
- <25 kg or <6 years:
  - 6 puffs—salbutamol
  - 2 puffs—ipratropium
- 25–35 kg:
  - 8 puffs salbutamol
  - 3 puffs ipratropium
- >35 kg:
  - 12 puffs—salbutamol
  - 4 puffs—ipratropium
- For moderate asthma use salbutamol only

The management of severe asthma is presented in **CHAPTERS 96 and 130.**

## Asthma in children

The prevalence of asthma is increasing in childhood and the management (especially in infants) is always a concern for the family doctor. The aim of treatment is to enable children to enjoy a normal life, comparable with that of non-asthmatic children, with the least amount of medication and at minimal risk of adverse events. Maintenance should be determined by symptom control and lung function, especially clinical criteria since PEFr is unreliable. A diagnosis of asthma should not be made if cough is the only or predominant symptom and no signs of airflow limitation.

### Key checkpoints

- Seek specialist advice for children under 6 months of age.
- Bronchodilators, inhaled or oral, are ineffective under 12 months.
- The delivery method is a problem in children and **TABLE 82.4** gives an indication of what systems can be used at various levels.
- In the very young (e.g. 1–2 years old), a spacer with a face mask such as Aerochamber or Breath-A-Tech can deliver the aerosol medication.
- The PEFr should be measured in all asthmatic children older than 6 years. Children under 6 years generally cannot cope with the meters and those with mild asthma don't usually need PEFr measurement.
- The Turbuhaler is usually not practical under 7–8 years.

### Practice tips

- Reassure the patient that 6–10 inhaled doses of a  $\beta_2$ -agonist is safe and appropriate for a severe attack of asthma.

- It is important to achieve a balance between undertreatment and overtreatment.
- Beware of patients, especially children, manipulating their peak flow.
- Get patients to rinse out their mouth with water and spit it out after inhaling corticosteroids.
- Patients who are sensitive to aspirin/salicylates need to be reminded that salicylates are present in common cold cure preparations and agents such as Alka-Seltzer.<sup>3</sup>
- Aspirin-sensitive asthma usually manifests late in life with associated rhinitis. It cross-sensitises with NSAIDs.
- Possible side effects of inhaled drugs can be reduced by always using a spacer with the inhaler, using the medication qid rather than bd, rinsing the mouth, gargling and spitting out after use, and using corticosteroid sparing medications.

## Prophylaxis in children

The non-steroidal medications, montelukast (oral) and SCG and/or nedocromil sodium by inhalation, are the prophylactic drugs of choice in childhood chronic asthma of mild-to-moderate severity.

If there is no clinical response to these agents in 4 weeks, consider use of inhaled corticosteroids, but the risks versus benefits must always be considered. Any dose equal to or greater than 400 mcg in children can have side effects, including growth suppression and adrenal suppression. Aim for a maintenance of 100–400 mcg, which keeps the child symptom-free. Once this stage is reached, consider stopping treatment or changing to the non-steroidal options.

Leucotriene antagonists taken orally for children aged 6 years and above is another option.

Delivery systems for children are presented in **TABLE 82.4**. Guidelines for the management of asthma in children are summarised in **TABLE 82.5**.

**Table 82.4** Delivery systems for asthma in children

Vehicle of administration	Age in years			
	Under 2	2–4	5–7	8 and over
MDI (puffer) alone			*	✓
MDI + small volume spacer** + face mask	✓	✓		
MDI + large volume spacer**		✓	✓	✓
Nebuliser/air compressor/face mask	✓	✓	✓	✓
Dry powder inhalers (e.g. Turbuhaler, Rotahaler)			*	✓
Breath-activated device			*	✓

\* Possible in some individual children

\*\* Small volume spacer—2 tidal breaths; large volume—3

Tobias Venner (1577–1660), *Via rect a ad vit am lo ngam*

Chronic obstructive pulmonary disease (COPD) is described by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) as a ‘common, preventable and treatable disease characterised by non-fully reversible persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases. Exacerbations and comorbidities contribute to the overall severity in individual patients’.<sup>1</sup>

COPD typically affects middle-aged and older people with the usual age of onset in the fifth and sixth decades. It is the fourth leading cause of death and the third leading burden of disease in Australia, affecting 12.4% of Australians between 45 and 70 years.

Cigarette smoking is undoubtedly the major cause of both chronic bronchitis and emphysema, although only 10–15% of smokers develop the diseases.<sup>2</sup>

Lifelong passive smoking exposure increases COPD risk by 2.2 to 4.0 times.

FIGURE 83.1 illustrates the influence of smoking on lung function.

## Factors in causation

- Cigarette smoking (usually 20/day for 20 years or more)<sup>4</sup>
- Natural fuel—wood, twigs, crop residue
- Air pollution (outdoor and indoor)
- Airway infection
- Occupation: related to cadmium, silica, dusts
- Familial factors: genetic predisposition
- Alpha<sub>1</sub>-antitrypsin deficiency (emphysema)
- Bronchial hyper-responsiveness

## Diagnosis and management of COPD

The COPDX Plan guidelines<sup>5</sup> developed by the Australian Lung Foundation and the Thoracic Society of Australia and New Zealand provide an appropriate framework for diagnosis and management. The key recommendations are: Confirm diagnosis, Optimise function, Prevent deterioration, Develop a self-management plan and manage eXacerbations.

FIGURE 83.1 Decline of FEV<sub>1</sub> with age

Source: Adapted from Fletcher and Peto<sup>3</sup>

## C—Confirm diagnosis and assess severity

### Symptoms

- Breathlessness
  - Cough
  - Sputum production
  - Chest tightness
  - Wheezing
  - Airway irritability
  - Fatigue
  - Anorexia
  - Weight loss
- } main symptoms
- } with advanced disease

Consider the diagnosis of COPD in all smokers and ex-smokers older than 35 years. The diagnosis of COPD rests on the demonstration of airflow obstruction.

The sensitivity of the physical examination for detecting mild to moderate COPD is poor.

### Signs

The signs vary according to the nature of the disease and the presence of infection. Signs may be completely absent in the early stages of COPD and there may be wheezing only with chronic bronchitis and dyspnoea with chronic airflow limitation.

Signs may include:

- tachypnoea
- reduced chest expansion
- hyperinflated lungs
- hyper-resonant percussion
- diminished breath sounds  $\pm$  wheeze
- 'pink puffer'—always breathless
- 'blue bloater'—oedematous and central cyanosis
- signs of respiratory failure
- signs of cor pulmonale

The diagnosis is usually clinical with a history of increasing dyspnoea and sputum production in a lifetime smoker with no features of asthma. It is unwise to make a diagnosis of chronic bronchitis and emphysema in the absence of cigarette smoking unless there is a family history suggestive of  $\alpha_1$ -antitrypsin deficiency.<sup>6</sup>

At diagnosis, up to 50% of lung function may have been lost.

### Investigations

#### Pulmonary function tests

Spirometry remains the gold standard for diagnosing, assessing and monitoring COPD. The PEFr is not a sensitive measure.

### Definition

**COPD** Post-bronchodilator  $FEV_1/FVC$  of  $<0.70$  ( $<70\%$ ) and  $FEV_1 <80\%$  predicted.

The Australian stages of severity based on  $FEV_1\%$  predicted are mild (60–80%) moderate (40–50%) and severe ( $<40\%$ ), while the GOLD staging is 1. mild ( $\geq 80\%$ ), 2. moderate (50–80%), 3. severe (30–50%), 4. very severe ( $<30\%$ ).

### Chest X-ray

This can be normal (even with advanced disease) but characteristic changes occur late in disease. May exclude lung cancer  $>1$  cm.

### Blood gases

- May be normal
- $PaCO_2 \uparrow$ ;  $PaO_2 \downarrow$  (advanced disease)

### ECG

- This may show evidence of cor pulmonale

### Sputum culture

- If resistant organism suspected

### FBE

- To identify anaemia and polycythaemia
- Haemoglobin and PCV may be raised.

## O—Optimise function

The principal goals of therapy are to stop smoking, to optimise function through relief of symptoms with medication and pulmonary rehabilitation, and to prevent or treat aggravating factors and complications.

TABLE 83.1 is a useful consultation checklist mnemonic.<sup>7</sup>

**Table 83.1** SMOKES, a consultation checklist for chronic obstructive pulmonary disease<sup>7</sup>

- S** = Smoking cessation
- M** = Medication—inhaled bronchodilator, vaccines (influenza, pneumococcus), corticosteroids (if indicated)
- O** = Oxygen—is it needed?
- K** = Komorbidity—cardiac dysfunction, sleep apnoea, osteoporosis, depression, asthma, GORD
- E** = Exercise and rehabilitation
- S** = Surgery—bullectomy, lung volume reduction surgery, single-lung transplantation

## Long-term treatment

### Advice to patient

- If you smoke, you must stop (persuading the patient to stop smoking is the key to management). The only treatment proven to slow the progression of COPD is smoking cessation.<sup>3</sup> Nicotine replacement therapy should be considered.
- Avoid places with polluted air and other irritants, such as smoke, paint fumes and fine dust.
- Go for walks in clean, fresh air.
- A warm, dry climate is preferable to a cold, damp place (if prone to infections).
- Get adequate rest.
- Avoid contact with people who have colds or flu.
- Optimal diet—reduce weight if necessary.

### Physiotherapy

Refer to a physiotherapist for chest physiotherapy, breathing exercises and an aerobic physical exercise program.

### Drug therapy<sup>6</sup>

In the long-term treatment of COPD, bronchodilators are recommended for the relief of wheezing and shortness of breath. These include short-acting  $\beta_2$ -agonists (SA $\beta$ As e.g. salbutamol, terbutaline) and short-acting anticholinergic drugs (ipratropium bromide); long-acting  $\beta_2$ -agonists (LA $\beta$ As e.g. eformoterol, salmeterol); long-acting anticholinergic drugs with muscarinic antagonist action (LAMAs e.g. tiotropium, glycopyrronium); and corticosteroids.

The preferred route of administration of bronchodilator is by inhalation but it requires correct device technique.

Inhaled drugs can be administered by MDIs, dry-powder devices or nebulisers. The evidence suggests that an MDI and spacer are as effective as a nebuliser, but the appropriate method depends on patient needs and preference.

The usefulness of a bronchodilator for an individual can only be assessed by a therapeutic trial, accepting either objective improvement in lung function or improvement in symptom control as endpoints.

### Short-acting bronchodilator therapy

Most studies suggest that short-acting  $\beta_2$ -agonists and ipratropium bromide are equally efficacious in patients with COPD. If patients do not respond adequately to one of these bronchodilators then it

is appropriate to consider a trial of a combination of the two classes of bronchodilator with objective monitoring of response.

Use the following by inhalation:<sup>6</sup>

salbutamol 100–200 mcg, up to 4 times daily

*or*

terbutaline 500 mcg, up to 4 times daily

*or*

ipratropium bromide 40–80 mcg, up to 4 times daily

For patients who are unable to use an MDI or a spacer, a nebuliser should be used, with the following doses:

salbutamol or terbutaline 2.5 to 5 mg

*and/or*

ipratropium bromide 250 to 500 mcg by nebuliser, up to 4 times a day

### Long-acting bronchodilator therapy

Long-acting  $\beta_2$ -agonists can be used in patients who remain symptomatic despite treatment with combinations of short-acting bronchodilators and those with frequent exacerbations. Used regularly they are more effective and convenient than use of short-acting bronchodilators (evidence level I).<sup>8</sup> Long-acting anticholinergic therapy<sup>2</sup> with tiotropium bromide (taken by inhalation) has been proven to reduce the frequency of exacerbations with COPD compared with short-acting anticholinergic drugs. The choice of drug can be determined by the patient's response to a trial of the drug, the drug's adverse effects and cost including PBS listing.

For treatment with long-acting bronchodilator use the following by inhalation:<sup>6</sup>

tiotropium bromide 18 mcg once daily

*or*

eformoterol 12 mcg twice daily

*or*

salmeterol 50 mcg twice daily

*or*

indacaterol (an ultra LA $\beta$ A) 150 mcg daily

### Corticosteroids<sup>6</sup>

Only 10% of patients with stable COPD benefit in the short term from inhaled corticosteroids (ICS). There are no distinguishing clinical features to predict in advance which patients may respond. The aim of treatment is to reduce exacerbation rates and slow the decline of the disease. Note that there may be possible coexisting asthma with COPD. Benefits are not seen in patients who continue to smoke.

Usual practice is ICS/LA $\beta$ A combination inhalers (fluticasone/salmeterol or budesonide/eformoterol), which are available on the PBS for use in symptomatic patients with moderate to severe COPD ( $FEV_1 < 50\%$  predicted).<sup>9</sup>

In this group, tiotropium combined with an ICS/LA $\beta$ A combination inhaler (triple therapy) is more beneficial than the individual treatments alone.<sup>9</sup>

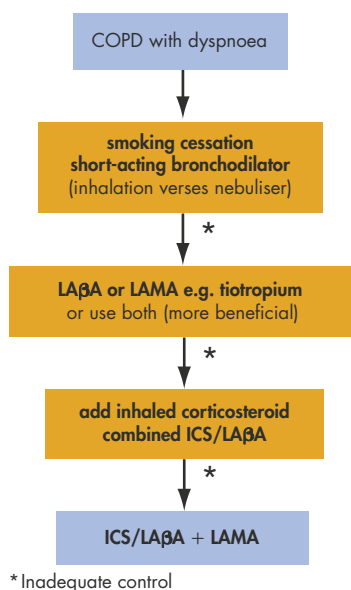

The future appears to be a 3-in-one (LA $\beta$ A, LAMA and ICS) once-a-day puffer.

## Inhaled corticosteroids

Guidelines for prescription include:

- documented evidence of responsiveness to inhaled corticosteroids, including functional status
- those with an  $FEV_1 \leq 50\%$  predicted
- two or more exacerbations requiring oral steroids in 12 months

Oral corticosteroids are not recommended for maintenance therapy in COPD, although they may be needed in patients with severe COPD where corticosteroids cannot be withdrawn following an acute exacerbation. A stepwise approach to management is outlined in **FIGURE 83.2**.

**FIGURE 83.2** Stepwise approach to management of COPD

## P—Prevent deterioration<sup>5</sup>

Reducing risk factors for COPD is a priority, and smoking is the most important and prime target if this continues to be a problem. Stopping is the only measure that slows the progression of COPD. Reinforce patient education programs.

## Annual influenza vaccination

Influenza vaccination reduces the risk of exacerbations, hospitalisation and death. It should be given in early autumn to all patients, especially those with moderate to severe COPD.

## Pneumococcal vaccination

Vaccination to prevent invasive bacteraemic pneumococcal pneumonia is recommended. It should be given at 5-yearly intervals.

## Long-term oxygen therapy

Long-term oxygen therapy (LTOT) reduces mortality in COPD. Long-term continuous therapy given for at least 15 hours a day (as close as possible to 24 hours a day) prolongs life in hypoxaemic patients—those who have  $PaO_2$  consistently  $< 55$  mm Hg (7.3 KPa;  $SpO_2$  88%) when breathing air. At assessment for ongoing therapy, the patient's condition must be stable and the patient must have stopped smoking at least 1 month previously. Flow should be set at the lowest rate needed to maintain a resting  $PaO_2$  of 60 mm Hg. A flow rate of 0.5–2.0 L/min is usually sufficient. There is no clear-cut evidence about the effectiveness of intermittent ambulatory domiciliary oxygen therapy, but patients with hypoxaemia during sleep may require nocturnal oxygen therapy.

## Check current smoking status

Smoking cessation clearly reduces the rate of decline of lung function. GPs and pharmacists can help smokers quit. Brief counselling is effective and every smoker should be offered at least this intervention at every visit.

Refer to strategies in **CHAPTER 21**, including effectiveness of treatment for nicotine dependence.

## Antibiotics

Current evidence does not support long-term antibiotic use to prevent exacerbations, but they should be used in exacerbations with an increase in cough, dyspnoea, sputum volume or purulence.

## Corticosteroids

No medication has yet been shown to prevent the long-term decline in lung function. Inhaled corticosteroids are indicated for patients with a documented response or those who have moderate to severe COPD with frequent exacerbations.

*Note:* fixed-dose combinations of LA $\beta$ A and inhaled corticosteroids (see **CHAPTER 82**) are used for patient convenience.<sup>6</sup>

### Mucolytic agents

Mucolytic agents may reduce the frequency and duration of exacerbations (evidence level I). Mucolytic therapy should be considered for patients with a chronic cough productive of sputum. Oral mucolytics include potassium iodide, bromhexine, N-acetylcysteine, ambroxol and glyceryl guaiacolate. Compounds containing codeine should be avoided.

### Antitussive agents

Regular use of antitussives in stable COPD is contraindicated.

### Regular review

Regular review with objective measures of function and medication review is recommended in anticipation of reducing complications, frequency and severity of exacerbations and admissions to hospital. Regular schedules for follow-up visits are appropriate.

### Lung surgery<sup>10</sup>

The options are bullectomy, lung volume reduction surgery and transplantation. Patients should be referred for consideration for bullectomy if they have a single large bulla on CT scan associated with breathlessness and an FEV<sub>1</sub> <50% predicted. Other lung surgery should be considered in patients with severe COPD who remain breathless with marked restriction of their activities of daily living, despite maximal therapy. Emphysema mainly involving the upper lobes with PaCO<sub>2</sub> <55 mm Hg and FEV >20% predicted are some factors required for lung volume reduction surgery.

## D—Develop support network and self-management plan<sup>5</sup>

COPD imposes a considerable handicap with heavy psychosocial issues, including fears about the outcome of the disease, on patients and carers.

### Respiratory physician referral

Early referral to a respiratory physician is appropriate in order to clarify the diagnosis, consider other therapies, consider long-term home oxygen and facilitate organisation of pulmonary rehabilitation.

### Pulmonary rehabilitation

One highly effective strategy is pulmonary rehabilitation, which aims to increase patient and carer knowledge and understanding, reduce carer strain and develop positive attitudes toward self-management and exercise. Integrated programs

include education, exercise, behaviour modification and support, which are more effective than separate components.

### The support team and multidisciplinary care plans

As the patient's primary health care provider, the GP is uniquely placed to identify smokers and help them quit, facilitate early diagnosis and coordinate the support team. The support team can enhance the quality of life and reduce morbidity for the COPD patient. The support team can include a nurse/respiratory educator, physiotherapist, occupational therapist, social worker, clinical psychologist, speech pathologist, pharmacist and dietician.

Government and community support services such as Home Care, home maintenance, exercise programs, Meals on Wheels and support groups can be galvanised to provide support.

### Self-management plans

Patients should be encouraged to take appropriate responsibility for their own management. The primary care team, supported by Extended Primary Care item numbers, should develop systems to identify those with more severe COPD who might benefit from more focused education and training in self-management skills.

### Psychological issues

The issues facing the COPD patient include fear, stress, sleep disturbance, anxiety, panic and depression. Proactive management, including optimal care of these problems as they arise, will facilitate coping. Management also focuses on symptom control and maximising the quality of life. These patients have to face palliative care at the end stage and ethical issues have to be handled sensitively.

### Referral to in-patient care

The management plan should include the identification of clinical markers indicating more intensive hospital treatment.

Indications for hospitalisation include:<sup>5</sup>

- rapid rate of onset of acute exacerbation with increased dyspnoea, cough or sputum
- inability to cope at home
- inability to walk between rooms when previously mobile
- severe breathlessness → inability to eat or sleep
- inadequate response to ambulatory treatment
- altered mental status suggestive of hypercapnia

- significant comorbidity (e.g. cardiac disease)
- new arrhythmia
- cyanosis

## X—manage eXacerbations<sup>5</sup>

Diagnosis is symptomatically the acute onset over minutes to hours of:

- increasing dyspnoea including use of accessory muscles at rest
- increased sputum
- more purulent sputum

Fever may be present, but fever and chest pain are uncommon symptoms. One-third have no identifiable cause, but infections and heavy pollutants can cause the exacerbation. Consider investigating with pulse oximetry, chest X-ray and sputum culture.

Patients should be treated with a bronchodilator, preferably with a large volume spacer. If nebulisers are used they should be driven by compressed air (to avoid the problem of potentially adverse oxygenation). Systemic glucocorticoids reduce the severity and shorten recovery.

Ventilatory support may be used if hypercapnia develops or worsens despite optimal drug therapy. Non-invasive ventilatory support may avoid the need for intubation.

## Treatment in summary<sup>6</sup>

### Bronchodilators

Initial therapy by SA $\beta$ A inhalation:

salbutamol 100 mcg MDI, up to 8 to 10 inhalations, repeat as required  
 or  
 terbutaline 500 mcg DPI, 1 to 2 inhalations, repeat as required  
 or  
 ipratropium bromide 20 mcg MDI, up to 4–6 inhalations, repeat as required

If control is inadequate, combine salbutamol or terbutaline with ipratropium bromide.

If a nebuliser is used (which is usually the case upon hospitalisation), use salbutamol 2.5–5 mg, terbutaline 2.5–5 mg or ipratropium bromide 250–500 mcg, as required.

### Oxygen therapy<sup>6</sup>

Controlled oxygen delivery—28% via Venturi mask or 2 L/min via nasal prongs should be commenced if the patient is hypoxaemic (oxygen saturation <92% with pulse oximetry). Maintain the arterial

oxyhaemoglobin saturation at 90%. It is important to obtain a direct measurement of arterial blood gases to confirm the degree of hypoxaemia and if hypercapnia or acidosis is present.

Note that patients with severe COPD are prone to hypercapnia if they breathe high oxygen concentrations. Supplemental oxygen should be kept to a minimum. If hypercapnia develops assisted ventilation may be required.

### Corticosteroids

Corticosteroids should be used routinely for severe exacerbations. Use:

prednisolone or prednisone 30 to 50 mg (o), daily

If oral medication cannot be tolerated, use:

hydrocortisone 100 mg IV 6 hourly (or equivalent dose of alternate corticosteroid)

Conversion to oral corticosteroid should occur as soon as practicable.

The duration of oral corticosteroid therapy for exacerbations of COPD is not well established; however, courses of 7 to 14 days are commonly used.

A tapering dose schedule is not required for short courses.

### Antibiotics<sup>6</sup>

The use of antibiotics for exacerbations is not routinely indicated as many episodes are due to viral infections. There are some patients who obviously have repeated exacerbations due to bacterial infection (usually *Haemophilus influenza*, *S. pneumoniae* or *Moraxella catarrhalis*) where antibiotics have been proven to be beneficial, reducing the risk of mortality by 77%.<sup>11</sup>

The indication for antibiotic treatment is:

- increased cough and dyspnoea *together with*
- increased sputum volume and/or purulence

When indicated, use:

amoxycillin 500 mg (o), 8 hourly for 5 days

or

doxycycline 200 mg (o) as 1 dose on day 1, then 100 mg (o) daily for a further 5 days

or

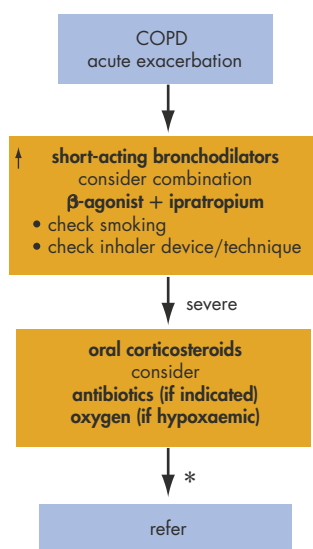

azithromycin 500 mg (o) daily for 5 days

A stepwise approach is summarised in **FIGURE 83.3**.

### Evidence update<sup>12,13</sup>

Evidence indicates that regular treatment with long-acting  $\beta_2$ -agonists is more effective than treatment with short-acting agents (evidence level I) and is

**FIGURE 83.3** Management plan for acute exacerbation of COPD

associated with improved quality of life (evidence level II), although they are more costly and do not significantly improve lung function. Current recommended guidelines based on the severity of disease are summarised in **TABLE 83.2**.

**Table 83.2** COPD therapy according to severity of disease<sup>9,12</sup>

Stage of COPD	Treatment
0 At risk	Avoidance of risk factors, esp. smoking  Influenza and pneumococcal vaccination ? <i>Haemophilus influenza</i> vaccination
1 Mild	<b>Add</b> short-acting bronchodilator
2 Moderate	<b>Add</b> long-acting bronchodilators LAMA + LA $\beta$ A  Consider LA $\beta$ A/ICS and referral <b>Add</b> pulmonary rehabilitation
3 Severe	<b>Add</b> inhaled corticosteroids LA $\beta$ A/ICS + LAMA
4 Very severe	<b>Add</b> long-term oxygen (if chronic respiratory failure)  Consider theophylline (o) or roflumilast  Consider surgical referral

## Practice tips

- COPD patients should be referred early for rehabilitation. Contact your respiratory physician or hospital for help.
- Pulmonary rehabilitation programs benefit most patients with pulmonary disease.
- Rehabilitation teams are interdisciplinary, usually comprising a rehabilitation physician, physiotherapist, occupational therapist, social worker and dietitian.
- Patients with COPD commonly present in the fifth decade with productive cough or an acute chest illness.<sup>4</sup>
- Diagnosis can only be established by objective measurement using spirometry with FEV<sub>1</sub> being the preferred parameter.
- Non-invasive positive pressure ventilation (NPPV) reduces mortality and hospital stay in patients with acute failure; it is also an effective weaning strategy for patients who require intubation.<sup>11</sup>
- The only treatment proven to slow the progression of COPD is smoking cessation.
- It is very difficult at times to distinguish COPD from the persistent airflow limitation of chronic asthma in older patients (see **TABLE 49.3**).
- COPD is reportedly 'massively' underdiagnosed—screening with good quality spirometry is important.

*The fit makes the patient fall down senseless; and without his will or consciousness presently every muscle is put in action; as if all the powers of the body were exerted to free itself from some great violence. In these strong and universal convulsions, the urine, excrements and seed, are sometimes forced away, and the mouth is covered with foam, which will be bloody, when the tongue is bit, as it often is in the agony.*

William Heberden (1710–1801)

Epilepsy is defined as a ‘tendency to recurrence of seizures’. It is a symptom, not a disease. A person should not be labelled ‘epileptic’ until at least two attacks have occurred.<sup>1</sup> Epilepsy is common and affects about one person in 50. Both sexes are about equally involved, and some forms run in some families. Famous people who have had epilepsy include Julius Caesar, Thomas Edison and George Frideric Handel.

The most important factors in the management of epilepsy are the accurate diagnosis of the type of seizures; identification of the cause and appropriate investigation; the use of first-line drugs as the sole therapy of some weeks; and adjustment of the dose, according to clinical experience and plasma levels, to give maximum benefit.

To be accurate in diagnosing seizures the diagnosis must be based on:<sup>2</sup>

- the patient’s memory of the seizure
- the patient’s history (e.g. family history, toxin exposure, accidents, febrile convulsions, eclampsia)
- the observation of a witness to the seizures
- a general and neurological examination
- an EEG, although this has considerable limitations
- a CT scan or preferably MRI (especially if the EEG is focal and a tumour is suspected)

Long-term ambulatory EEG recording now provides more information and, coupled with video monitoring, it will make a permanent record of the seizure which can be reviewed at will. The CT scan or MRI scan is necessary to exclude a focal cause (such as a cyst, tumour, malformation or abscess) which might be treatable by surgery. The MRI scan now shows developmental migration disorders.

The scans will identify mesotemporal sclerosis (an abnormality in the hippocampus due to birth hypoxia), thereby making some ‘idiopathic’ seizures into secondary seizures from a known cause.

Epilepsy usually starts in early childhood.

Optimal management includes adequate psychosocial support with education, counselling, advocacy and appropriate referral. Advice about appropriate lifestyle using the NEAT approach (see CHAPTER 7) is important.

An underlying organic lesion becomes more common in epilepsy presented for the first time in patients over the age of 25 years and thus more detailed investigation is required.<sup>1</sup>

Secondary causes of seizures include:

- trauma—head injuries
- postcerebral surgery
- metabolic (e.g. calcium and sodium electrolyte disturbances, hypoglycaemia, uraemia, hepatic failure)
- drugs and other toxins (e.g. alcohol, amphetamines including withdrawal)
- infections (e.g. meningitis)
- vascular—cerebrovascular, arteritis
- hypoxia
- degenerative diseases
- sleep deprivation
- prescribed drugs, including antidepressants (e.g. SSRIs, TIAs, venlafaxine, mirtazapine), antibiotics (e.g. norfloxacin, ganciclovir, isoniazid), amantadine, antipsychotics, chloroquine, interferons, pizotifen, promethazine, theophylline

## Types of epileptic seizures/syndromes

Epileptic seizures are classified in general terms as generalised and partial (see TABLE 84.1). Some others are unclassifiable. Partial seizures are about twice as common as generalised seizures and are usually due to acquired pathology.<sup>2</sup> Epilepsy syndromes including those first encountered in children are presented in CHAPTER 54.

## Generalised seizures

Generalised seizures arise in both cerebral hemispheres simultaneously from the outset. The seizure may be primary with generalised onset (no focus), or secondary, which starts focally and spreads to become secondary and may be due to acquired cerebral pathology.

**Table 84.1** Classification of epileptic seizures<sup>2</sup>

### 1 Generalised seizures

Convulsive:

- tonic-clonic (previously called grand mal)
- clonic

Non-convulsive:

- tonic (drop attacks)
- atonic (drop attacks)
- typical absence-childhood (petit mal) and juvenile
- atypical absence
- myoclonic

### 2 Partial seizures

Simple partial (consciousness retained):

- with motor signs (Jacksonian)
- with somatosensory symptoms
- with psychic symptoms

Complex partial (consciousness impaired)

Secondary generalised

The main features are:

- abrupt impairment or loss of consciousness
- possible bilateral symmetrical motor events

### Types

- Tonic-clonic (formerly called grand mal) seizure: this is the classic convulsive seizure with muscle jerking (see CHAPTER 54)
- Tonic seizure: stiffness only, often with a 'drop' (hallmark of Lennox-Gastaut syndrome)
- Clonic seizure: jerks only
- Atonic seizure: loss of tone, and 'drops'
- Absence seizure (formerly called petit mal): involves loss of consciousness with no or only very minor bilateral muscle jerking, mainly of the face<sup>2</sup>
- Myoclonic seizure: bilateral discrete muscle jerks, which may be very severe, and loss of consciousness

## Partial seizures

In partial seizures the epileptic discharge begins in a localised focus of the brain and then spreads out from

this focus. The clinical pattern depends on the part of the brain affected:

- simple partial seizures: consciousness is retained (see CHAPTER 54)
- complex partial seizures: consciousness is clouded so that the patient does not recall the complete seizure (see CHAPTER 54)

Both these types of partial seizure can evolve into a bilateral tonic-clonic seizure; this is termed a secondary generalised seizure and is usually due to diffuse brain pathology.<sup>1</sup>

## Investigations

Standard minimum investigations are:

- serum calcium, magnesium and electrolytes
- fasting glucose
- EEG (usually with sleep deprivation)
- syphilis serology

Other tests may include:

- chest X-ray
- ECG (? ↑ QT interval)
- video EEG (limited mainly to frequent seizures or to diagnostic dilemmas)
- MRI
- CT scanning (if MRI unavailable)
- Other cerebral imaging (e.g. SPECT and PET)

A patient presenting with the first seizure after the age of 25 years will require more detailed investigation.

## The single unprovoked seizure: to treat or not

Starting drugs after a single afebrile seizure can be a difficult decision. It basically depends on the EEG findings and also on whether the impact of further seizures outweighs the risk of treatment. If not treated, the risk of recurrence over a 3-year period is 40% with a risk of approximately 25% if treated.<sup>3</sup> The lowest recurrence rates are associated with a normal EEG. Drug therapy should be offered to the patient following two or more seizures within 6–12 months except when there is a clear avoidable precipitant.

## Approaches to management

- Shared care between GP and consultant is optimal management.
- An accurate diagnosis of the seizure type is essential.

- An underlying brain disease has to be investigated and treated.
- Treatment is based on drugs and lifestyle management. Alcohol abstinence is preferable.
- A decision has to be made about whether drug therapy is appropriate. Pharmacotherapy should be offered if the patient has had two or more seizures within 6–12 months.<sup>3,4</sup> Most seizures require long-term anti-epileptic (anticonvulsant) drug therapy aimed at suppressing the underlying seizure activity in the hope that it may subside, so that 'cure' ultimately occurs and treatment may be ceased. A summary of anti-epileptic drugs is presented in TABLE 84.2.

**Table 84.2** Anti-epileptic drugs

The following anti-epileptic drugs are used

**Benzodiazepines:**

- clobazam
- clonazepam
- diazepam
- midazolam
- nitrazepam

**Carbamazepine**

**Tetracosactrin**

**Phenobarbitone and related drugs:**

- methylphenobarbitone
- primidone

**Phenytoin**

**Sodium valproate (valproate)**

**Succinimides:**

- ethosuximide

**Newer drugs (mainly as 'added on' therapy)**

**Gabapentin**

**Lacosamide**

**Lamotrigine**

**Levetiracetam**

**Oxcarbazepine**

**Pregabalin**

**Sulthiame**

**Tiagabine**

**Topiramate**

**Vigabatrin**

- The choice of drug depends on the seizure type, on consideration of the age and sex of the patient and on efficacy in relation to toxicity.
- Treatment should be initiated with one drug and pushed until it controls the events or causes side effects, irrespective of the medication blood level. The disorder can usually be controlled by one drug provided adequate serum or plasma concentrations are reached.<sup>4</sup> Seventy to eighty per cent of people will have no seizures after treatment with a first-line drug (see TABLE 84.3).
- If a maximum tolerated dosage of this single drug fails to control the seizures, replace it with an alternative agent with a different action. Add the second drug and obtain a therapeutic effect before removing the first drug.
- An example of an initial drug regimen in a young man with idiopathic generalised tonic-clonic seizures is: valproate 500 mg (o) daily for

**Table 84.3** Recommended selection of anti-epileptics in epilepsy<sup>3,4</sup>

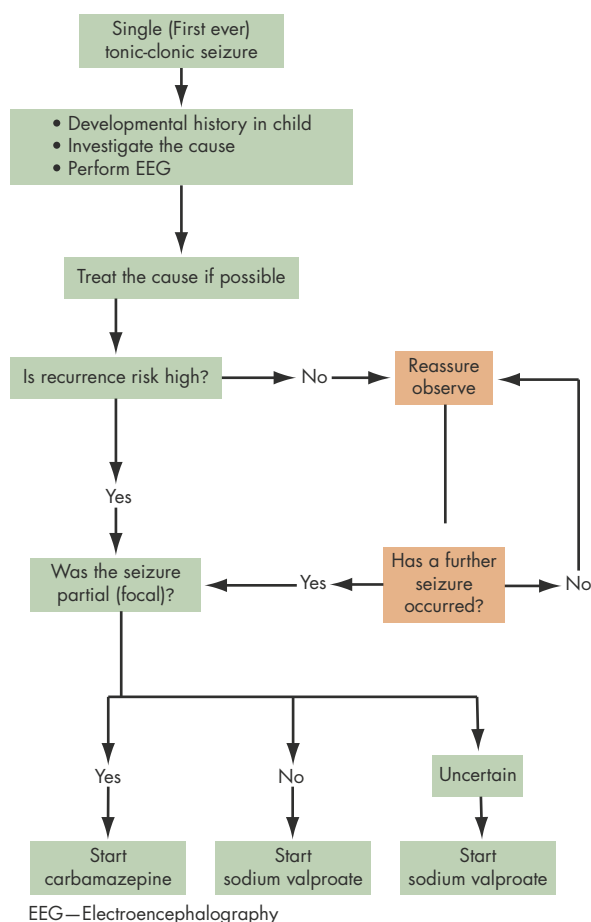

Type of seizure	Firstline therapy	Second-line therapy (select from)
Tonic-clonic	Valproate	Carbamazepine Phenytoin Oxcarbazepine Lamotrigine Levetiracetam Topiramate Phenobarbitone
Absence (petit mal)	Ethosuximide Valproate (especially if associated with other seizure type)	Clobazam Clonazepam Lamotrigine
Myoclonic	Valproate	Clobazam Clonazepam Levetiracetam Phenobarbitone
Simple partial (Jacksonian) and complex partial	Carbamazepine	Phenytoin Valproate Topiramate Gabapentin Lamotrigine Tiagabine Phenobarbitone
Infantile spasms	Tetracosactrin Prednisolone	Clonazepam Valproate Nitrazepam

2 weeks, then bd, up to 3 g or more daily.

*If not controlled second-line (add on):* lamotrigine 12.5 mg (o) once daily for 2 weeks up to 100 mg.

- Special attention should be given to the adverse psychological and social effects of epilepsy. Emotional and social support is important and advice about epilepsy support groups is appropriate.

A flow chart for the initial management of epilepsy is presented in **FIGURE 84.1**.

**FIGURE 84.1** Initial management of epilepsy

Source: Adapted from *Therapeutic Guidelines: Neurology*<sup>3</sup>

## Drug therapy

The following are important specific considerations:

- The basic aim is to prevent seizure recurrence preferably with monotherapy and to minimise adverse effects.

- It is best to select the most effective recommended drug for a specific seizure type (see **TABLE 84.3**).
- Carbamazepine is the initial choice for focal (partial) seizures, while valproate is the first choice for generalised seizures.<sup>5</sup>
- Young women prefer carbamazepine to phenytoin because of the adverse effects of gingival hypertrophy and hirsutism of phenytoin.
- Each drug has specific adverse effects while all drugs tend to be sedating, especially phenobarbitone and its derivatives.
- Twice daily dosage is usually practical.
- Phenytoin (Dilantin) is no longer a first-line agent because of saturable metabolism and the range of unwanted side effects.<sup>5</sup>
- Phenytoin or carbamazepine will bring about control in at least 80% of patients with tonic-clonic seizures.<sup>1</sup> Do not use these drugs together as they have a similar action.

## Cessation of drug therapy

It is important to review the need for anti-epileptics every 12 months. They may be ceased if the patient has been free of seizures for at least 2–3 years, particularly if epileptiform activity has disappeared from the EEG (best under specialist supervision). Up to 60% of children have a mild, self-limiting condition and can settle after medication is withdrawn. It is usual to wean children off drugs after 2–3 years (seizure free) and advise about buccal midazolam in the eventuality of a seizure.

## Adverse drug reactions

Patients should be warned about significant side effects:

- nausea, dizziness, ataxia, visual disturbance or excessive tiredness/fatigue indicate excessive dosage of carbamazepine or phenytoin
- most drugs can cause a rash
- gingival hyperplasia is a classic effect of phenytoin
- hirsutism can occur with phenytoin while hair loss can occur with sodium valproate
- sodium valproate has rare but potentially serious toxic effects
  - liver toxicity
  - dysmorphic effects (specifically spina bifida) on fetus during pregnancy (therefore it is a risk in women of child-bearing age, especially if inadvertent pregnancy occurs due to pill failure related to anti-epileptic interaction)

**Table 84.4** Commonly used anti-epileptics: usual oral dose

	Usual starting adult dose
<b>Carbamazepine</b>	100 bd, increasing gradually to control (max. 2 g/day) Usual range: 400 mg–1.2 g daily
<b>Clonazepam</b>	0.25 mg bd increasing to control
<b>Ethosuximide</b> (used only in absence seizures)	20–30 mg/kg/day in 2 divided doses usual starting dose: 250 mg bd
<b>Gabapentin</b>	300 mg bd or tds, increasing to 3.6 g daily (max.)
<b>Lamotrigine</b>	25 mg/day increasing to 100–200 mg/day
<b>Levetiracetam</b>	250 mg bd for 7 days increasing to 500 mg bd (max 3 g/day)
<b>Phenobarbitone</b>	60–240 mg daily at bed time usual dose: 60–120 mg
<b>Phenytoin</b>	5 mg/kg/day in 2 divided doses average adult: 300 mg
<b>Sodium valproate</b>	500 mg daily for 7 days then bd, increasing to achieve control (up to 2–3 g/day)

- LFTs should be performed every 2 months for 6 months after starting sodium valproate;<sup>1</sup> liver toxicity is much more common in the under-2-years age group

## Patient education

The following points are worth emphasising.

- Most patients can achieve complete control of seizures.
- Most people lead a normal life—they can expect to marry, have a normal sexual life and have normal children.
- Patients need good dental care, especially if they are taking phenytoin.
- A seizure in itself will not usually cause death or brain damage unless in a risk situation such as swimming, or prolonged.
- Patients cannot swallow their tongue during a seizure.
- Take special care with open fires.
- Encourage patients to cease intake of alcohol. Intoxication is very harmful.
- Adequate sleep is important. Deprivation is harmful.

- Avoid fatigue.
- Advise showering in preference to bathing.

## Driving

One has to be very careful about driving. Most people with epilepsy can drive but each case has to be considered individually. Applicants for a learner's licence need to be seizure-free for 2 years, with an annual medical review for 5 years following receipt of the licence. Restrictions range from 1 month to 2 years, depending on the circumstances of the seizures. For a new patient the usual rule is suspension of driving until 3 months seizure free.

## Employment

People with epilepsy can hold down most jobs, but if liable to seizures they should not work close to heavy machinery, in dangerous surroundings, at heights (such as climbing ladders) or near deep water. Careers are not available in some services, such as the police, military, aviation (pilot, traffic controller) or public transport (e.g. bus driver).

## Sport and leisure activities

Most activities are fine, but epileptics should avoid dangerous sports such as scuba diving, hang-gliding, parachuting, rock climbing, car racing and swimming alone, especially surfing.

TABLE 84.5 outlines contraindications for sporting activities. These apply to patients who suffer from very frequent seizures, especially the complex partial seizures with prolonged postictal states.<sup>4</sup>

## Avoid trigger factors

- Fatigue
- Lack of sleep
- Physical exhaustion
- Stress
- Excess alcohol
- Prolonged flashing lights if photosensitive (e.g. video games—this applies to those with a proven response to a proper EEG with photic stimulation)

## Epilepsy in children

Refer to CHAPTER 54.

### Single (first) episode tonic-clonic seizure in school-aged child

- 1 Take a comprehensive history: family history, past history, developmental history, any loss of

**Table 84.5** Sporting activities: contraindications<sup>6</sup>

Absolute contraindications

Flying and parachuting

Motor racing

Mountain and rock-climbing

High diving

Scuba diving

Underwater swimming, especially competitive

Hang-gliding

Abseiling

Relative contraindications

Aiming sports such as archery and pistol shooting

Contact sports such as boxing, rugby, football, including soccer, where heading the ball is involved

Competitive cycling for children with absence epilepsy

Bathing and swimming

Gymnastics, especially activities such as trampolining and climbing on bars

Ice skating and skiing

Javelin throwing

skills, recent head injury, headache, drowsiness, dizziness, recent school performance?

2 Investigations:

biochemistry (glucose, electrolytes incl.

Ca<sup>++</sup>, Mg<sup>++</sup>)

ECG (? QT interval)

EEG (specialist input)

Imaging—brain CT or MRI

3 Management

Reassure may be one-off event

Usually no medication

If recurs, start sodium valproate (see FIG. 84.1)

## Photosensitive epilepsy in children

Some children suffer from photosensitive epilepsy related to exposure to computer and video games and 3D television. There is some evidence that such children may not have seizures if they keep one eye covered. If television provokes seizures, strategies such as watching it with ambient lighting and using the remote control rather than approaching the set will minimise the problem.

## Epilepsy in the elderly

The elderly require the same diagnostic approach as any other age group. However, they are sensitive to side effects of drugs and may require a lower dose than younger patients. It must be remembered that antidepressant or major tranquilliser drugs can precipitate a generalised seizure.

## Menstrual period and epilepsy

Should seizures occur only during the menstrual period, then the addition of clobazam 1–2 days before the period and 1–2 days into the menses may be all that is required.<sup>5</sup>

## Pregnancy and epilepsy<sup>4,7</sup>

Pregnancy is associated with a 30% increase in seizures. Although the outcome is successful for more than 90% of epileptic women, there is a slightly increased risk of prematurity, low birthweight, mortality, defects and intervention. About 45% of women have an increased number of seizures, due mainly to a fall in anti-epileptic drug levels.

All anti-epileptic drugs are potentially teratogenic, with different drugs being related to different defects: phenytoin has been related to cleft lip and palate and congenital heart disease, while sodium valproate (in particular) and carbamazepine have been associated with spina bifida. Sodium valproate should be avoided unless other drugs are unlikely to prevent seizures. All anti-epileptic drugs are expressed in breast milk but in such reduced concentrations as not to preclude breastfeeding, although it is preferable for mothers taking lamotrigine and levetiracetam to abstain from breastfeeding.<sup>8</sup>

## Neurosurgical treatment

Surgical techniques are based on resection such as for temporal lobe epilepsy for a highly select group of patients and also on disconnection techniques. The latter includes corpus callosotomy, multiple subpial transection, hemispherectomy and vagal nerve stimulation. The treatments are limited to a select group with poorly controlled seizures who require detailed evaluation in a specialist centre.

## Pitfalls in management of epilepsy<sup>3</sup>

### Misdiagnosis

The main pitfall associated with seizure disorders and epilepsy is misdiagnosis. It should be realised that not

all seizures are generalised tonic–clonic in type. The most common misdiagnosed seizure disorders are those of complex partial seizures (an underdiagnosed disorder) or the tonic or atonic seizures.

The diagnosis of epilepsy is made on the history rather than the EEG so a very detailed description of the events from eyewitnesses is important.

The features of complex partial seizure (described in [CHAPTER 54](#)) have many variations, the commonest being a slight disturbance of perception or consciousness. The complex partial seizure may evolve to a generalised tonic–clonic seizure. A simple partial seizure may also do this.

In tonic–clonic seizures the patient may become momentarily rigid or fall to the ground and perhaps have one or two jerks only.

### Misdiagnosing behavioural disorders

It is important to differentiate between a fit and a behavioural disorder, but it can be difficult. About 20% of apparently intractable ‘seizures’ are considered to be non-epileptic (pseudoseizures, i.e. emotionally based).<sup>9</sup> These often resemble tonic–clonic seizures but usually there are bizarre limb movements. Ancillary testing, especially with video EEG recording, can help overcome these diagnostic problems but the differentiation may be difficult as the most common situation for pseudoseizures is in the person who has real fits.

### Overtreatment

#### Polypharmacy

Polypharmacy may be counterproductive for the patient and the seizure disorder. This is especially applicable to drugs with a high incidence of side effects. If a patient is taking several medications, management of the case needs questioning and perhaps reconsidering with a consultant’s help.

Seizure control may be improved by reducing polypharmacy. When initiating treatment it is best to select one drug and increase its dose until its maximum recommended level, the onset of side effects or appropriate control. If control is not obtained, the drug should be replaced with an alternative agent but a crossover period is essential. Monotherapy is preferred but combination therapy is often acceptable.

#### Prolonged treatment

The question should be asked at some stage ‘Does this patient really need medication?’ Some patients are kept on anti-epileptics for too long without any attempt being made to wean them off medication or to transfer them

onto anti-epileptics less prone to side effects. Patients should not be left on inappropriate drugs especially if side effects and drug interactions are a problem.

### Drug interactions

Drug interactions with anti-epileptics should always be kept in mind. The most serious of all is the interaction with the oral contraceptive pill because pregnancy can occur. Erythromycin and carbamazepine interact.

## Management of status epilepticus

### Definition

Status epilepticus is the situation in which a patient suffers from two or more generalised seizures without regaining consciousness between seizures, or suffers from continuous partial seizures;<sup>3</sup> refer to [CHAPTER 130](#).

### Focal status

- A high index of suspicion is needed to diagnose
- Oral medication usually adequate
- Avoid overtreatment

### Generalised status

#### Absence attack (*petit mal*)

- Hospitalisation
- IV diazepam

*Note:* This can cause long-term damage.

#### Tonic–clonic (*dangerous!*)<sup>3</sup>

- Ensure adequate oxygenation: attend to airway (e.g. Guedel tube); give oxygen  
midazolam 5–10 mg (child: 0.15–0.2 mg/kg up to 10 mg) IM or IV, over 2–5 minutes  
*or*  
midazolam 5–10 mg (child: 0.2–0.3 mg/kg up to 10 mg) buccally or intranasally. Repeat once 15 minutes later if seizure continues  
*or*  
diazepam 10–20 mg (child: 0.1–0.25 mg/kg up to 20 mg) IV, over 2–5 minutes (max 5 mg/min). Repeat once 15 minutes later if seizure continues (beware of respiratory depression)  
*or*  
clonazepam 1–2 mg (child 0.25–0.5 mg) IV over 2–5 minutes. Repeat once 15 minutes later if necessary  
*followed immediately (for all of above) by*  
phenytoin 15–20 mg/kg IV over 30 minutes (for adults)  
*or* phenobarbitone *or* sodium valproate

*Note:* Midazolam is suitable for all types of seizures and can be given IM, buccally or intranasally.

Diazepam can be given rectally. In an adult, 10 mg is diluted in 5 mL of isotonic saline and introduced via the nozzle of the syringe into the rectum. The dose in children is 0.5 mg/kg.

Intranasal midazolam (0.3–0.5 mg/kg/dose) up to maximum of 10 mg may be given in children.

### DOs and DON'Ts for the onlookers of a seizure

- Don't move the person (unless necessary for safety).
- Don't force anything into the person's mouth.
- Don't try to stop the fit.
- Do roll the person on to his or her side with the head turned to one side and chin up.
- Do call for medical help if the seizure lasts longer than 10 minutes or starts again.
- Do remove false teeth and help clear the airway once the fit is over.

### Recurrent prolonged or repetitive status epilepticus

Patients having recurrent prolonged convulsive seizures or serial seizures can have the following medication options (following appropriate training of carers):

midazolam 10 mg buccally

or

diazepam 10–20 mg rectally (may be available from hospital pharmacies)

### When to refer<sup>2</sup>

Specialist referral is advisable under the following circumstances:

- uncertainty of diagnosis
- at onset of seizure disorder to help obtain a precise diagnosis
- when seizures are not controlled by apparent suitable therapy ? wrong drug ? suboptimal dose ? progressive underlying disorder
- when the patient is unwell, irrespective of laboratory investigation
- when a woman is considering pregnancy (preferable) or has become pregnant: to obtain therapeutic guidance during a difficult phase of management

- for assessment of the prospects for withdrawing treatment after some years of absolute seizure control

### Practice tips

- The EEG has considerable limitations in diagnosis. It is diagnostic in less than 50%,<sup>1</sup> although more diagnostic if conducted under sleep deprivation. An accurate eyewitness account of the seizure is the most reliable diagnostic aid.
- During evaluation look for evidence of neurofibromatosis.
- Beware of interactions between anti-epileptics and the oral contraceptive pill.
- Interactions between erythromycin and carbamazepine can cause toxicity.
- Always aim to achieve monotherapy.
- An important toxic reaction can occur with combined phenytoin and carbamazepine.
- Patients should not drive while medication is being adjusted, particularly if weaning is being attempted. Patients must not drive if they do not meet national guidelines on seizure-free periods.
- The development of sophisticated surgical techniques means that surgery can be used in selected patients with poor control. Evaluation for surgery is a very specialised area.

*Of all the ailments which may blow out life's little candle, heart disease is the chief.*

William Boyd (1885–1979), *Pathology for the Surgeon*

Cardiovascular disease includes mainly:

- coronary heart disease—myocardial ischaemia (CHAPTER 40)
- cerebrovascular disease—strokes and transient ischaemia (CHAPTER 132)
- peripheral vascular disease (CHAPTER 66)

The number one cause of death in the world is coronary heart disease (CHD),<sup>1</sup> whether from sudden fatal acute coronary events, particularly myocardial infarction (CHAPTER 40) or blocked arteries causing angina and eventually cardiac failure (CHAPTER 88). CHD is responsible for about 3 in 10 deaths in Australia.<sup>2</sup> However, there has been a pleasing reduction in deaths from coronary heart disease and stroke in recent years because of improved preventive measures.

## Risk factors for CVD

Modifiable:

- Hypertension (CHAPTER 86)
- Dyslipidaemia (CHAPTER 87)
- Smoking (CHAPTER 21)
- Obesity (CHAPTER 78)
- Sedentary lifestyle
- Alcohol excess (CHAPTER 21)
- Poor nutrition (CHAPTER 10)
- Mental stress<sup>3</sup> (CHAPTER 81)

## Non-modifiable

- Family history
- Increasing age
- Male gender
- Social history inc. cultural/ethnic identity

Related conditions:

- Diabetes (CHAPTER 20)
- Chronic kidney disease

## Assessment of absolute cardiovascular risk

Target groups—recommended every 2 years:

- all adults  $\geq 45$  years without known history of CVD
- ATSIP  $\geq 35$  years

People for whom a high CVD risk can be assumed (e.g. diabetes, established CVD, hypertension) do not need an absolute CVD risk assessment using the Framingham Risk Equation.<sup>4</sup>

## Specific screening recommendations<sup>4</sup>

- Blood pressure should be measured in all adults from age 18 years at least every 2 years.
- Adults should have their fasting blood lipids assessed starting at age 45 years, every 5 years (ATSIP: 35 years).
- Adults should be screened for diabetes (fasting plasma glucose) every 3 years from age 40 years (ATSIP: from 18 years).
- Adults at high risk should be screened for kidney disease every 1–2 years (ACR ratio and eGFR).

Estimation of cardiovascular risk guidelines based on the key parameters—hypertension, diabetes, total cholesterol:HDL ratio, age and sex—are presented in FIGURES 85.1 and 85.2.

## Secondary prevention of CHD for established risk<sup>5</sup>

### 1 Management of biomedical risk factors with targets

- Blood pressure:  $<130/80$  mmHg
- Lipids: total C 4 mmol/L; LDL-C  $<1.8$  mmol/L; HDL-C  $\geq 1.0$  mmol/L; NHDL-C  $<2.5$  mmol/L; TG  $<2.0$  mmol/L<sup>5</sup>
- Lowering LDL-C is essential to reduce cardiovascular risk
- Every 1 mmol/L decrease equates to an RRR of major vascular events<sup>6</sup>
- Diabetes: maintain optimal blood sugar level 4.0–6.0 mmol/L (ideal), NHMRC 6.1–8.0 mmol/L; HbA1c  $\leq 7\%$
- Antiplatelet agent: all patients should take aspirin 75–150 mg/day unless contraindicated

### 2 Management of lifestyle/behavioural risk factors with goals

- Smoking: patients completely stop smoking and avoid second-hand smoke. The death rate

**How to use the charts**

- Σ Identify the chart relating to the person's sex, diabetic status, smoking history and age.
- Σ Within the chart choose the cell nearest to the person's age, blood pressure (BP) and TC:HDL ratio.  
When the systolic and diastolic values fall in different risk levels, the higher category applies.
- Σ For Example, the lower left cell contains all non-smokers without diabetes who are less than 45 years and have a TC:HDL ratio of less than 4.5 and a BP of less than 130/80 mm Hg. People who fall exactly on a threshold between cells are placed in the cell indicating higher risk.

Certain groups may have CVD risk underestimated using these charts, see **TABLE 86.8** in **CHAPTER 86** for recommended adjustments.

**FIGURE 85.1** Estimation of cardiovascular risk—women

Source: New Zealand Guidelines Group. *New Zealand Cardiovascular Guidelines Handbook: Developed for primary care practitioners*. Wellington: June 2005 <www.nzgg.org.nz>. Courtesy of the New Zealand Ministry of Health

Risk level: 5-year CVD risk (fatal and non-fatal)	Benefits: NNT for 5 years to prevent one event (CVD events prevented per 100 people treated for 5 years)		
	1 intervention (25% risk reduction)	2 interventions (45% risk reduction)	3 interventions (55% risk reduction)
30%	13 (7.5 per 100)	7 (14 per 100)	6 (16 per 100)
20%	20 (5 per 100)	11 (9 per 100)	9 (11 per 100)
15%	27 (4 per 100)	15 (7 per 100)	12 (8 per 100)
10%	40 (2.5 per 100)	22 (4.5 per 100)	18 (5.5 per 100)
5%	80 (1.25 per 100)	44 (2.25 per 100)	36 (3 per 100)

Based on the conservative estimate that each intervention: aspirin, blood pressure treatment (lowering systolic blood pressure by 10 mm Hg) or lipid modification (lowering LDL-C by 20%) reduces CV risk by about 25% over 5 years.

**Note:** Cardiovascular events are defined as myocardial infarction, new angina, ischaemic stroke, transient ischaemic attack (TIA), peripheral vascular disease, congestive heart failure and cardiovascular-related death.

NNT = Number needed to treat

**FIGURE 85.2** Estimation of cardiovascular risk—men

Source: New Zealand Guidelines Group. *New Zealand Cardiovascular Guidelines Handbook: Developed for primary care practitioners*. Wellington: June 2005 <[www.nzgg.org.nz](http://www.nzgg.org.nz)>. Courtesy of the New Zealand Ministry of Health

from CHD is about twice that for smokers than for non-smokers

- Alcohol: patients consume a low-risk quantity—maximum 2 standard drinks per day; 1 standard drink for women with hypertension
- Nutrition: maintain healthy eating including limiting saturated fatty acid and trans fat intake and salt intake to  $\leq 4$  g/day
- Physical activity: if possible, at least 30 minutes of moderate-intensity physical activity on most days of the week (150 minutes/week minimum)
- Healthy weight: waist measurement men  $<94$  cm, women  $<80$  cm; BMI range 18.5–25
- Stress management: encourage promotion of recreation, relaxation techniques, meditation, social support. Treat anxiety disorders and depression

*The greatest danger to a man is that someone will discover hypertension and some fool will try to reduce it.*

John Hay 1931

Hypertension is a serious community disorder and the most common condition requiring long-term drug therapy in Australia. It is a silent killer because most people with hypertension are asymptomatic and unaware of their problem. Epidemiological studies have demonstrated the association between hypertension and stroke, coronary heart disease, kidney disease, heart failure and atrial fibrillation. Treatment may be lifelong, hence the need for careful work-up.

- Target organs (including some specific examples) that can be damaged by hypertension include the heart (failure, LVH, ischaemic disease), the kidney (kidney insufficiency), the retina (retinopathy), the blood vessels (peripheral vascular disease, aortic dissection) and the brain (cerebrovascular disease).
- Deaths in hypertensive patients have been shown to be due to stroke 45%, heart failure 35%, kidney failure 3% and others 17%.<sup>1</sup>
- Factors increasing chances of dying in hypertensive patients are: male patient, young patient, family history, increasing diastolic pressure.<sup>1</sup>

## Definitions and classification

- The various categories of BP are arbitrarily defined according to BP values for both diastolic and systolic readings (see TABLE 86.1).<sup>2,3</sup>

**For adults aged 18 years and older hypertension is:**

- diastolic pressure >90 mmHg and/or
- systolic pressure >140 mmHg
- Isolated systolic hypertension is that of  $\geq 140$  mmHg in the presence of a diastolic pressure <90 mmHg.
- Hypertension is either essential or secondary (see TABLE 86.2).
- Essential hypertension is the presence of sustained hypertension in the absence of underlying, potentially correctable kidney, adrenal or other factors.

**Table 86.1**

Definition and classification of blood pressure adults aged 18 years and older measured as sitting blood pressure (mmHg)<sup>2,3</sup>

Category	Systolic	Diastolic
Normal	<120	<80
High normal	120–139	80–89
Grade 1 hypertension (mild)	140–159	90–99
Grade 2 hypertension (moderate)	160–179	100–109
Grade 3 hypertension (severe)	$\geq 180$	$\geq 110$
Isolated systolic hypertension	$\geq 140$	<90

When a patient's systolic and diastolic BPs fall into different categories, the higher category should apply.

- Malignant hypertension is that with a diastolic pressure >120 mmHg and exudative vasculopathy in the retinal and kidney circulations.
- Refractory hypertension is a BP >140/90 mmHg despite maximum dosage of two drugs for 3–4 months.

**Table 86.2**

Causes of hypertension

Essential (90–95%)  
 Secondary (approximately 5–10%)  
 Kidney <3%  
 • glomerulonephritis  
 • reflux nephropathy  
 • kidney artery stenosis (see later in this chapter)  
 • other renovascular disease  
 • diabetes  
 Endocrine: 0.3–1%  
 • primary aldosteronism (Conn syndrome) (see CHAPTER 23)  
 • Cushing syndrome (see CHAPTER 23)  
 • pheochromocytoma (see CHAPTER 23)  
 • oral contraceptives  
 • other endocrine factors  
 Coarctation of the aorta  
 Immune disorder (e.g. polyarteritis nodosa)  
 Drugs (e.g. NSAIDs, corticosteroids)  
 Pregnancy

## Risk stratification and calculation of cardiovascular risk<sup>2,3</sup>

Treatment of hypertension is generally indefinite and it is important to establish the risk status and the prognosis prior to commencing therapy, especially if hypertension is an isolated factor. The World Health Organization–International Society of Hypertension (WHO–ISH) recommendation is that decisions about management of patients with hypertension should not be based on BP alone but also on the presence or absence of other risk factors, including important factors such as age, diabetes and smoking. Cardiovascular risk should be stratified according to the BP level and the presence of:

- absolute cardiovascular risk factors
- associated clinical conditions
- target organ damage (see TABLE 86.3)

A practical approach to stratifying total cardiovascular risk is proposed in TABLE 86.4. The terms 'low', 'moderate' (medium), 'high' and 'very high' added risk are calibrated to indicate an absolute 10-year risk of cardiovascular disease of >15%, 15–20%, 20–30% and >30% respectively (based on Framingham criteria). For example, 'low risk' indicates starting treatment and monitoring, high risk indicates treating immediately.

Risk estimation can be determined by referring to various cardiovascular risk tables on the website (and in CHAPTER 85). A commonly used tool in Australasia is the modified New Zealand Cardiovascular Risk Charts ([www.nzgg.org.nz](http://www.nzgg.org.nz) or [www.heartfoundation.com.au](http://www.heartfoundation.com.au)). See CHAPTERS 20 and 85.

It is important to collaborate with patients in decision making, and thus discussing cardiovascular risk assessment and blood pressure (BP) level should be the starting point when discussing the risks and benefits of treatment.

**Table 86.3** Factors influencing prognosis in hypertension<sup>3</sup>

Risk factors for cardiovascular disease used for stratification	Associated clinical condition (ACC)	Target organ damage (TOD)
Levels of systolic and diastolic BP	Cerebrovascular disease:	Left ventricular hypertrophy
Men >55 years	• ischaemic stroke	Microalbuminuria and/or proteinuria and/or eGFR <60 ml/minute
Women >65 years	• cerebral haemorrhage	Ultrasound or angiographic evidence of atherosclerotic disease
Smoking	• transient ischaemic attack	Hypertensive retinopathy (grade II or more)
Diabetes mellitus	Heart disease:	
Dyslipidaemia (total cholesterol >6.5 mmol/L, >250 mg/dL or LDL-cholesterol >4.0 mmol/L, >155 mg/dL or HDL-cholesterol M <1.0, W <1.2 mmol/L)	• myocardial infarction	
	• angina	
	• coronary revascularisation	
	• congestive heart failure	
Family history of premature cardiovascular disease (at age <55 years M, <65 years W)	Kidney disease:	
Abdominal obesity (abdominal circumference M ≥102 cm, W ≥88 cm)	• diabetic nephropathy	
	• kidney impairment	
	• proteinuria (>300 mg/24 h)	
• C-reactive protein ≥ 1 mg/dL	Peripheral vascular disease	
Other factors affecting prognosis	Advanced retinopathy:	
Excessive alcohol intake	• haemorrhages or exudates	
Sedentary lifestyle	• papilloedema	
High-risk socioeconomic group		
High-risk ethnic group		

**Table 86.4** Stratification of cardiovascular risk to quantify prognosis<sup>2</sup>

Other risk factors and disease history	Normal BP	High normal BP	Mild hypertension	Moderate hypertension	Severe hypertension
No other risk factors	Average risk	Low risk	Average risk	Moderate risk	High risk
1 or 2 risk factors but not diabetes	Low risk	Low risk	Moderate risk	Moderate risk	Very high risk
3 or more risk factors or target organ damage or diabetes mellitus	Moderate risk	High risk	High risk	High risk	Very high risk
Associated clinical conditions	High risk	Very high risk	Very high risk	Very high risk	Very high risk

## Secondary hypertension

Secondary hypertension may be suggested in patients below 40 years by the history (see [TABLE 86.5](#)), physical examination, severity of hypertension or the initial laboratory findings. It is also more likely in patients whose BP is responding poorly to drug therapy, patients with well-controlled hypertension whose BP begins to increase, and patients with accelerated or malignant hypertension.<sup>2</sup>

The most common causes of secondary hypertension are various kidney diseases, such as renovascular disease, chronic glomerulonephritis, chronic pyelonephritis (often associated with reflux nephropathy) and analgesic nephropathy.<sup>1</sup> There will often be no physical findings to suggest the existence of such kidney diseases, but an indication will generally be obtained by the presence of one or more abnormalities when the urine is examined. Clinical pointers include proteinuria, an abnormal urine sediment, general atheroma, smokers and abdominal bruit.

**Table 86.5** Clinical features suggesting secondary hypertension<sup>4</sup>

Clinical features	Likely cause
Abdominal systolic bruit	Kidney artery stenosis
Proteinuria, haematuria, casts	Glomerulonephritis
Bilateral kidney masses with or without haematuria	Polycystic disease
History of claudication and delayed femoral pulse	Coarctation of the aorta
Progressive nocturia, weakness	Primary aldosteronism (check serum potassium)
Paroxysmal hypertension with headache, pallor, sweating, palpitations	Phaeochromocytoma

Physical findings that may suggest secondary hypertension include epigastric bruits (indicating possible kidney artery stenosis) and abdominal aortic aneurysm. Less common findings include abdominal flank masses (polycystic kidneys), delayed or absent femoral pulses (coarctation of the aorta), truncal obesity with pigmented striae (Cushing syndrome), and tachycardia, sweating and pallor (phaeochromocytoma). Endocrine causes are presented in [CHAPTER 23](#).

Further investigation will be required to confirm or reveal secondary hypertension.

## Kidney artery stenosis

Atherosclerotic kidney artery stenosis accounts for the majority of cases, while fibromuscular dysplasia remains an important cause. Doppler ultrasound is a highly sensitive and specific investigation.

## Detection of hypertension<sup>1</sup>

Hypertension can only be detected when BP is measured. Therefore every reasonable opportunity should be taken to measure BP.

Diagnosis should not be made on the basis of a single visit. Initial raised BP readings should be confirmed on at least two other visits within the space of 3 months; average levels of 90 mmHg diastolic or more, or 140 mmHg systolic or more, are needed before hypertension can be diagnosed. This will avoid the possibility of an incorrect diagnosis, committing an asymptomatic, normotensive individual to unjustified, lifelong treatment.

## Measurement guidelines<sup>2</sup>

BP varies continuously and can be affected by many outside factors. Care should therefore be taken to ensure that readings accurately represent the patient's usual pressure.

### BP measurement recommendations<sup>5</sup>

- All people aged 18 years and over
- Frequency—every 2 years

### Office BP measurement guidelines<sup>2</sup>

- Allow the patient to sit quietly for several minutes.
- Use a validated (calibrated) device.
- Take at least two measurements spaced by 60 seconds.
- Use a standard bladder (12–13 × 35 cm), but a larger one for big arms.
- Have the cuff at the heart level (see FIG. 86.1).
- Deflate the cuff slowly (2 mmHg/s).
- Measure BP also in standing position in elderly patients and diabetic patients.

### Recording

On each occasion when the BP is taken, two or more readings should be averaged. Wait at least 30 seconds before repeating the procedure. If the first two readings differ by more than 6 mmHg systolic or 4 mmHg diastolic, more readings should be taken.

Both systolic and diastolic levels should be recorded. For the diastolic reading the disappearance of sound (Phase 5)—that is, the pressure when the last sound is heard and after which all sound disappears—should be used.<sup>6</sup> This is more accurate than the muffling of sounds (phase 4) (see FIG. 86.2), which should only be used if the sound continues to zero.

*Note:* Measure sitting and standing BP in elderly and diabetic patients.

### Heart rate and pulse

At the same time the BP is measured, the heart rate and rhythm should be measured and recorded. A high heart rate may indicate undue stress that is causing the associated elevated BP reading. An irregular heart rhythm may cause difficulty in obtaining an accurate BP reading.

### BP modifying factors

Apprehension	Patient should be rested for at least 5 minutes and made as relaxed as possible.
Caffeine	Patients should not take caffeine for 4–6 hours before measurement.
Smoking	Patients should also avoid smoking for 2 hours before measurement.
Eating	Patients should not have eaten for 30 minutes.

FIGURE 86.1 Correct placement of the cuff

### Strategies for high initial readings

If the initial reading is high (DBP >90 mmHg, SBP >140 mmHg) repeat the measures after 10 minutes of quiet rest. The 'white coat' influence in the medical practitioner's office may cause higher readings so measurement in other settings such as the home or the workplace should be managed whenever possible.

### Confirmation and follow-up<sup>1</sup>

Repeated BP readings will determine whether initial high levels are confirmed and need attention, or whether they return to normal and need only periodic checking. Particular attention should be paid to younger patients to ensure that they are regularly followed up.

Initial diastolic BP readings of 115 mmHg or more, particularly for patients with target organ damage, may need immediate drug therapy.

Once an elevated level has been detected, the timing of subsequent readings should be based on the initial pressure level, as shown in TABLE 86.6.

If mild hypertension is found, observation with repeated measurement over 3–6 months should be followed before beginning therapy. This is because levels often return to normal.

### Ambulatory 24-hour monitoring

This is required for the diagnosis and follow-up of patients with fluctuating levels, borderline hypertension or refractory hypertension (especially where the 'white coat' effect may be significant). For these patients, ambulatory monitoring has a place in management. Studies have shown that this method provides a more precise estimate of BP variability than casual recordings. This has implications for the timing of drug therapy in individual patients.

FIGURE 86.2 Illustration of blood pressure measurement in relation to arterial blood flow, cuff pressure and auscultation

Guidelines for ambulatory BP measurement:

- unusual variability of office BP
- marked discrepancy between office and house BP
- resistance to drug treatment
- suspected sleep apnoea
- when two BP readings  $>140/90$

### 'White coat' hypertension

This group may comprise up to 25% of patients presenting with hypertension. These people have a type of conditioned response to the clinic or office setting and their home BP and ambulatory BP profiles are normal. They appear to be at low risk of cardiovascular disease but may progress to sustained hypertension. Ambulatory 24-hour monitoring has a place in managing these subjects.

### Evaluation

As well as defining the BP problem, the clinical evaluation for suspected hypertension should also determine:

- whether the patient has potentially reversible secondary hypertension
- whether target organ damage is present
- whether there are other potentially modifiable cardiovascular risk factors present and
- what comorbid factors exist

### Medical history

The following should be included in the medical history of the patient.

**Table 86.6** Follow-up criteria for initial blood pressure measurement for adults 18 years and older<sup>7</sup>

Systolic (mmHg)	Diastolic (mmHg)	Action/recommended follow-up*
<120	<80	Recheck in 2 years.
120–139	80–89	Recheck in 1 year—lifestyle advice.
140–159	90–99	* Confirm within 2 months—lifestyle advice.
160–179	100–109	* Evaluate or refer within 1 month—lifestyle advice.
≥ 180	≥ 110	* Further evaluate and refer within 1 week (or immediately depending on clinical situation). If BP has been confirmed at ≥ 180 mm Hg systolic and/or ≥ 110 diastolic mmHg (after multiple readings and excluding 'white coat' hypertension), drug treatment should be commenced.

If systolic and diastolic categories are different, follow recommendations for shorter follow-up (e.g. BP 160/86 mmHg evaluate or refer within 1 month).

\*Note: Earlier initiation of drug therapy may be indicated for some patients.

## History of hypertension

- Method and date of initial diagnosis
- Known duration and levels of elevated BP
- Symptoms that may indicate the effects of high BP on target organ damage, such as headache, dyspnoea, chest pain, claudication, ankle oedema and haematuria
- Symptoms suggesting secondary hypertension (see TABLE 86.5)
- The results and side effects of all previous antihypertensive treatment

## Presence of other diseases and risk factors

- A history of cardiovascular, cerebrovascular or peripheral vascular disease, kidney disease, diabetes mellitus or recent weight gain
- Other cardiovascular risk factors, including obesity, hyperlipidaemia, carbohydrate intolerance, smoking, salt intake, alcohol consumption, exercise levels and analgesic intake
- Other relevant conditions, such as asthma or psychiatric illness (particularly depressive illness)

## Family history

Particular attention should be paid to the family history of hypertension, cardiovascular or cerebrovascular disease, hyperlipidaemia, obesity, diabetes mellitus, kidney disease, alcohol abuse and premature sudden death.

## Medication history

A history of all medications, including over-the-counter products, should be obtained because some can raise BP or interfere with antihypertensive therapy. Prohypertensive substances include:

- alcohol
- oral and depot contraceptives
- hormone replacement therapy
- steroids
- NSAIDs/COX-2 inhibitors
- nasal decongestants and other cold remedies, pseudoephedrine
- appetite suppressants
- amphetamines
- irreversible monoamine oxidase inhibitors
- analgesics
- ergotamine
- cyclosporin
- tacrolimus
- liquorice
- bupropion
- venlafaxine (dose related)

## Alcohol intake<sup>1</sup>

Alcohol has a direct pressor effect that is dose-related. An assessment of the average daily number of standard drinks is important—more than two standard drinks (20 g alcohol) a day is significant.

## Examination

The approach to the physical examination is to examine possible target organ damage and possible causes of secondary hypertension. The main features to consider in the physical examination are illustrated in FIGURE 86.3.

The four grades of hypertensive retinopathy are illustrated in FIGURE 86.4.

## Leg pulses and pressure

To assess the remote possibility of coarctation of the aorta in the hypertensive patient, perform at least one observation comparing:

- 1 the volume and timing of the radial and femoral pulses

**Evidence of endocrine disorders**

Cushings  
multiple endocrine neoplasia  
thyrotoxicosis

**Blood pressure**

two or more readings while sitting  
measure in both arms  
measure standing

**Kidneys**

kidney artery bruit best heard in epigastrium  
? enlarged kidneys

**Waist circumference**  
**Height and weight**  
measure BMI

FIGURE 86.3 Examination of patient with hypertension: what to look for

- 2 the BP in the arm and leg
- 3 comparison of BP in the two arms

**Blood pressure measurement in the leg**

- Place the patient prone.
- Use a wide, long cuff at mid-thigh level.
- Position the bladder over the posterior surface and fix it firmly.
- Auscultate over the popliteal artery.

**Investigations<sup>2,5</sup>****Routine tests**

- Plasma glucose (preferably fasting)
- Serum total and high-density lipoprotein (HDL) cholesterol, fasting serum triglycerides

- Serum creatinine/eGFR/ACR
- Serum uric acid
- Serum potassium and sodium
- Haemoglobin and haematocrit
- Urinalysis (dipstick test and urinary sediment)
- Electrocardiogram

**Recommended tests**

- Echocardiogram
- Carotid (and femoral) ultrasound
- Postprandial plasma glucose (when fasting value  $\geq 6.1$  mmol/L or 110 mg/dL)
- C-reactive protein (high sensitivity)
- Microalbuminuria (essential test in diabetes)
- Quantitative proteinuria (if dipstick +ve)
- Fundoscopy (in severe hypertension)

FIGURE 86.4 The four grades of hypertensive retinopathy

Other investigations, such as echocardiography, kidney imaging studies (especially kidney ultrasound), 24-hour urinary catecholamines, aldosterone and plasma renin, are not routine and should be done only if specifically indicated. A chest X-ray may serve as a baseline against which to measure future changes. However, if a chest X-ray shows the heart is enlarged, it is more likely to represent chamber dilatation than increased ventricular wall thickness.<sup>1</sup> Specific kidney studies now favoured include isotope scans, Doppler ultrasound studies of kidney arteries and kidney arteriography.

## Treatment

A correct diagnosis is the basis of management. Assuming that the uncommon secondary causes are identified and treated, treatment will focus on essential hypertension.

## Benefits of treatment

Trials have shown that lowering BP reduces:

- cardiovascular and total mortality
- stroke
- coronary events

Benefits have been proven:

- in patients with systolic/diastolic hypertension
- in elderly patients with isolated systolic hypertension

## Principles of management<sup>7</sup>

- The overall goal is to improve the long-term survival and quality of life.
- Promote an effective physician–patient working relationship.
- Aim to reduce the levels to 140/90 mmHg or less (ideal).
- Undertake a thorough assessment of all cardiovascular risk factors.
- Instruct all patients in the use of non-drug treatment strategies and their potential benefits.
- In patients with mild-to-moderate hypertension and no target organ damage, consider ambulatory or home BP monitoring.
- Drug therapy should be given to those with:
  - sustained high initial readings (e.g. DBP 95 mmHg)
  - target organ damage
  - failed non-drug measures

- Make a careful selection of an antihypertensive drug and an appraisal of the side effects against the benefits of treatment.
- Avoid drug-related problems such as postural hypotension.
- Avoid excessive lowering of BP—aim for steady and graduated control.
- Aim to counter the problem of patient non-compliance.
- Be aware of factors that may contribute to drug resistance.

## Patient education

Patient education should include appropriate reassurances, clear information and easy-to-follow instructions. It is important to establish patients' understanding of the concept of hypertension and its consequences by quizzing them about their knowledge and feelings.

## Correction of patients' misconceptions<sup>1</sup>

Patients are likely to have several misconceptions about hypertension that may adversely affect their treatment.

For example, they might believe that:

- hypertension can be cured
- they do not need to continue treatment once their BP is controlled
- they do not have a problem because they do not have symptoms
- they need to take additional pills, or stop treatment in response to symptoms they believe are caused by high or low BP levels
- they need not take prescribed pills if they attend to lifestyle factors such as exercise and diet
- they can gauge their BP by how they feel

## Tips for optimal compliance

- Establish a good, caring rapport.
- Give patients a card of their history with BP readings.
- Give advice about pill-taking times.
- Set therapeutic goals.
- Establish a recall system.
- Provide patient education material.

On review:

- Ask if any pills were missed by accident.
- Attempt to reduce waiting time to a minimum (e.g. direct a patient to a spare room upon arrival).
- Review all cardiovascular risk factors.
- Enquire about any side effects.

## Non-pharmacological (lifestyle) management measures

If the average diastolic BP at the initial visit is 90–100 mmHg, and there is no evidence of end organ damage, non-pharmacological therapy is indicated for a 3-month period without use of antihypertensive drugs. Remember to remove, revise or substitute drugs that may be causing hypertension (e.g. NSAIDs, corticosteroids, oral contraceptives, hormone replacement therapy).

## Behaviour intervention measures

- *Weight reduction*  
There is considerable evidence that weight loss and gain are linked to a corresponding fall and rise in BP. Hovell has estimated that for every 1 kg of weight lost, BP dropped by 2.5 mmHg systolic and 1.5 mmHg diastolic.<sup>8</sup> The BMI should be calculated for all patients and where required a weight loss program organised to reduce the BMI to between 20 and 25.
- *Reduction of excessive alcohol intake<sup>1</sup>*  
The direct pressor effect of alcohol is reversible. Drinking more than 20 g of alcohol a day raises BP and makes treatment of established hypertension more difficult. People with hypertension should limit their alcohol intake to one or two standard drinks (10 g) per day. Reduction or withdrawal of regular alcohol intake reduces BP by 5–10 mmHg.
- *Reduction of sodium intake*  
Some individuals seem to be more sensitive to salt restriction. Advise patients to put away the salt shaker and use only a little salt with their food. Reduction of sodium intake to less than 100 mmol sodium per day is advised. Special care should be taken with processed and take-away foods.
- *Increased exercise*  
Regular aerobic or isotonic exercise helps to reduce BP.<sup>9</sup> Hypertensive patients beginning an exercise program should do so gradually. Walking is an appropriate exercise. Weights and other forms of isometric exercises should be avoided because they will significantly elevate BP in the hypertensive subject.
- *Reduction of particular stress*  
If avoiding stress or overwork is difficult, recommend relaxation and/or meditation therapy.
- *Other dietary factors*  
There is evidence that lacto-vegetarian diets and magnesium supplementation can reduce BP.<sup>10</sup> A

diet high in calcium, and low in fat and caffeine, may also be beneficial. Avoid or minimise liquorice and liquorice-containing substances.

- *Smoking*

Smoking causes acute rises in BP but does not appear to cause sustained hypertension. However, the elimination of smoking is important as it is a strong risk factor for cardiovascular disease and continuing to smoke may negate any benefits of antihypertensive therapy.<sup>1</sup>

- *Management of sleep apnoea*

## Pharmacological therapy

The benefits of drug therapy appear to outweigh any known risks to individuals with a persistently raised diastolic pressure >95 mmHg. Although the ideal

antihypertensive drug has yet to be discovered, there are many effective antihypertensive drugs available from all the major classes of antihypertensive drugs.<sup>11</sup> Deciding which one to use first involves an assessment of the patient's general health, the medication's known side effects, the simplicity of its administration and its cost. A useful plan is outlined in **FIGURE 86.5**.

Various disorders such as diabetes, asthma, COPD, Raynaud phenomenon, heart failure, and elevated serum urate and/or lipid levels may restrict the use of some classes of drugs.

## When to treat

- Failed genuine non-pharmacological trial
- All cases of SBP 140–180 mmHg or DBP 90–110 mmHg (see **TABLE 86.7**)

**FIGURE 86.5** Common combinations of the therapeutic drug classes used for first-line therapy of hypertension

- Adjacent drug classes are useful combinations in that effects on BP are additive and adverse effects are no more likely than with either drug used alone.
- Non-dihydropyridine CCBs: verapamil (V) and diltiazem (D) generally should not be used with  $\beta_2$ -antagonists.
- Drug groups that are diametrically located on the diagram may be used together, but may not have fully additive effects.
- Drugs on the left side should be combined in patients with hypertension and heart failure, and those on the right side are useful in patients with hypertension and coexisting coronary disease.
- Drug groups on the lower panel lack metabolic effects and may be preferred combinations in the presence of diabetes or lipid abnormalities as well as hypertension.
- Prazosin and other  $\alpha$ -antagonists are also sometimes used as monotherapy and may be combined with any of the above drug groups.
- Small doses of centrally acting anti-adrenergic drugs (e.g. methyldopa, clonidine) can probably also be used with any of the other agents although data on their use in combination are scarce with the newer drug groups.

**Table 86.7** BP treatment targets for adults (mm Hg)<sup>7,12</sup>

People with proteinuria >1 g/day (with or without diabetes)	<125/75
People with associated condition(s) or end-organ damage:	<130/80
• coronary heart disease	
• diabetes	
• chronic kidney disease	
• proteinuria (>300 mg/day)	
• stroke/TIA	
People with none of the above	<140/90 or lower if tolerated

## Guidelines<sup>12</sup>

- Start with a single drug at low dose.
- A period of 4–6 weeks is needed for the effect to become fully apparent.
- If ineffective, consider increasing the drug to its maximum recommended dose, or add an agent from another compatible class, or substitute with a drug from another class.
- Use only one drug from any one class at the same time.
- A summary of first-line therapy options and the uses of the various pharmacological agents is shown in **TABLE 86.8**.
- Measure the BP at the same time each day.
- A good strategy is to get patients to self-measure.

## Starting regimens

The traditional method has been to use stepwise therapy until ideal control has been reached, commencing with:

### Starting medication

- 1 ACE inhibitor or ARB  
or  
calcium-channel blocker (CCB)  
or  
low-dose thiazide diuretic (if aged ≥ 65 years)
- 2 If target not reached: combination  
ACEI or ARB + CCB (best evidence)<sup>13,14</sup>  
or  
ACEI or ARB + thiazide
- 3 If target not reached:  
ACEI/ARB + CCB + thiazide

The following are useful combinations:<sup>7,14</sup>

Initial agent	Additional drugs
Thiazide diuretic	ACEI/ARB or CCB or β-blocker
β-blocker	Diuretic or dihydropyridine calcium-channel blocker
ACE inhibitor or ARB	Diuretic or β-blocker or calcium-channel blocker

## Relatively ineffective combinations<sup>7,12</sup>

- Diuretic and calcium-channel blocker
- β-blockers and ACE inhibitors

## Undesirable combinations<sup>7,12</sup>

- More than one drug from a particular pharmacological group:
  - β-blockers and verapamil (heart block, heart failure)
  - potassium-sparing diuretics and ACE inhibitors or ARB (hyperkalaemia)

## Diuretics<sup>4,7,15</sup>

- Thiazides are good first-line therapy for hypertension.
- Hypokalaemia can be corrected with potassium-sparing diuretics or by changing to another first-line drug.
- Loop diuretics are less potent as antihypertensive agents but are indicated where there is concomitant cardiac or kidney failure and in resistant hypertension.
- Thiazides are less effective where there is kidney impairment.
- Thiazides may precipitate acute gout.
- NSAIDs may antagonise the antihypertensive and natriuretic effectiveness of diuretics.
- A diet high in potassium and magnesium should accompany diuretic therapy (e.g. lentils, nuts, high fibre).
- Avoid use if significant dyslipidaemia.
- Indapamide has different properties to the thiazide and loop diuretics and has less effect on serum lipids.

## Beta blockers

- NSAIDs may interfere with the hypotensive effect of β-blockers.
- If BP is not reduced by one β-blocker it is unlikely to be reduced by changing to another.

**Table 86.8** First-line pharmacological options for the management of hypertension<sup>7,12,15</sup>

Drug class				
Thiazide diuretic	Beta blocker	Calcium-channel blocker	ACE inhibitor	ARB (sartans)
Typical examples and starting dose (oral therapy)				
Chlorthalidone 12.5–25 mg daily	Atenolol 25–50 mg daily	<i>Dihydropyridine CCBs</i> Amlodipine 2.5 mg daily	Captopril 6.25 mg bd Enalapril 5 mg daily Lisinopril 5 mg daily	Candesartan 8 mg daily Eprosartan 600 mg daily
Hydrochlorothiazide 12.5 mg daily	Metoprolol 50 mg daily	Felodipine SR 2.5 mg daily	Perindopril 2.5 mg daily	Irbesartan 150 mg daily
Indapamide(SR) 1.5 mg or 2.5 mg daily	Pindolol 5 mg daily Propranolol 40 mg daily	Lercanidipine 10 mg daily Nifedipine CR 20 mg daily Nimodipine CR 20 mg daily	Ramipril 2.5 mg daily Cilazapril 1 mg daily Fosinopril 10 mg daily Quinapril 5 mg daily Trandolapril 1 mg daily	Losartan 50 mg daily Olmesartan 10 mg daily Telmisartan 40 mg daily Valsartan 80 mg daily
		<i>Non-dihydropyridine</i> Diltiazem CD 180 mg daily Verapamil SR 120–180 mg daily		
Recommended in				
Heart failure (mild)	Anxious patient	Asthma	Heart failure	Heart failure
Older patients	Young patients	Angina	PVD	Diabetes
	Angina	PVD	Diabetes	PVD
	Postmyocardial infarction	Raynaud phenomenon	Raynaud	
	Migraine			
Contraindications				
Type 2 diabetics	Asthma COPD	Heart block 2nd and 3rd degree	Bilateral kidney artery stenosis	Pregnancy (first trimester)
Hyperuricaemia	History of wheeze	Heart failure	Pregnancy	Severe kidney failure
Kidney failure	Heart failure	(verapamil, diltiazem)	Hyperkalaemia	
	Heart block (2nd and 3rd degree)			
	PVD			
	Brittle type I diabetes			
Precautions				
Hypokalaemia	Avoid abrupt cessation with angina	With $\beta$ -blockers and digoxin CCF	Chronic kidney disease	Electrolyte imbalance
Thiazides + ACE inhibitors	Use with verapamil		Avoid K-sparing diuretics and NSAIDs	Renal impairment
Kidney failure	Use with NSAIDs			Hepatic impairment
	Use in smokers			
Important side effects				
Rashes	Fatigue	Headache	Cough	Headache
Sexual dysfunction	Insomnia	Flushing	Weakness	Dizziness
Weakness	Vivid dreams	Ankle oedema	Rash	Orthostatic hypotension
Blood dyscrasias	Bronchospasm	Palpitations	Dysgeusia (taste)	Fatigue
Muscular cramps	Cold extremities	Dizziness	Hyperkalaemia	Weakness
Hypokalaemia	Sexual dysfunction	Nausea	First dose hypotension	Hyperkalaemia
Hyponatraemia	Lipid metabolism effect	Constipation (verapamil)	Angioedema	Allergies
Hyperuricaemia		Nocturia, urinary frequency		Angle closure glaucoma
Hyperglycaemia		Gum hyperplasia		
Lipid metabolism effect				

- Verapamil plus a  $\beta$ -blocker may unmask conduction abnormalities causing heart block.
- In patients with ischaemic heart disease, or susceptibility to it, treatment must not be stopped suddenly—this can precipitate angina at rest.

### Calcium-channel blockers

- These drugs reduce BP by vasodilatation.
- The properties of individual drugs vary, especially their effects on cardiac function.
- The dihydropyridine compounds (nifedipine and felodipine) tend to produce more vasodilatation and thus related side effects.
- Unlike verapamil or diltiazem (which slow the heart), dihydropyridine drugs can be used safely with a  $\beta$ -blocker.
- Verapamil is contraindicated in second and third degree heart block.
- Verapamil and diltiazem should be used with caution in patients with heart failure.
- These drugs are efficacious with ACE inhibitors,  $\beta$ -blockers, prazosin and methyldopa.

### ACE inhibitors

Angiotensin-converting enzyme is responsible for converting angiotensin I to angiotensin II (a potent vasoconstrictor and stimulator of aldosterone secretion) and for the breakdown of bradykinin (a vasodilator). ACE inhibitors are effective in the elderly; improve survival and performance status in cardiac failure; are protective of kidney function in diabetes; and are cardioprotective in postmyocardial infarction.

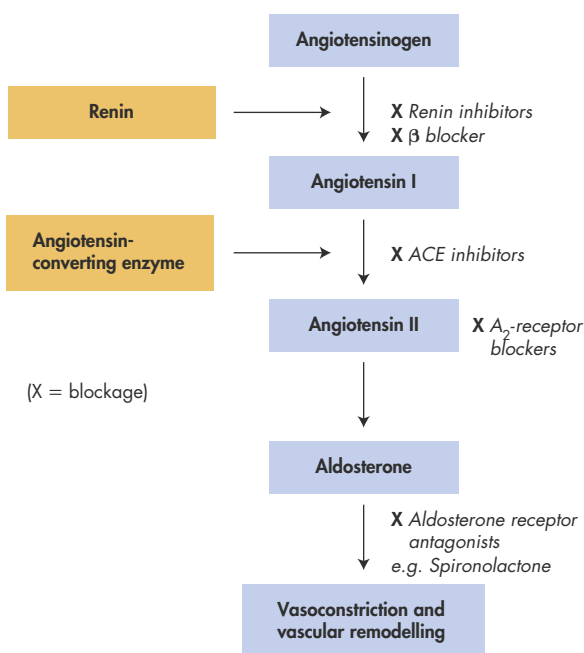

Disturbance in taste is usually transitory and may resolve with continued treatment. Cough, which occurs in about 15% of patients, may disappear with time or a reduction in dose but it often persists and requires a change in drug in some patients. Angioedema, a potentially life-threatening condition, may occur in 0.1–0.2% of subjects. Like cough, it is a class effect and will militate against use of any ACE inhibitor in patients with such an adverse effect. The Heart Outcomes Prevention Evaluation (HOPE) trial demonstrated that the ACE inhibitor ramipril reduces the number of cardiovascular deaths, non-fatal myocardial infarctions, non-fatal strokes and instances of new onset heart failure in a high-risk population. The data also indicated that all diabetic patients with microalbuminuria or pre-existing vascular disease will benefit from ACE I treatment, even if normotensive.<sup>14,16</sup>

### Angiotensin II receptor antagonists (sartans)

These agents competitively block the binding of angiotensin II to type I angiotensin receptors and block the effects of angiotensin more selectively than the ACE inhibitors. This reduces angiotensin-induced vasoconstriction, sodium reabsorption and aldosterone release. The action of the ACEIs and ARBs on the renin–angiotensin–aldosterone pathway system is illustrated in **FIGURE 86.6**. They have a similar adverse kidney profile and other adverse effects to the ACE inhibitors but cough does not appear to be a significant adverse effect. This group is used for mild-to-moderate hypertension alone or with other antihypertensive agents. They are useful alternatives for hypertensive patients who discontinue an ACE inhibitor because of cough and may be used in combination with thiazide diuretics.

### Prazosin

A specific problem of this alpha blocker is the ‘first-dose phenomenon’; this involves acute syncope about 90 minutes after the first dose, hence treatment is best initiated at bedtime. Prazosin potentiates  $\beta$ -blockers and works best if used with them. It is a useful first-line therapy in patients who are

**FIGURE 86.6** Drugs targeting the renin–angiotensin–aldosterone system

unsuitable for diuretic or  $\beta$ -blocker therapy (e.g. those with diabetes, asthma or hyperlipidaemia).

### Vascular smooth muscle relaxants

Other than calcium-channel blockers these include hydralazine, minoxidil and diazoxide, which are not used for first-line therapy but for refractory hypertensive states and hypertensive emergencies.

### Sympathetic nervous system inhibitors

A newer class of antihypertensive agents has been developed to reduce peripheral sympathetic activity by inhibiting the sympathetic nervous system. One example of such a central acting agent is moxonidine, which apparently stimulates the imidazoline 1 receptors in the brain to inhibit sympathetic outflow in the body. At this stage of development this class of drug is considered to be useful 'add-on' therapy.

### Hypertensive emergencies<sup>12</sup>

A hypertensive emergency occurs when high BP causes the presenting cardiovascular problem. Typical presentations of hypertensive emergencies (which are rare) include hypertensive encephalopathy, acute stroke, heart failure, dissecting aortic aneurysm and eclampsia. Symptomatically patients may present with headache and confusion.

In all such cases referral to a specialist is essential and the patient should be hospitalised immediately for monitoring and treatment. Treatment must be individualised, mindful of the nature of the underlying problem and associated disorders.

The BP lowering must be gradual because a sudden fall can precipitate a stroke. Aim to reduce the BP by no more than 25% within the first 2 hours then towards 160/100 mmHg within 2 to 6 hours.<sup>12</sup>

Such treatment is the same as for severe hypertension with a dihydropyridine CCB and/or an ACE inhibitor. Otherwise, sodium nitroprusside IV in an intensive care setting is the optimal treatment.

Magnesium sulphate reduces the risk of eclampsia and maternal death in women with pre-eclampsia (see CHAPTER 110).

### Isolated systolic hypertension<sup>1</sup>

Isolated systolic hypertension is most frequently seen in elderly people.

#### Definition

**SBP**  $\geq 140$  mmHg with a DBP  $< 90$  mmHg

Patients with isolated systolic hypertension should be treated in the same way as those with classic systolic/diastolic hypertension. Evidence that reducing isolated systolic BP decreases the mortality and morbidity risk has been demonstrated by the SHEP (systolic hypertension in the elderly) study.<sup>17</sup>

Non-pharmacological therapy should be commenced as is relevant to the patient. If drugs are used the systolic BP should be cautiously lowered to between 140 and 160 mmHg. The drugs of choice are diuretics, calcium-channel blocking agents and ACE inhibitors.

### Refractory hypertension

Refractory hypertension exists where control has not been achieved despite reasonable treatment for 3–4 months. A review of a possible secondary cause is appropriate. Consider non-compliance, sleep apnoea, hypertensive effects of other drugs and undisclosed use of alcohol and recreational drugs, also spurious factors (e.g. instrument factors such as small cuff, 'white coat' hypertension).

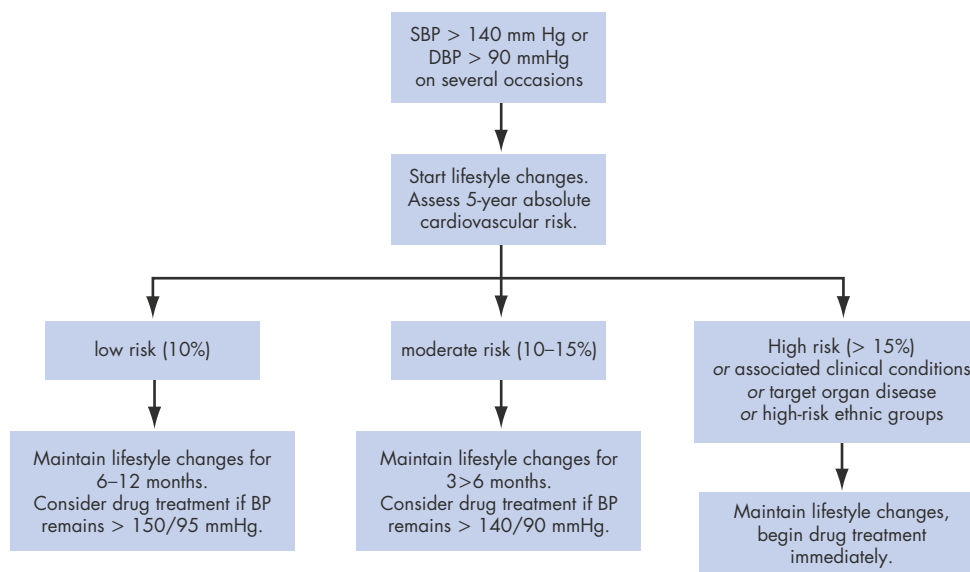

When adequate control is not possible and the cause is not obvious, the patient should be referred to a specialist. Measurement outside the clinic may help in the assessment of such people, as may 24-hour ambulatory monitoring.

### Hypertension in children and adolescents

The recording of BP should be part of the normal examination in children and used in their continuing care. BP should be measured in all children who are unwell. BP is less frequently measured in children for a number of reasons, such as the unavailability of an appropriately sized cuff or difficulty in measuring BP in the infant or toddler.

The children of parents with hypertension should be closely watched. Those at risk of secondary hypertension (e.g. kidney or cardiovascular disease, urological abnormalities and diabetes mellitus) should have routine measurements. Those children with visual changes, headache or recurrent abdominal pain or seizures, and those on drugs such as corticosteroids or the pill, should have their BP checked regularly.

Although secondary causes of hypertension are more common in children than in adults, young people are still more prone to developing essential rather than secondary hypertension. Kidney parenchymal disease and kidney artery stenosis are the major secondary causes.

**FIGURE 86.7** Decision tree for managing hypertension  
As recommended by the National Heart Foundation

The upper limits of normal BP for children in different age groups are:<sup>1</sup>

Age (in years)	Arterial pressure (mmHg)
14–18	135/90
10–13	125/85
6–9	120/80
5 or less	110/75

The proper cuff size is very important to avoid inaccurate readings and a larger rather than a smaller cuff is recommended. The width of the bladder should cover 75% of the upper arm. In infants and toddlers, use of an electronic unit may be necessary. Although cessation of sound (phase 5) is the better reflection of true diastolic pressure, there is often no disappearance of sound in children and so estimation of the point of muffling has to be recorded.

Diagnostic evaluation and drug treatment for children are similar to those for adults. When a child is obese, reduction in weight may adequately lower BP. ACE inhibitors or calcium-channel blocking agents are preferable in the young hypertensive, with diuretics a second agent. ACE inhibitors should be avoided in postpubertal girls.

## Hypertension in the elderly

BP shows a gradual increasing linear relationship with age.

## Guidelines for treatment

- Isolated systolic hypertension is worth treating.<sup>17</sup>
- Older patients may respond to non-pharmacological treatment.
- Reducing dietary sodium is more beneficial than with younger patients.
- If drug treatment is necessary, commence with half the normal recommended adult dosage—‘start low and go slow’.
- Patients over 70 years and in good health should be treated the same as younger patients.
- A gradual reduction in BP is recommended.
- Drug reactions are a limiting factor.
- Drug interactions are also a problem: these include NSAIDs, antiparkinson drugs and phenothiazines.

## Specific treatment

- *First-line choice:* indapamide (preferred) or thiazide diuretic (low dose);<sup>1</sup> check electrolytes in 2–4 weeks: if hypokalaemia develops add a K-sparing diuretic rather than K supplements. Use a combination thiazide and K-sparing diuretic. Diuretics may aggravate bladder difficulties (e.g. incontinence).
- *Second line choice:* ACE (or ARB) inhibitors (especially with heart failure)

Other effective drugs (especially for isolated systolic hypertension):

- $\beta$ -blockers (low dose) where diuretic cannot be prescribed or if angina

- calcium-channel blockers

Both these groups are generally well tolerated but constipation may be a problem with verapamil.

Kidney function and electrolytes should be monitored when ACE inhibitors are started.

## Special management problems

These conditions are summarised in TABLE 86.9.

## Step-down treatment of mild hypertension<sup>7</sup>

This is an important concept that recognises that drug treatment need not necessarily be lifelong. If BP has been well controlled for several months to years it is often worth reducing the dosage or the number of drugs.

A 'drug holiday' (cessation of treatment) can be hazardous, however, because satisfactory control may be temporary and hypertension will re-emerge. Careful monitoring under such circumstances is mandatory.

## When to refer<sup>4</sup>

- Refractory hypertension—adequate control not possible and cause not obvious
- Suspected 'white coat' hypertension—for ambulatory BP monitoring
- Severe hypertension—diastolic BP >115 mmHg
- Hypertensive emergency
- If there is evidence of ongoing target organ impairment
- If there is significant kidney impairment eGFR <60 mL/min
- If a treatable cause of secondary hypertension is found

## Practice tips

- Hypertension should not be diagnosed on a single reading.
- At least two follow-up measurements with average systolic pressure >140 mmHg or diastolic pressures >90 mmHg are required for the diagnosis.

Table 86.9 Choice of drugs in patients with coexisting conditions

	Diuretic	ACE inhibitors ARBs	Calcium-channel blockers	β-blockers
Asthma/COPD	✓	✓	✓	X Caution
Bowel disease/constipation	X	✓	X	X
Bradycardia/heart block	✓	✓	Care	X
Cardiac failure	✓*	✓*	Care	X
Depression	✓	✓	✓ Care	X
Diabetes	X	✓*	✓	X Care
Dyslipidaemia	X	✓	✓	X
Hyperuricaemia/gout	X	✓*	✓*	X
Impotence	X	✓	✓	X
Ischaemic heart disease	✓	✓	✓*	✓*
Peripheral vascular disease	✓	✓	✓*	X
Pregnancy	X	X	✓	✓ Not in late term
Raynaud phenomenon	✓	✓	✓*	X
Kidney artery stenosis	✓	X	✓* Care	✓* Care
Kidney failure	✓	Care	✓	✓
Tachycardia (resting)	X	X	Care	✓*

\*Drugs of choice. Calcium-channel blockers need to be selected with care—some are suitable, others not.

- Beware of using  $\beta$ -blockers in a patient with a history of wheezing.
- Add only one agent at a time and wait about 4 weeks between dosage adjustments.
- Excessive intake of alcohol can cause hypertension and hypertension refractory to treatment.
- If hypertension fails to respond to therapy, an underlying kidney or adrenal lesion may have been missed.
- The low-pitched bruits of kidney artery stenosis are best heard by placing the diaphragm of the stethoscope firmly in the epigastric area.
- Older patients may respond better to diuretics, calcium-channel blockers and ACE inhibitors.
- Younger patients may respond better to  $\beta$ -blockers or ACE inhibitors.

*The landmark Scandinavian Simvastatin Survival Study (4S) published in 1994, may well be remembered as the study that finally put to rest many of the apprehensions and misconceptions regarding lipid-lowering therapy.*

Duffy and Meredith 1996<sup>1</sup>

Dyslipidaemia is the presence of an abnormal lipid/lipoprotein profile in the serum and can be classified as:

- predominant hypertriglyceridaemia
- predominant hypercholesterolaemia
- mixed pattern with elevation of both cholesterol and triglyceride (TG)

Modern epidemiological studies have established the facts that elevated plasma cholesterol causes pathological changes in the arterial wall leading to CAD, and that lipid-lowering therapy results in reduction of coronary and cerebrovascular events with improved survival.

These studies, which can be summarised by their acronyms—4S,<sup>2</sup> PLACI,<sup>3</sup> PLACII,<sup>4</sup> ACAPS,<sup>5</sup> KAPS<sup>6</sup> and REGRESS<sup>7</sup>—all reinforce the benefits of lipid-lowering therapy for dyslipidaemia and the primary prevention of coronary heart disease (CHD).

One systematic review showed that statins and n-3 fatty acids are the most favourable lipid-lowering interventions, with reduced risks of overall and cardiac mortality.<sup>8</sup>

The main focus of treatment will be on primary dyslipidaemia but secondary causes (see TABLE 87.1) also need to be addressed. LDL-C is the lipid with the highest correlation with CHD.

### Established facts<sup>9,10,11</sup>

- Major risk factors for CAD include:
  - increased LDL cholesterol + reduced HDL cholesterol
  - ratio LDL-C:HDL-C >4
- Risk increases with increasing cholesterol levels (90% if >7.8 mmol/L)
- TG levels >10 mmol/L increases risk of pancreatitis
- Management should be correlated with risk factors
- 10% reduction of total cholesterol gives 20% reduction in CAD after 3 years

- LDL-C reduction with statin therapy reduces heart attacks, stroke, the need for revascularisation and death

**Table 87.1** Common causes of secondary dyslipidaemia

Hypothyroidism  
Nephrotic syndrome  
Type 2 diabetes  
Cholestasis  
Anorexia nervosa  
Obesity  
Kidney impairment  
Alcohol excess  
Obstructive liver disease

### Investigations<sup>10</sup>

The following fasting tests are recommended in all adult patients 18 years and over:

- serum triglyceride level
- serum cholesterol level and HDL-C and LDL-C levels if cholesterol  $\geq 5.5$  mmol/L
- TFTs if overweight elderly female

Confirm an initial high result with a second test at 6–8 weeks. Patients requiring treatment are summarised in TABLE 87.2. Testing should occur at least every 5 years.

### Recommended treatment goals

- Total cholesterol <4.0 mmol/L
- LDL-C <2.0 mmol/L\*
- HDL-C  $\geq 1.0$  mmol/L
- non-HDL-C <2.5 mmol/L
- TG <2 mmol/L

Treat all risk factors.

\* <1.8 in high-risk patients following a cardiac event (NHF/CSANZ guidelines)

**Table 87.2** Patients requiring treatment (National Heart Foundation and PBS guidelines)<sup>9</sup>

Risk category	Initiate drug therapy if lipid level (mmol/L) is	Target levels
Patients with existing coronary heart disease	Cholesterol >4 mmol/L	Cholesterol <4 mmol/L
Other patients at high risk with one or more of the following: <ul style="list-style-type: none"> <li>• diabetes mellitus</li> <li>• familial hypercholesterolaemia</li> <li>• family history of coronary heart disease (first degree relative less than 60 years of age)</li> <li>• hypertension</li> <li>• peripheral vascular disease</li> </ul>	Cholesterol >6.5 mmol/L or Cholesterol >5.5 mmol/L and HDL <1 mmol/L	LDL cholesterol <2 mmol/L  HDL cholesterol >1.0 mmol/L
Patients with HDL <1 mmol/L	Cholesterol >6.5 mmol/L	Triglycerides <1.8 mmol/L
Patients not eligible under the above: <ul style="list-style-type: none"> <li>• men 35–75 years</li> <li>• postmenopausal women up to 75 years</li> </ul>	Cholesterol >7.5 mmol/L or Triglyceride >4 mmol/L	
Other patients not included in the above	Cholesterol >9 mmol/L or Triglyceride >8 mmol/L	

## Non-pharmacological measures

- Dietary measures:
  - keep to ideal weight
  - reduce fat intake, especially dairy products and meat
  - avoid fast foods and deep-fried foods
  - replace saturated fats with mono or polyunsaturated fats
  - limit high-cholesterol foods (e.g. egg yolk, offal, fish roe)
  - use approved cooking methods (e.g. steaming, grilling)
  - always trim fat off meat, remove skin from chicken
  - avoid biscuits and cakes between meals
  - eat fish at least twice a week
  - high-fibre diet, especially fruit and vegetables
  - increase complex carbohydrates
  - alcohol intake 0–2 standard drinks/day
  - drink more water
- Regular exercise
- Cessation of smoking
- Cooperation of family is essential
- Exclude secondary causes (e.g. kidney disease, type 2 diabetes, hypothyroidism, obesity, alcohol excess—especially ↑ TG), specific diuretics

## Checkpoints

- Diet therapy effective (TG ↓, LDL-C ↓) within 6–8 weeks
- Continue at least 6 months before considering drug therapy in all but the highest-risk category

## Pharmacological measures

The choice of the lipid-lowering agent depends on the pattern of the lipid disorder.<sup>10,11</sup> See **TABLE 87.3**. Use the following agents in addition to diet.

Treatment should commence with a statin. If LDL-C levels are not reduced to target levels or a maximally tolerated dose on a statin, add one of ezetimibe,<sup>12</sup> bile acid binding resin or nicotinic acid. These agents can be used as monotherapy if statins cannot be tolerated.

## Hypercholesterolaemia especially ↑ LDL-C

Choose from the following.<sup>11</sup>

### First-line agent

- 1 HMG-CoA reductase inhibitors (statins—see **TABLE 87.3**)
  - adverse effects: GIT side effects, myalgia, abnormal liver function (uncommon)
  - monitor: measure LFTs (ALT and CPK) and CK as baseline

**Table 87.3** Lipid-lowering drugs

Drug	Dose (average)	Usage	Adverse effects	Safety monitoring
The statins	Dose range from starting			
Atorvastatin	10–80 mg	↑ cholesterol	Muscle pains, raised liver enzymes	Liver enzymes: creatine kinase and ALT
Pravastatin	20–80 mg			
Simvastatin	10–80 mg			
Fluvastatin	20–80 mg			
Rosuvastatin	5–40 mg			
Bile acid binding resins				
Cholestyramine	8 g bd	↑ cholesterol	GIT dysfunction, drug interactions	
Colestipol	10 g bd			
Fibrates				
Gemfibrozil	600 mg bd	↑ triglycerides mixed	GIT dysfunction, myositis, interaction with statins and warfarin	Liver enzymes
Fenofibrate	145 mg daily	hyperlipidaemia		coagulation
Other agents				
Ezetimibe	10 mg daily	↑ cholesterol	Arthralgia, myalgia, myositis, liver dysfunction	Liver enzymes
Nicotinic acid	100 mg tds to 500 mg tds	↑ cholesterol and triglycerides	Flushing, raised glucose, urate and liver enzymes	Glucose urate Liver enzymes
Fish oils n-3 fatty acids	2 g daily	↑ triglycerides	Minimal	Bleeding time

- repeat LFTs after 4–8 weeks, then every 6 weeks for 6 months

Additional drug therapy:

- 2 Ezetimibe 10 mg daily (especially if statin-intolerant)
- 3 Combination: ezetimibe + statin (especially if cholesterol below target)
- 4 Bile acid binding resins:
  - e.g. cholestyramine 4 g daily in fruit juice increasing to maximum tolerated dose
  - adverse effects: GIT side effects (e.g. constipation, offensive wind)
- 5 Fibrates: consider if above drugs not tolerated
- 6 Nicotinic acid
  - nicotinic acid 250 mg (o) bd with food daily, increase gradually to max. 1000 mg tds if necessary
  - adverse effects: flushing, gastric irritation, gout

- minimise side effects with gradual introduction; take with food and aspirin cover

### Resistant LDL-C elevation

- 1 Combination statin + ezetimibe
- 2 Combined statin and resin cholestyramine 4–8 g (o) mane  
*plus*  
a statin

### Moderate to severe (isolated or predominant) TG elevation<sup>11</sup>

Fibrate:

gemfibrozil 600 mg (o) bd  
*or*  
fenofibrate 145 mg (o) daily

*Note:* Slow response; monitor LFTs; predisposes to gallstones and myopathy.

and/or

n-3 fish oil concentrate 6 g (o) daily in divided doses to max. 15 g/day

add

nicotinic acid if insufficient response

*Note:* Reduction in alcohol intake is important.

## Massive hypertriglyceridaemia (TG) 10 mmol/L:

- fibrate plus fish oil plus (if necessary) nicotinic acid

## Mixed hyperlipidaemia (↑ TG + ↑ LDL-C)

- If TG <4: a statin
- If TG >4: a fibrate

Consider combination therapy, e.g.:

- fish oil + 'statin'
- fibrate + resin

*Note:* Statin + gemfibrozil increases risk of myopathy and requires specialised supervision.

## Special considerations

The decision to commence drug therapy should be based on at least two separate measurements at an accredited laboratory.

Be careful with β-blockers and diuretics affecting lipid levels.

## Length of treatment

- Possibly lifelong (up to 75 years)

## Follow-up investigations

- Serum lipids
- LFTs (ALT and CPK)
- Possibly CK

## Special groups

### Children

In general there is little justification for using lipid-regulating drugs in children, especially as the drugs have been shown to reduce heart disease within 2–5 years in adults.<sup>11</sup> Initial dietary advice and avoidance of smoking is recommended. Bile acid binding resins are safe to use.

## The elderly<sup>10</sup>

The role of lipid therapy remains unclear. Generally, elderly patients with established CHD should receive standard lipid management unless their general medical status is poor.

## Pregnancy<sup>11</sup>

As a general rule the increase in cholesterol level associated with pregnancy subsides after delivery. Systemically absorbed lipid-lowering agents may be unsafe during pregnancy and should be avoided.

## Complementary therapy

Claims have been made for the cholesterol-lowering properties of policosanols (derived from sugar cane), fish oils, plant sterols, vitamin E, garlic and lecithin. The evidence from RCTs to date indicates a modest benefit from policosanols, fish oils (consuming a fish-based meal at least twice a week is recommended) and plant sterols but there is insufficient evidence to recommend vitamin E, garlic and lecithin.<sup>13</sup>

*In the year 1775 my opinion was asked concerning a family recipe for the cure of the dropsy. I was told that it had long been kept a secret by an old woman in Shropshire who had sometimes made cures after the more regular practitioners had failed—this medicine was composed of twenty or more different herbs and the active herb could be no other than the Foxglove.*

William Withering (1741–99), *On the Use of Foxglove (Digitalis) in the Treatment of Heart Disease*

Heart failure occurs when the heart is unable to maintain sufficient cardiac output to meet the demands of the body for blood supply during rest and activity.

Chronic heart failure (CHF) remains a very serious problem with a poor prognosis. It has a 50% mortality within 3 years of the first hospital admission.<sup>1</sup> Overseas data indicate that 1.5% of the adult population have heart failure. The prevalence of CHF has been shown to increase from approximately 1% in those aged 50–59 years to over 5% in those 65 and older, to over 50% in those 85 years and older.<sup>2</sup> Australian research suggests that under-treatment with the all-important ACE inhibitors continues to be a problem. ACE inhibitors (or ARBs) and  $\beta$ -blockers are the gold standard for treating systolic heart failure, with aldosterone antagonists providing added benefit if symptoms persist.<sup>3</sup> A major goal of management of CHF is the identification and reversal where possible of underlying causes and/or precipitating factors. CHF is characterised by two pathophysiological factors: fluid retention and reduction in cardiac output.

## Diagnosis

The classic symptom of CHF is dyspnoea on exertion but symptoms may be reported relatively late, mainly due to a sedentary lifestyle. Dyspnoea can progress as follows: exertional dyspnoea → dyspnoea at rest → orthopnoea → paroxysmal nocturnal dyspnoea.

## Symptoms in summary

- Dyspnoea (as above)
- Irritating cough (especially at night)
- Lethargy/fatigue
- Weight change: gain or loss
- Dizzy spells/syncope

- Abdominal discomfort
- Palpitations
- Ankle oedema

The irritating cough due to left ventricular failure can be mistaken for asthma, bronchitis or ACE-inhibitor-induced cough.

## Examination

The physical examination is very important for the initial diagnosis and evaluation of progress. The signs are as follows.

## Signs

There may be no abnormal signs initially. It is helpful clinically to differentiate between the signs of right and left heart failure:

### Left heart failure

- Tachycardia
- Low volume pulse
- Tachypnoea
- Laterally displaced apex beat
- Bilateral basal crackles
- Gallop rhythm (3rd heart sound)
- Pleural effusion
- Poor peripheral perfusion

### Right heart failure

- Elevated jugular venous pressure
- Right ventricular heave
- Peripheral/ankle oedema
- Hepatomegaly
- Ascites

Auscultation is important to identify adventitious sounds, a third heart sound and possible underlying valvular disease.

## Systolic versus diastolic heart failure

The classic heart failure is systolic failure due to an inadequate pumping action of the heart. The ventricle is dilated and contracting poorly (left ventricular ejection fraction <40%).<sup>4</sup>

However, diastolic heart failure, which is being recognised more widely, is due to impairment of left ventricular filling with preserved systolic function. At least one-third to half of heart failure presentations are due to diastolic heart failure (impaired ventricular relaxation).<sup>2</sup> It should be suspected in the elderly with hypertension and a normal heart size on chest X-ray who present with dyspnoea or pulmonary oedema.<sup>3</sup>

It is particularly common in elderly females.

Note that patients can have simultaneous systolic and diastolic failure.

## The oedema of heart failure

Peripheral oedema appears initially on the lower legs as 'pitting'. To assess the presence of pitting, which is usually graded on a four-point scale, press firmly yet gently with the thumb for 5–10 seconds over the dorsum of the feet, behind each medial malleolus and over the shins. With increasing severity of failure the oedema extends proximally to involve the abdomen. In the recumbent position it may be apparent over the sacrum.<sup>5</sup>

## Determining severity of heart failure

The severity of heart failure can be considered from three different perspectives: the severity of the symptoms, the degree of impairment of cardiac function and the severity of the congestive state. The severity of the symptoms or the degree of functional disability is usually described according to the New York Heart Association criteria (see TABLE 88.1).<sup>6</sup> The left ventricular ejection fraction provides an indication of cardiac function.

## Causes of heart failure

Causes of CHF can be classified under systolic heart failure (impaired ventricular contraction) and diastolic heart failure (impaired ventricular relaxation). Diagnosis is based on echocardiography.

## Systolic heart failure

Ischaemic heart disease, including previous myocardial infarction, is the most common cause, accounting for approximately three-quarters. There is often a history of at least one myocardial infarction.<sup>2</sup> Essential hypertension is the other common cause.

Other causes:

- valvular heart disease, mainly aortic and mitral incompetence
- high output states (e.g. anaemia, hyperthyroidism, Paget disease)
- non-ischaemic idiopathic dilated cardiomyopathy
- viral cardiomyopathy
- alcoholic cardiomyopathy
- other cardiomyopathies—diabetic, familial
- persistent arrhythmias, especially atrial fibrillation
- other systemic illness (e.g. sarcoidosis, scleroderma, myxoedema)

## Diastolic heart failure

Obesity, hypertension and diabetes are significant risk factors. Common causes include ischaemic heart disease, systemic hypertension, aortic stenosis, atrial fibrillation (inadequate filling), hypertrophic cardiomyopathy and pericardial disease.

## Investigations

The following should be considered:

- Echocardiography<sup>2</sup>

**Table 88.1** New York Heart Association (NYHA) functional classification of CHF symptoms<sup>2,6</sup>

Class	Disability	Approximate 1-year mortalities
I (asymptomatic)	No limitation: cardiac disease present, but ordinary physical activity causes no symptoms such as fatigue, dyspnoea or palpitation, or rapid forceful breathing	5%
II (mild)	Slight limitation: ordinary activity (moderate exertion) causes symptoms but patients comfortable at rest	10%
III (moderate)	Marked limitation: symptoms with less than ordinary physical activity (mild exertion) although patients still comfortable at rest	20%
IV (severe)	Unable to carry out any physical activity without symptoms; may have symptoms at rest	50%

The transthoracic echocardiogram is the investigation of choice to measure ventricular function. It can differentiate between systolic dysfunction and those with normal systolic function but abnormal diastolic filling. It gives information about left and right ventricular systolic and ventricular diastolic function, left and right ventricular size, volumes, thickness, structure and function. Similarly it provides other information about cardiac valves, congenital heart defects and pericardial disease.

- Electrocardiogram—a key investigation to look for evidence of ischaemia, conduction abnormalities, arrhythmias and LV hypertrophy
- Chest X-ray to look for:
  - cardiomegaly and interstitial oedema
  - upper lobe blood diversion
  - fluid in fissures
  - oedema in perihilar area with prominent vascular markings
  - small basal pleural effusions
  - Kerley B lines = raised pulmonary venous pressure
  - frank pulmonary oedema (A normal CXR does not exclude CHF.)
- Spirometry/respiratory function testing: to detect associated airways dysfunction
- B type natriuretic peptide: a hormone secreted from the ventricular myocardium is an indicator of severity of CHF and prognosis

### Peripheral markers

- FBE and ESR: anaemia can occur with CHF; severe anaemia may cause CHF
- Serum electrolytes: usually normal in CHF, important to monitor management
- Kidney function tests: for monitoring drug therapy
- Liver function tests: congestive hepatomegaly gives abnormal LFTs
- Urinalysis
- Thyroid function tests, especially if atrial fibrillation
- Viral studies: for suspected viral myocarditis

### Specialised cardiac investigation (specialist directive)

- Coronary angiography—for suspected and known ischaemia. CT angiography and cardiovascular MRI preferred
- Haemodynamic testing
- Endomyocardial biopsy
- Nuclear cardiology

## Treatment of heart failure

The treatment of heart failure includes determination and treatment of the cause, removal of any precipitating factors, appropriate patient education, general non-pharmaceutical measures and drug treatment. Studies have shown the benefit of an integrated, multidisciplinary approach to management.

### Prevention of heart failure

The emphasis on prevention is very important since the onset of heart failure is generally associated with a very poor prognosis. Approximately 50% of patients with heart failure die within 5 years of diagnosis.<sup>7</sup>

The scope for prevention includes the following measures:<sup>8</sup>

- dietary advice (e.g. achievement of ideal weight, optimal nutrition)
- emphasising the dangers of smoking and excessive alcohol
- control of hypertension
- control of other risk factors (e.g. hypercholesterolaemia)
- early detection and control of diabetes mellitus
- early intervention of myocardial infarction to preserve myocardial function (e.g. thrombolytic therapy, stenting)
- secondary prevention after the occurrence of myocardial infarction (e.g. beta blockers, ACE inhibitors and aspirin)
- appropriate timing of surgery or angioplasty for ischaemic or valvular heart disease

### Treatment of causes and precipitating factors

Determination and treatment of the causes has been largely covered in the section on prevention. Precipitating factors that should be treated include:

- arrhythmias (e.g. atrial fibrillation)
- electrolyte imbalance, especially hypokalaemia
- anaemia
- myocardial ischaemia, especially myocardial infarction
- dietary factors (e.g. malnutrition, excessive salt or alcohol intake)
- adverse drug reactions (e.g. fluid retention with NSAIDs and COX-2 agents) (see TABLE 88.2)<sup>9</sup>
- infection (e.g. bronchopneumonia, endocarditis)
- hyper- and hypothyroidism
- lack of compliance with therapy
- fluid overload

**Table 88.2** Drugs that can aggravate CHF

NSAIDs including COX-2 inhibitors
Corticosteroids
Tricyclic antidepressants
Calcium-channel blockers (verapamil and diltiazem)
Selected anti-arrhythmics (e.g. quinidine)
Macrolide antibiotic
Type 1 antihistamines
H <sub>2</sub> -receptor antagonists
Thiazolidinediones (glitazones)
TNF-alpha inhibitors
Ethanol or illicit drug (e.g. cocaine) use

88

## General non-pharmacological management

- Education and support
- Smoking: encourage no smoking
- Refer for a rehabilitation program with interdisciplinary care
- Encourage physical activity especially when symptoms absent or mild
- Rest if symptoms are severe
- Weight reduction, if patient obese
- Advice on food supplementation—dietician
- Salt restriction: advise no-added-salt diet (<2 g or 60–100 mmol/day)
- Water restriction: water intake should be limited to 1.5 L/day or less in patients with advanced heart failure, especially when the serum sodium level falls below 130 mmol/day<sup>7</sup>
- Limit caffeine to 1–2 cups coffee/tea a day
- Limit alcohol to 1 Standard drink a day
- Fluid aspiration if a pleural effusion or pericardial effusion if present
- Daily weighing—check significant weight gain or loss

## Other general measures<sup>1</sup>

- Optimise cardiovascular risk factors (e.g. BP, lipids, HbA<sub>1c</sub>)
- Monitor emotional factors including depression
- Regular review
- Vaccination: annual influenza, 5-yearly pneumococcus
- 2-yearly echocardiography (or more) as indicated
- pleurocentesis or pericardiocentesis (if applicable)

## Drug therapy of heart failure due to left ventricular systolic dysfunction

Any identified underlying factor should be treated.

Evidence from RCTs shows the beneficial results from ACE inhibitors,<sup>2,9</sup> (or angiotensin II blockers), digoxin (improves outcome in people already receiving diuretics and ACE inhibitors), beta blockers and spironolactone (in severe heart failure).

Atrial fibrillation should be treated with digoxin. Vasodilators are widely used for heart failure and angiotensin converting enzyme inhibitors (ACEI) are currently the most favoured vasodilator.

*Note:* Monitor and maintain normal potassium level in all patients.

ACE inhibitors improve prognosis in all grades of heart failure and should be employed as the initial therapy in all patients, except where they are contraindicated (e.g. kidney artery stenosis, angioedema).

Diuretics have an important place in patients with fluid overload. As a rule they should be added to an ACEI to achieve euvolaemia. Diuretics should be used in moderation and excessive doses of a single drug avoided. In patients with systolic LV dysfunction they should not be used as monotherapy.<sup>8</sup> Close monitoring of weight, kidney function and electrolytes is required. Loop diuretics such as frusemide, bumetanide or ethacrynic acid are commonly used, especially for heart failure of moderate severity.<sup>8</sup> Thiazide and related diuretics produce a gradual diuresis and are recommended for mild heart failure. Examples include hydrochlorothiazide, bendroflumazide, chlorthalidone or indapamide.

Digoxin has two indications for its use in CHF leading to improved symptoms, namely heart failure and atrial fibrillation to control ventricular rate and in heart failure and sinus rhythm to relieve symptoms not controlled by the three first-line drugs.

## Initial therapy of heart failure<sup>7,10</sup>

- 1 ACE inhibitor (start low, aim high)  
Dosage of ACE inhibitor: commence with  $\frac{1}{4}$  to  $\frac{1}{2}$  lowest recommended therapeutic dose and then adjust it for the individual patient by gradually increasing it to the maintenance or maximum dose (see TABLE 88.3). Once-daily agents are preferred. Use an ARB if cough is problematic.

## ACE inhibitors

- ACE inhibitors are regarded as the agents of first choice because they correct neuroendocrine abnormalities and reduce cardiac load by their vasodilator action.

**Table 88.3** Some ACE inhibitors in common usage<sup>6</sup>

ACE inhibitor	Initial daily dose	Usual maintenance daily dose
Captopril	6.25 mg (o) nocte	25 mg (o) tds
Enalapril	2.5 mg (o) nocte	10 mg (o) bd
Fosinopril	5 mg (o) nocte	20 mg (o) nocte
Lisinopril	2.5 mg (o) nocte	5–20 mg (o) nocte
Perindopril	2 mg (o) nocte	4 mg (o) nocte
Quinapril	2.5 mg (o) nocte	20 mg (o) nocte
Ramipril	1.25 mg (o) nocte	5 mg (o) nocte
Trandolapril	0.5 mg (o) nocte	2–4 mg (o) daily

- Every effort should be made to up-titrate to the highest tolerated dose.
  - The first dose should be given at bedtime to minimise orthostatic hypotension.
  - If the ACEI is not tolerated (e.g. due to cough) consider an angiotensin II receptor blocker (ARB) as they have proven benefit in CHF.<sup>11</sup>
  - In practice the usual initial treatment of heart failure is an ACE inhibitor plus diuretic. This combination optimises response and improves diuretic safety.
  - Consider stopping any diuretic for 24 hours before starting treatment with an ACEI.
  - Potassium-sparing diuretics or supplements should not be given with (or should at least be used with caution) ACEI because of the danger of hyperkalaemia.
  - Kidney function and potassium levels should be monitored in all patients.
- 2 Add a diuretic (if congestion):
- loop diuretic (preferred)  
frusemide 20–40 mg (o) once or twice daily  
*or*  
bumetanide 0.5–1 mg (o) daily  
*or*  
ethacrynic acid 50 mg (o) daily  
*or*  
(thiazide-type diuretic)  
hydrochlorothiazide 25–50 mg (o) daily (or other thiazide)  
*or*  
indapamide 1.5–2.5 mg(o) daily

- 3 Add an aldosterone antagonist diuretic (if fluid overload not controlled):

spironolactone 12.5–50 mg (o) daily  
*or*  
eplerenone 25–50 mg (o) daily

Some authorities are concerned about the over-reliance on diuretics and also about compliance as well as side effects. Once the diuretic effect has been achieved, diuretics may be withdrawn and fluid restriction advised. The ACEI is then used alone or with a beta blocker.

### Beta blockers

Selective beta blockers have been shown to prolong survival of patients with mild to moderate CHF taking ACE inhibitors who are stabilised. Start with extremely low doses (see TABLE 88.4). Commence when patient stable and euvolaemic.

**Table 88.4** Beta blockers approved to treat heart failure

Beta blocker	Initial daily dose	Target dose
Bisoprolol	1.25 mg (o) daily	10 mg (o) daily
Carvedilol	3.125 mg (o) bd	25 mg (o) daily
Metoprolol extended release	23.75 mg (o) daily	190 mg (o) daily
Nebivolol	1.25 mg (o)	10 mg (o) daily

### Digoxin

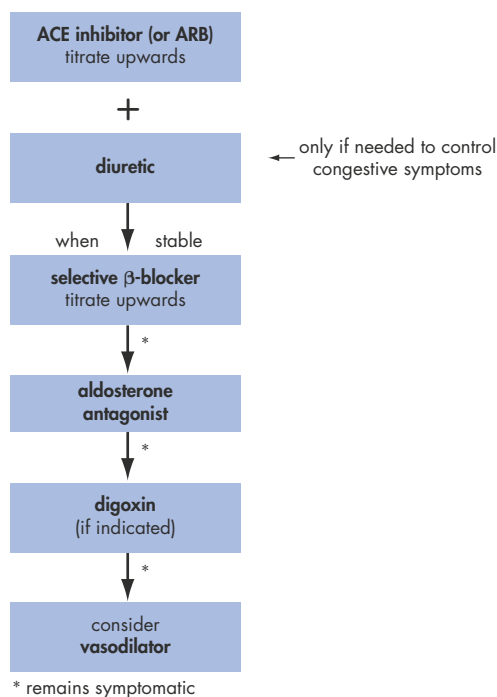

Digoxin was the mainstay of treatment of heart failure for decades prior to the use of ACE inhibitors. It was an effective agent but limited. The two indications for its current use are in patients with atrial fibrillation to control rapid ventricular rate and in patients with sinus rhythm not adequately controlled by the other agents above it in FIGURE 88.1. Most patients are started on a low dose digoxin:

62.5–250 mcg (o) daily

### Heart failure (unresponsive to first-line therapy) — stepwise strategy<sup>2,7</sup>

ACE inhibitor  
*plus*  
frusemide 40–80 mg (o) bd  
*plus*  
spironolactone 12.5 (starting)—25 mg (o) daily  
(monitor potassium and RFTs), if still congestion

**FIGURE 88.1** A stepwise pharmacological management approach to heart failure<sup>10,12</sup>

\* remains symptomatic

*plus*

a selective beta blocker (if patient euvolaemic)

*plus*

digoxin (if not already taking it):<sup>7</sup> loading dose:

- 0.5–0.75 mg (o) statim (depending on kidney function)
- then 0.5 mg (o) 4 hours later
- then 0.5 mg the following day
- then individualise maintenance

### Severe heart failure<sup>7,10</sup>

Seek specialist advice.

Hospital with bed rest.

ACE inhibitor (o) to maximum tolerated dose

*plus*

frusemide to max. 500 mg/day

*plus*

spironolactone (low dose) 25 mg/day

If poorly controlled, consider adding:

- thiazide diuretic
- spironolactone—doses up to 100–200 mg daily
- a beta blocker

- digoxin
- heparin (if confined to bed)

### Vasodilators

If still uncontrolled consider vasodilators other than ACEs or ARBs:

isosorbide dinitrate 20–40 mg (o) 6 hourly

*plus*

hydralazine 50–100 mg (o) 6 hourly

A glyceryl nitrate patch can be used for the relief of symptoms, especially nocturnal dyspnoea.

Consider cardiac transplantation for appropriate patients with end-stage heart failure (e.g. patients under 50 with no other major disease). Other surgical options include heart valvular surgery, coronary artery bypass surgery and surgical ventricular restoration (surgical reduction of an enlarged left ventricle).

A flow chart for the basic management of heart failure is presented in **FIGURE 88.1**.

### Diastolic heart failure<sup>2,8</sup>

Management is based on treating the cause such as hypertension, ischaemia and diabetes. The basic treatment is with inotropic agents such as calcium-channel blockers (verapamil or diltiazem) and beta blockers. If possible avoid diuretics (except for congestion), digoxin, nitrates/vasodilators and nifedipine. Excessive diuresis from overzealous diuretic therapy can cause severe consequences for cardiac output. ACE inhibitors can be used with caution.

### Pitfalls in management

- The most common treatment error—excessive use of diuretics<sup>3</sup>
- Giving an excessive loading dose of ACE inhibitor
- Failure to correct remedial causes or precipitating factors
- Failure to measure left ventricular function
- Failure to monitor electrolytes and kidney function

ACE inhibitors, beta blockers and spironolactone have been shown to improve survival in CHF.<sup>9</sup>

### Acute severe heart failure

For the treatment of acute pulmonary oedema refer to **CHAPTER 130**.

## Device-based heart failure treatments<sup>1</sup>

The use of mechanical devices to treat patients with severe failure is gaining momentum. They include:

- implantable cardiac defibrillators
- biventricular pacemakers
- left ventricular assist devices (definitive VentrAssist)

The evidence for the efficacy of these devices is good, but limitations include cost and infection. Biventricular pacing or cardiac resynchronisation therapy resynchronises cardiac contraction in patients with systolic CHF and left branch bundle block. VentrAssist is based on a continuous flow rotary blood pump that is surgically implanted in the abdominal wall and attached to the apex of the ventricle.

## When to refer

- Uncertainty of diagnosis, especially diastolic heart failure
- Complex management issues (especially with  $\beta$ -blockers, digoxin)
- Age <65 years
- Acute decompensation
- Refractory symptoms

## Practice tips

- Echocardiography is the gold standard for diagnosing CHF.
- Use a multidisciplinary team approach for the patient with CHF and refer early and readily for specialist advice.
- ACE inhibitors, if tolerated, are recommended for all patients with heart failure, whether symptoms are mild, moderate or severe.<sup>1</sup>
- The primary reason for prescribing an ACE inhibitor is to reduce the risk of death or hospitalisation.
- Diuretics are very effective in the presence of fluid overload, but should be used in combination with an ACE inhibitor—not as monotherapy.
- Drug treatment should include an ACE inhibitor and beta blocker wherever possible.<sup>1</sup>

- Device-based heart failure therapy is an expanding field and includes three major groups of devices: biventricular pacemakers (cardiac resynchronisation therapy), implantable cardiac defibrillators and left ventricular assist devices.<sup>1</sup>

*Like bones which, broke in sunder, and well set, knit the more strongly . . . but old bones are brittle.*

John Webster (1580–1625)

Osteoporosis, which literally means porous bone, is reduced bone mass per unit volume (see FIG. 89.1), thus predisposing the person with it to an increased risk of fracture. It also refers to the increased bone fragility that accompanies ageing and many illnesses. Following the menopause, women begin to lose calcium from their bone at a much faster rate than men, presumably as a direct response to low levels of oestrogen. Within 5–10 years of the menopause, women can be seen to suffer from osteoporosis and by the age of 65 the rate of fractures in women has increased to 3–5 times that of men.<sup>1</sup> However, a third of all hip fractures in the community occur in men.

In recent decades osteoporosis was largely prevented by correction of oestrogen deficiency through the use of hormone replacement therapy but the balance has changed since the association of HRT with breast cancer was reported.

FIGURE 89.1 Osteoporosis is reduced bone mass per unit volume

### Key facts and checkpoints

- Osteoporosis is silent, common, measurable, treatable and potentially lethal (analogous to hypertension).<sup>2</sup>
- Osteoporosis is commonest in postmenopausal women.
- Up to 50% of women will develop fractures in their lifetime and 30% of all women reaching 90 years of age will suffer a hip fracture.<sup>1,3</sup>

- Osteoporosis leads to reduced bone strength and susceptibility to fracture, even with minor trauma.
- Osteoporosis usually causes pain when complicated by fracture.
- First presentation is usually a fracture (Colles, femoral neck and vertebra) or height shrinkage.
- Vertebral collapse is the hallmark of osteoporosis.
- The disorder is of low bone mass.
- For osteoporosis in a vertebra including a pathological fracture, multiple myeloma needs exclusion.
- The first step in prevention is regular exercise, an adequate dietary intake of calcium (1500 mg per day) and maintenance of adequate serum vitamin D levels.

## Classification<sup>4</sup>

### Primary

**Type 1:** Postmenopausal (vertebral or distal forearm fractures between the ages of 51 and 75). Due to increased osteoclast activity. It is six times more common in women than men.

**Type 2:** Involutional or senile osteoporosis (fracture of proximal femur and other bones). It affects patients over 60 years and is twice as common in women as in men.

**Idiopathic osteoporosis:** Occurs in children and young adults of both sexes with normal gonadal function.

### Secondary

Secondary to various endocrine disorders, malabsorption and malignancies. Various causes and risk factors are presented in TABLE 89.1.

## Investigations

- Plain radiography is of limited value. Osteoporosis is not detectable until 40–50% of bone is lost.
- 25-hydroxy vitamin D (most useful test): normal range 75–250 nmol/L.

**Table 89.1** Osteoporosis: risk factors and/or causes<sup>3</sup>

Constitutional and non-modifiable
Female sex
Ageing
Thin build; low BMI <18; short stature
Race: Asian, Caucasian
Family history (e.g. maternal hip fracture <75 yrs)
Premenopausal oestrogen deficiency (e.g. amenorrhoea)
Late menarche
Early menopause <45 years (natural or surgical)
Modifiable lifestyle factors
Cigarette smoking
High alcohol intake >2 standard drinks per day
Low calcium intake
Lack of vitamin D
Physical inactivity
Medical causes
Eating disorders (e.g. anorexia nervosa)
Malabsorption syndrome (e.g. coeliac disease)
Endocrine disorders:
• Cushing syndrome
• diabetes mellitus
• hyperparathyroidism
• thyrotoxicosis
• amenorrhoea in elite athletes
• hypogonadism/sex hormone deficiency
• acromegaly
Connective tissue disorders (e.g. RA)
Chronic organ failure (kidney, liver, heart, lungs)
Drugs causing bone loss:
• corticosteroids
• anti-epileptic drugs, especially hepatic enzyme inducers
• thiazolidinediones for diabetes
• long-term heparin
• excessive thyroid hormone
• prostate cancer hormone therapy
• breast cancer hormone therapy
Prolonged immobilisation

- Plasma calcium, phosphate and alkaline phosphatase (usually normal).
- Thyroid stimulating hormone.
- Consider tests for multiple myeloma in an osteoporotic area.
- Densitometry can predict an increased risk of osteoporosis and fracture, the best current modality being dual energy X-ray absorptiometry (DEXA scan) in a facility with high-standard quality control.<sup>3</sup> The spine and femoral neck are targeted: the femoral neck is the most useful index.

## DEXA, T scores and Z scores<sup>5</sup>

Dual energy X-ray absorptiometry (DEXA) is the current gold standard for the diagnosis of osteoporosis. It assesses both whole-body and regional bone mass (lumbar spine and proximal femur). Bone mass is measured as bone mineral density (BMD) in g/cm<sup>2</sup> and the lower the BMD, the higher the risk of fracture. There are actually different normal ranges of BMD for each bone and for each type of DEXA measuring machine.

The BMD 'T score' is the number of standard deviations (SD) away from the mean BMD of a 30-year-old adult (see **TABLE 89.2**). Osteopenia (low bone density) is 1–2.5 SDs below the young adult standard mean. Osteoporosis is >2.5 SD below this mean. This is a strong indicator of bone fragility. Consider treatment if T score is <−2.5.

**Table 89.2** Interpretation of T scores (WHO criteria)

T score	Interpretation
≥ −1.0	Normal
−1 to −2.5	Osteopenia
≤ −2.5	Osteoporosis
<−2.5 with fracture	Severe osteoporosis

The BMD 'Z score' is the number of SDs away from the age- and sex-matched mean BMD. The Z score is used to express bone density in patients <50 years, premenopausal women, younger men and children. If low (<−2) it indicates prompt investigation for underlying causes of a bone deficit.

BMD is recommended for healthy women aged over 50 with all the risk factors for osteoporosis of:

- postmenopause
- fracture after age 40 with minimal trauma
- family history of osteoporosis, smoking habit or low BMI (<18)<sup>2</sup>

## Treatment

The goal of treatment is to prevent osteoporosis or reduce further loss. Eliminate risk factors where possible and focus on optimal lifestyle measures as a baseline for management. No treatment has been shown to replace lost bone effectively. Anabolic agents such as nandrolone decanoate may reduce further loss but the side effects are problematic.

## Medications of value in decreasing further loss<sup>3</sup>

The following medications may be valuable in preventing further bone loss, possibly reversing the osteoporosis process and preventing further fractures.

- HRT (long-term use is not recommended but weigh potential benefits versus harms with the patient)  
or
- bisphosphonates (decrease bone absorption)<sup>3</sup>—can be used alone or combined with other agents (take care with potential adverse effects of oesophagitis and osteonecrosis of jaw):
  - alendronate 10 mg (o) daily or 70 mg (o) once weekly (take care with potential side effect of oesophagitis)
  - etidronate 400 mg (o) for 14 days then calcium carbonate 1250 mg (o) for 76 days
  - risedronate 5 mg (o) daily or 150 mg (o) once monthly or 35 mg (o) once weekly or in combination therapy with calcium carbonate  $\pm$  vitamin D

- zoledronic acid, single annual IV injection
- raloxifene (a selective oestrogen-receptor modulator) (SERM) 60 mg (o) daily
- strontium ranelate (uncouples bone resorption and formation):
  - 2 g (o), as a powder in water, daily (nocte). Reported adverse effects include vascular complications—to be used with caution in patients with vascular disease and renal impairment
- teriparatide (a synthetic form of human parathyroid hormone) increases bone formation. Give 20 mcg SC once daily
- denosumab (a monoclonal antibody) 60 mg SC, once every 6 months, once calcium intake and vitamin D levels are optimal. It is a potential risk factor for osteonecrosis of the jaw especially in patients with bone cancer

The choice depends on the clinical status, such as the age of the patient and the extent of disease, the patient's tolerance of drugs and further clinical trials of these drugs. The one preferable solution is to give prophylaxis for individuals identified as high risk and the only widely accepted proven therapy is oestrogen therapy but it has limitations.

## Recommendations for prevention<sup>6,7</sup>

- Adequate dietary intake of calcium: 1200–1300 mg per day in both men and women. Dairy food is the main source of dietary calcium.<sup>2</sup> Calcium-rich foods include low-fat calcium-enriched milk (500 mL contains 1000 mg), other low-fat dairy products (e.g. yoghurt or

FIGURE 89.2 Illustration of T scores and Z scores

cheese), fish (including tinned fish such as salmon with the bone), citrus fruits, sesame and sunflower seeds, almonds, brazil nuts and hazel nuts.

Oral calcium supplements will be necessary in postmenopausal women or where a person's diet does not meet their daily calcium requirements.

Calcium citrate is better absorbed than carbonate. Recommend:<sup>3</sup>

calcium citrate 2.38 g (= 500 mg elemental calcium) daily

or

calcium carbonate 1.5 g (= 600 mg elemental calcium) daily with food

- Vitamin D deficiency and sunlight: there is evidence we need significant exposure to sunlight of the face, arms and hands to produce natural vitamin D (e.g. 15–30 minutes a day in all climates, up to 50 minutes a day in winter in temperate climates).<sup>6</sup> Refer to regional recommendations.<sup>7</sup> Measure serum 25-hydroxy vitamin D and maintain it at 75 nmol/L. If supplementation is required use colecalciferol 25–50 mcg (1000–2000 IU) (o) daily.<sup>3</sup>
- Exercise: moderate exercise against gravity—walking (brisk walking for 30 minutes four times a week), jogging or tennis—may make a small contribution to retarding bone loss.
- Lifestyle factors: stop smoking and limit alcohol and caffeine intake.<sup>8</sup>
- Adequate nutrition: keep BMI >18.
- Attention to falls prevention, including avoiding (refer to [CHAPTER 8](#))<sup>9</sup> sedative medication.
- Provide 'hip protectors' especially to osteoporotic patients at increasing risk of fractures after falling, but adherence is poor.

## Natural remedies

An Australian review investigating the effect of natural remedies on BMD commented that there is good evidence that exercise increases BMD in postmenopausal women with osteoporosis, little good-quality empirical evidence to support the use of natural progesterone cream and insufficient evidence to support the use of boron, cod liver oil or chelated calcium supplements (as opposed to calcium carbonate).<sup>10</sup>

There is no evidence that complex mineral preparations have added benefit and often they contain less elemental calcium than simple preparations.<sup>3</sup>

## Monitoring osteoporosis treatment<sup>3</sup>

Recommendations are to measure BMD at the lumbar spine and hip:

- 2 years after therapy begins
- 1–2 years after therapy changes significantly
- more frequently in patients at higher risk of bone loss

## Osteoporosis in children

The main problem in children is secondary osteoporosis, which is usually related to chronic inflammatory disorders and their treatment with corticosteroids and also to reduced mobility. Other medical causes are malignancy, malabsorption syndromes, poor nutrition, anorexia nervosa and hypogonadism. Use DEXA to assess and monitor BMD and Z scores. Refer for treatment, which may be based on bisphosphonates.

## Osteoporosis in men

Refer to [CHAPTER 112](#).

## When to refer

- Refer postmenopausal women and older men to a specialist according to individual needs
- Osteoporosis appears to be secondary to an underlying illness
- Advice is required about the management of a patient with pathological osteoporotic fractures or loss of height

## Child and adolescent health

---

*In every child who is born, under no matter the circumstances, and of no matter what parents, the potentiality of the human race is born again; and in him, too, once more, and of each of us, our terrific responsibility towards human life; towards the utmost idea of goodness, of the horror of error, and of God.*

James Agee (1909–55)

Seeing a child as a patient means you are dealing with at least one extra person in the room. Communication and rapport building need to be done with both the child and those who have brought the child (usually the parents). By engaging the child, you will usually win over the parent. Parents are often apprehensive about bringing their child to the doctor, concerned to the child might misbehave or do or say something to embarrass them. By displaying a natural interest in and ease with the child, a tolerance of child behaviour (or misbehaviour) and being generally ‘child friendly’, the consultation is more likely to be successful.

Engaging children can be done from the moment they are called from the waiting room. All of the usual rapport-building skills we use for adults (see **CHAPTER 4**) can be utilised with children. Respect, genuine interest in them, active listening and use of body language all matter with children, perhaps even more so than for adults as children naturally have less developed communication skills.

There is also a different style of communication required and this is age dependent. Infants will be dominated by emerging object permanence skills (e.g. playing peek-a-boo), attachment (they will constantly refer to their parent), separation and stranger anxiety. Toddler and preschooler communication is dominated by play, particularly ‘pretend’ or ‘imaginative’ play. Pretending to be a scary bear, to see animals in their ears when you examine them or to believe they are a different age from what they actually are will fire their imagination and make them curious in and more comfortable with you.

Primary school-aged children are old enough to have conversations about their pets, favourite toys, TV shows or movies (merchandised clothing they are wearing or accessories they are holding can give clues to these), their friends, teachers or school. Other rapport-building strategies include:

- greeting children as well as parents
- asking their name (even though you already know it) and/or what they like to be called
- asking their age (even though you already know it)
- if present, engaging the siblings too (e.g. asking a small child whether he or she is helping Mummy with the new baby)
- talking at their level, not down to them (e.g. child sitting on parent’s knee, or the doctor squatting down or sitting on the floor)
- having a vague idea of current children’s films, TV shows and their characters (e.g. Disney movies, Thomas the Tank Engine, The Wiggles)
- having toys in the room, both displayed for them to play with and for you to bring out as a surprise
- having special stickers or stamps (e.g. for the backs of hands)
- blowing bubbles (particularly to distract post-vaccination)<sup>1</sup>
- showing them and letting them hold examination equipment before you use it
- treating them as individuals to be engaged, not clinical puzzles to be solved (this is especially important for children with special needs, who may have greater communication challenges and may also be more used to being treated as a medical condition)

All of this effort will help set the scene for easier history taking and physical examination.

## Parent–child interaction

It is advisable to observe carefully the parent–child interaction at all times, including in the waiting room (sometimes you will hear a dysfunctional parent–child interaction before you see it!). The parent’s manner in talking to and handling the child will provide useful clues about any possible problems in terms of the parent’s ability to nurture the child adequately, and how well they are coping, especially in the postnatal period.<sup>2</sup>

## An approach to the parent

Parenting has recently become a lot more complicated. Controversies have arisen and flourished, such as those over vaccination and supposed adverse reactions or parenting styles (e.g. 'attachment parenting'). Much of this is driven by information on the internet, with mothers in particular increasingly spending time on 'mummy blogs' and parenting websites.

Cultural backgrounds also often strongly influence attitudes to aspects of parenting such as how to communicate with children, diet, discipline and punishment, and the role of the mother or father.

Being a parent is laden with intense emotion, and this intensity can lead to very concrete beliefs about different parenting issues (e.g. that MMR vaccination causes autism, that hitting a child improves behaviour). Being aware of these possibilities and not 'putting your foot in it' by making assumptions about parenting attitudes can help avoid communication breakdowns with the parents of your paediatric patients.

## History

Obtaining information in the following sequence is recommended:

- *presenting problem* or problems (focus on this first):
  - allow the parents to elaborate without interruption
  - be a listener
  - never judge a parental concern as trivial (especially with a new parent)
- *past history*:
  - medical and surgical history
  - pregnancy, birth and neonatal history
  - vaccination history, medications and allergies
- *family history* (e.g. inherited disorders)
- *growth* (percentiles) and feeding/diet
- *development*:
  - gross motor
  - fine motor
  - speech and communication
  - social skills
- *family and social function* (relationships, behaviour, sleep)

## Physical examination

As mentioned above, the approach to the child and parent from the waiting room will help determine the ease or difficulty of examining a child. A good aphorism is 'Win the child, win the mother (parent)'.

## Observation

As always, observation is critical. Not only looking at the parent-child interaction, but closely observing the appearance and behaviour of a child can give a multitude of clues as to how unwell the child is. What is the child's general appearance? How active and alert is the child? How interactive is he or she with you and the parents? Is he or she breathing comfortably? Does the child look distressed? This information should be recorded in the medical record as the first line of examination (i.e. above the 'obs').

Growth and development should always be assessed when seeing a child (see below) and the growth parameters are part of the general measurable observations. Temperature should be recorded, but the presence of fever, the degree of fever and the response to antipyretics are poor predictors of serious disease.<sup>3</sup> Also, the thermometers parents and GPs use are often unreliable—tympanic and per axilla thermometers miss a lot of raised temperatures found on PR measurement.<sup>4</sup> A raised temperature tells you something is going on, and not much else. Caveats to this are children in the first 3 months of life, or those in special circumstances (such as those who are immunocompromised) or the worrying presentation of fever combined with drowsiness and pallor (see CHAPTER 96).

Increasingly, oxygen saturation measurement is being incorporated into the general observations of children in general practice, especially in children with a significant respiratory infection.

Observations of the child, parents and their interactions are also important in picking up clues concerning psychosocial issues, such as family dysfunction (e.g. marital issues, drug and alcohol abuse in parents, mental health issues in parents), attachment issues, neglect or child abuse (see CHAPTER 95).

## Achieving cooperation of small children

Children, especially if they are sick and irritable, can be very difficult to examine and may be most uncooperative, particularly if distressed by past experiences. However, they can be readily distracted, a characteristic that the family doctor can use effectively to achieve some degree of cooperation.

It is generally better to examine younger children on their parent's lap. An older child can be made to feel 'grown up' and important by being examined on the couch (a good strategy if unsure is to ask them what they would prefer first).

## Distraction and humour

A variety of techniques can be used to distract the small child or make a game of the physical examination. Individual doctors will often develop their own repertoire of jokes, pretend play and sleight of hand to get the job done without distressing child and parent. Apart from the distress, it is easier to get a good look at an eardrum or to hear a heart murmur when a child is not crying or fighting your invasion of their personal space.

Techniques include:

- tickling games
- peek-a-boo
- using pretend animal noises
- looking for/hearing animals, fairies, monsters, trains (or whatever the child is most interested in at the time) in the child's ears, mouth, chest or abdomen
- getting the older child to block the non-examined ear with a finger to stop the light going through his or her head
- toys (including those that make a noise) being held by your non-examining hand, the parent, a nurse or medical student
- bubbles (and games popping bubbles)
- animal images on stethoscope heads
- images drawn on the unused end of spatulas<sup>5</sup>
- a musical or moving toy above an examination couch
- distracting conversation while examining an abdomen ('how old are you *really*?')
- distracting images (such as a home page of their favourite TV or film character) on your computer screen

Despite your best efforts, sometimes it just doesn't work, especially with a sick child. In these circumstances, you should give clear instructions in advance to the parent (who will often be flustered) on how to best restrain the distressed child. Talk slowly, simply and, if necessary, loudly (if the child is crying), so the parent can understand. Don't ask the child for permission in these circumstances; the answer will be no! The doctor's tone of voice and body language should display to both parent and child that he or she is calm, in charge and not bothered by crying, screaming or lashing out by the child. Getting angry at the child can make the situation worse.

## Growth and development

Checking a child's growth and development is a core role of the GP, as we will generally see an infant in

our practice quite frequently. The immunisation visits, routine baby and child checks in the Personal Health Record (PHR, see below) and other visits for viral URTIs and other presentations provide perfect opportunities for GPs to assess appropriate growth and development over time.

This longitudinal monitoring is more reliable at picking up issues than screening programs, which are a mere snapshot. That is why growth parameters (weight, height/length and head circumference, known as anthropometric data) and a quick developmental check at each visit should be done.

In terms of growth, if there are concerns—either of crossing growth percentiles, or worse, of decreasing growth parameters—then obviously further exploration and possible investigation is warranted (see the section on failure to thrive in [CHAPTER 91](#)).

Development is normally thought of in 4 domains: gross motor, fine motor, speech/communication and social development. Even if not doing a formal screening check from the PHR or other sources, a few screening questions from each domain will help pick up developmental concerns (see [TABLE 90.1](#)). Gross motor and fine motor are grouped together, as are speech/communication and social development for simplicity, and useful screening questions at each visit on the Australian Immunisation Program are suggested). A useful standardised screening tool to use for further evaluation in a GP setting, if there are concerns regarding development, is the Denver-II Developmental Screening Test,<sup>6</sup> and any significant concerns regarding development should have specialist review.

## Gross motor development

The neurological control of the infant's body travels from the top down (caudo-equinal) and the inside out (see [FIG. 90.1](#)). It is analogous to a flag unfolding. If you are in an art class drawing an adult, you will draw the hips at the halfway point, the nipple line a quarter of the way down and the knees three-quarters of the way down. If you divide the first 12 months of a child's life into quarters, you will quite conveniently find the gross motor development roughly progressing down at these points (see [FIG. 90.1](#)). That is, at 3 months a baby should have control of his or her chest, at 6 months the hips (sitting usually happens at 7–8 months; see [FIG. 90.2](#)), at 9 months the knees (e.g. crawling, bum-shuffling or commando crawling), and at 1 year the feet (standing holding on, not necessarily walking).<sup>7,8</sup>

**Table 90.1** Developmental milestones to check at vaccination visits

Age	Gross motor/fine motor milestones	Social/speech/communication milestones
<b>6 weeks</b>	<ul style="list-style-type: none"> <li>• Eyes mostly moving together</li> <li>• Some head control—not flopping everywhere</li> <li>• Symmetrical movements of limbs</li> </ul>	<ul style="list-style-type: none"> <li>• Cooing (vowels) emerging</li> <li>• Starting to smile (probably)</li> <li>• Some brief eye contact</li> </ul>
<b>4 months</b>	<ul style="list-style-type: none"> <li>• Hands to midline and then to mouth</li> <li>• Has hand regard</li> <li>• Lifts knees</li> <li>• Tracks objects through 180 degrees</li> <li>• Lifts head up 90 degrees when lying prone</li> <li>• Grasps objects handed to him or her</li> </ul>	<ul style="list-style-type: none"> <li>• Cooing well established</li> <li>• Social smiling (smiling in response to a smile) and laughs</li> <li>• Eye contact more prolonged at times</li> <li>• Babble (consonants) emerging (possibly)</li> </ul>
<b>6 months</b>	<ul style="list-style-type: none"> <li>• Propped up sitting (independent sitting 7–8 months)</li> <li>• Hands down in front of him or her, hands to feet</li> <li>• Keeping head level with body when pulled to a sitting position</li> <li>• Rolling-up on extended arm when placed in prone and creeping when placed in prone</li> <li>• Possibly bangs objects on a surface</li> </ul>	<ul style="list-style-type: none"> <li>• Babbling well established</li> <li>• Quietens and attends when spoken to (listening)</li> <li>• ‘Vocal play’—experimenting with new sounds (e.g. blowing raspberries)</li> <li>• Enjoys interactive games</li> <li>• Smiles when sees parent</li> <li>• Laughs/squeals with delight</li> </ul>
<b>12 months</b>	<ul style="list-style-type: none"> <li>• Takes weight on feet when feet plonked on ground in standing position (parachutes them) or standing holding onto furniture</li> <li>• Transitions by moving in and out of positions</li> <li>• Cruising (probably) and crawling</li> <li>• Points and follows a point (possibly)</li> <li>• Grasps with index and thumb</li> <li>• Claps hands</li> <li>• Waves goodbye</li> </ul>	<ul style="list-style-type: none"> <li>• Lots of conversational babble</li> <li>• A couple of words (‘Mum’, ‘Dad’, other) probably</li> <li>• Possible separation and/or stranger anxiety</li> <li>• Looks for objects out of direct line of vision (dropped toy)</li> <li>• Co-looking at pictures in books or objects (shared attention)</li> <li>• Possible pointing or following a point (‘look at the ...’)</li> <li>• Waves bye-bye</li> </ul>
<b>18 months</b>	<ul style="list-style-type: none"> <li>• Walks well and probably holding hand upstairs</li> <li>• Climbs on and off everything</li> <li>• Attempts a jump</li> <li>• Isolated ‘tip to tip’ pincer</li> <li>• Bilateral play—hands doing different things</li> <li>• Eyes point, focus and track a moving object</li> <li>• Posting objects into containers</li> </ul>	<ul style="list-style-type: none"> <li>• Follows 1-step commands (when he or she wants to)</li> <li>• Does pretend play—tea sets, dolls, kitchen toys</li> <li>• Interested in everything, especially people</li> <li>• Pointing and following a point well established</li> <li>• Good understanding of what is said, maybe developing lots of words (or soon)</li> <li>• Points to body parts</li> <li>• Uses at least 2 words by 16.5 months</li> </ul>
<b>3.5–4 years</b>	<ul style="list-style-type: none"> <li>• Moves towards learning to ride a bike</li> <li>• Catches a ball onto chest</li> <li>• Catches a larger ball with the hands</li> <li>• Throws a ball overarm</li> <li>• Hops</li> <li>• Washes and dries hands</li> <li>• Does puzzles independently</li> </ul>	<ul style="list-style-type: none"> <li>• Clear and intelligible speech</li> <li>• Able to have a long reciprocal (back and forth) conversation with parents and siblings/peers</li> <li>• Plays with siblings/peers</li> <li>• Unwanted behaviours not standing out among peers (e.g. childcare, preschool)</li> </ul>

**FIGURE 90.1** With gross motor development, at 3 months you are at the chest, at 6 months the hips, at 9 months the knees and at 12 months you have control of the feet

**FIGURE 90.2** Normally a child will sit without support at 7–8 months

Beyond 12 months, children will expand this neurological connection into increasingly complex activities (see [TABLE 90.2](#)).

**Table 90.2** Gross motor skills we want to see emerge (12 months to 6 years)

- **2 years**—walking up stairs holding onto an adult hand, and possibly attempting alternating feet with each stair
- **2½ years**—observing a child being able to jump
- **3 years**—starting to try and to use a tricycle
- **5–6 years**—weaning the trainer wheels off the bike
- **6 years**—skipping

*Note:* any loss of gross motor (or any other developmental) skill is a red flag.

## Fine motor development

Fine motor development mimics that of gross motor, with a steady progression down the body over the first year of life then an ‘unfolding’ pattern of control of movement with extension and opening out of joints (particularly hands and fingers) followed by an increasing complexity of movements. An easy way to remember the principles of fine motor development is to think of the first 9 months in terms of whole-hand activity, and the second 9 months (9–18 months of age) as individual digit activity<sup>7,8</sup> (see [TABLE 90.3](#)).

## Speech and communication development

Newborns squawk, squeak and cry. At around 1–2 months, cooing (vowels that use the vocal cords) will start to appear, much to the parents’ delight. Between 3 and 6 months, babble (using consonants—that is, involving the tongue and lips to change sounds) will appear. The babble then becomes something the baby starts to play with, and then banters back-and-forth with the parent and others. This ‘conversational babble’ becomes more sophisticated over the second half of the first year. Into this conversational babble, the first words appear, usually at the end of the first year.

In the second year, there is frequently a rapid expansion in vocabulary around the middle of the year, with girls often having this expansion earlier than boys. Receptive language usually precedes expression, so at the 18-month check, even if a child is not saying many words, his or her increasing understanding of speech should be evident.

Between 18 months and 3 years, the combination of words and small sentences and increasingly reciprocal (back-and-forth) conversation expand markedly. Articulation also improves over this time, with around 25% of articulation intelligible at 18 months, 50–75% intelligible at 2 years and 75–100% at 3 years. Other articulation issues such as lisps and stutters can also be important.

**Table 90.3** Fine motor skills we like to see emerge over the first 18 months

Whole-hand activities (0–9 months)

- **3–6 months**—includes grasping objects passed to the child, looking at objects he or she is holding ('object regard') and banging objects onto a surface, such as a tray in a high chair.
- **6–9 months**—banging objects together. By 9 months, babies should be doing hand-to-hand transfers and purposefully releasing objects.

Individual finger activities (9–18 months)

- **Pinching** (pulp-to-pulp), **pincing** (tip-to-tip with curled fingers) and **pointing**, all of which can emerge progressively.
- **Pointing** is an important milestone, and is often there by 12 months and *should be there by 18 months*. Prior to children developing their own point, they will reach out towards things, straightening out their fingers as they reach. This action will be followed by the index finger being straightened in isolation while the other fingers are curled. We start in the first year of life by 'following a point'; that is, looking at an object when someone says 'look at the . . .' As well as following a point, children will often point at themselves by 12 months. A young child points for several different reasons. Sometimes it is to share something interesting with another person, sometimes it is to get something they want and sometimes it is to find out what something is called.

## Social development

As a species, human beings are very socially immature at the time of birth. We are completely dependent on our carer, and remain so for a long time. Soon, though, through attachment, a baby will learn social skills from his or her parents by having a *shared understanding*. This is where the baby's and (usually) the mother's thoughts connect—a 'meeting of minds'.<sup>2</sup>

At around 6 months of age, separation anxiety<sup>9</sup> will usually appear. Separation anxiety is a normal developmental phenomenon as the infant becomes more aware of object permanence (something existing when it is out of sight). Parents, particularly mothers, may worry that they are doing something wrong by causing distress through separation (e.g. leaving the baby in the cot to self-settle), though this is something that we want the child to learn to handle. A stepladder approach (gently increasing the exposure to separation as the child increases the skill to cope) will help. Separation anxiety often peaks around 14–18 months and then decreases through the preschool years.

Stranger anxiety,<sup>10</sup> usually appearing around 7–9 months and reducing after 14 months of age, is similar in many ways to separation anxiety. It too is best managed through a gradual exposure, especially when the child is feeling comfortable.

Tantrums,<sup>11</sup> which are common between 18 months and 3 years (or older), occur because the child lacks the skills to deal with an emotionally challenging event. If a child is not developing some coping skills through this period, his or her social development should be assessed.

In the second year of life, two emerging skill sets dominate social development: speech and play, particularly pretend play.<sup>2,7,8</sup> Play is far more important than children simply acting out their wishes. It's the training ground for life, it's how children learn to interact with others and the world. Deficits in the social use of speech and pretend play should alert the GP to consider autism (see Red flags for autism box, and CHAPTER 94).

### Red flags for autism<sup>12</sup>

- Lack of babbling or pointing by 12 months
- No sharing of interest in objects or activities with another person
- No single words by 16 months, or no two-word (non-echoed) phrases by 24 months
- Any loss of language or social skills at any age

## GUIDELINES FOR FEEDING INFANTS

### The benefits of breastfeeding

For the infant,<sup>12</sup> the benefits include a potential lower risk of:

- gastrointestinal and respiratory infections
- asthma
- otitis media
- urinary tract infections
- necrotising enterocolitis
- insulin-dependent diabetes
- inflammatory bowel disease
- lymphoma
- atopy

The benefits for the mother<sup>13</sup> include:

- a potential lower risk of postpartum bleeding
- delayed resumption of ovulation
- improved bone mineralisation postpartum
- potential lower risk of ovarian and postmenopausal breast cancer

Breastfeeding also improves bonding, is less costly and is beneficial to the environment. Most (96%)<sup>14</sup> Australian women initiate breastfeeding, but almost a third will have introduced formula or stopped breastfeeding by 3 months,<sup>13</sup> and few will achieve the goal of exclusive breastfeeding to 6 months (EBF6).<sup>14</sup> This goal is recommended in the WHO and NHMRC guidelines and endorsed by the RACGP, but other guidelines<sup>15</sup> suggest exclusive breastfeeding to 4–6 months (EBF4-6), with the introduction of solids at this age. It is also recommended that the woman continues to breastfeed while introducing appropriate solid food until 12 months of age and beyond, and for as long as the mother and infant desire.<sup>14</sup> Exclusively breastfed infants do not require additional fluids up to 6 months of age.

## Formulas

If formula is used, a cow's milk-based type should be used up until 12 months (note: all infant formulas available in Australia are iron-fortified).<sup>14</sup> Specialty formulas are indicated only for confirmed pathology. If a woman cannot or chooses not to breastfeed, it is important that she does not feel that she is being judged, as postpartum women are vulnerable to suggestions of lactation failure, which is a risk factor for postnatal depression.

Cow's milk itself should not be given as the main drink to infants under 12 months, though small amounts may be used in the preparation of solid foods. The only other fluid besides breast milk and formulas suitable to be given to infants is boiled and cooled tap water (i.e. no bottled water, juice, cordial or other beverages).

## Starting solid foods

Solids should be introduced one at a time. They should be offered after a feed or between feeds of milk.

Examples of solid foods for beginners are:

- baby rice cereal mixed with the usual milk or cooled boiled water
- fruits such as banana, cooked apple or pear
- pureed meat and poultry dishes

The texture should be pureed (no lumps) at first. Introduce a new food only after 3–4 days, early in the day. Start with 1–2 teaspoons of solids and build up to three meals a day at your baby's own pace. Lumpy foods can be introduced at 6–9 months, as by this time babies learn to chew.

By 9–10 months, more solids should be eaten each mealtime and the milk gradually decreased. Foods with poor nutritional value and high saturated fats, added sugars (which will increase risk of dental caries) and added salt should be avoided. Honey should be avoided because of the risk of botulism.<sup>14</sup> Hard, small, round (e.g. whole nuts) and/or sticky foods are not recommended because of choking and aspiration risk. Low-fat milks should not be used in the first 2 years of life, and soy and other milks (e.g. goat's milk, sheep's milk, coconut milk, almond milk) are inappropriate alternatives to breast or formula or pasteurised whole cow's milk.<sup>14</sup>

From 12 months onwards, cow's milk can be introduced and more solid foods, especially meats, vegetables and fruits. From 12 months, milk and other drinks should be offered in a cup rather than a feeding bottle (i.e. no need for tipping cups or transitional bottles) and toddler milks and supplements are not required for healthy children.<sup>14</sup>

## Toilet training<sup>16,17</sup>

As a rule, children will learn to use the toilet when they are ready.

The ages by which most children are fully trained are:

- daytime—between 2½ and 4 years
- night-time—by 8 years of age

Once they start training it can take weeks to months to achieve dryness or the ability to open their bowels on the toilet.

## General rules for parents

- Be relaxed about toilet training.
- Avoid rushing toilet training.
- Do not force your child to go to the toilet.
- Nagging does not work; a positive-reinforcement approach is far better. This can include reward systems such as reward charts and stickers.
- Punishing will not work.

## Indications that a child is ready to start toilet training

- Interest in others going to the toilet
- Has a dry nappy for 1–2 hours or more
- Tells you when they have wet or soiled their nappy or are about to go
- Doesn't like wearing a nappy, especially when it is wet or soiled

- Has the motor skills to pull training pants up and down and get on and off the toilet (may need a step) or potty

### Best times to sit children on the toilet

- First thing in the morning
- After meals
- When you sense their need to go
- Before going out
- Upon returning home

### Key points for parents

- Consider using a potty or toilet with a seat ring and a step.
- Explain the process in simple terms (there are good resources available, such as books suitable for children of this age).
- Sit both boys and girls on the toilet to pass urine.
- Do not force them if they refuse to use it.
- Help the child relax on the toilet (e.g. using distraction, or having favourite toys).
- Stop using nappies (except when sleeping).
- Don't make a fuss if there are any accidents.
- If the training upsets them, wait for a month and try again.

### Child safety

Parents will often be bombarded with child safety messages, many of them valid but many of them not. An excellent resource to point them towards is <[www.kidsafe.com.au](http://www.kidsafe.com.au)>, which gives reliable advice on child safety issues.

**Table 90.4** Accidents don't have to happen: key points

- Have cupboards made child-resistant for the storage of medicines and household chemicals. Pesticides and petroleum products should be locked away in the shed. Don't store in ordinary food and drink containers.
- Fires and radiators should be adequately guarded.
- Cords on electrical food and drink heaters need to be shortened or hooked up out of toddlers' reach. Do not use tablecloths. Put hot food and drinks into the centre of the table.
- Fit dummy plugs in unused power points.
- Restrain children in cars according to the child restraint guidelines.<sup>18</sup>

- Infants are safest if they remain in a rear-facing restraint as long as they still fit into it.
- Supervise your toddler at all times in or near water. The swimming pool needs to be adequately fenced (all 4 sides and gate secure) and never leave a child alone in a bath.
- Keep matches and lighters locked away and out of reach. Put scissors, knives, needles and pins well out of reach.
- Have the play yard safely fenced from the street.
- Parents: walk right round the car before reversing down the drive, or place your child in the car first.

### Personal health record

Many children have a personal health record (PHR), which is given to the child's parents or carers as a means of improving health care delivery, including the enhancement of preventive care. The PHR is a small, loose-leaf booklet with a sturdy plastic cover that can be easily carried around by the parent. The contents can vary from one state to another (as does the colour of the cover) and from edition to edition but generally it contains:

- records of birth details and newborn examination
- percentile charts for weight gain
- visual check
- hearing check
- developmental check
- immunisation schedules and recordings
- progress notes
- advice on accident prevention (see [TABLE 90.4](#))
- other health educational material

The PHR provides a very practical method of promoting communication between various health professionals involved in the child's care and also between the family and their doctor. It promotes the concept of self-care by encouraging a sense of responsibility in parents for the child's health and is also a medium for enhancing preventive care, especially with regard to immunisation, growth and development.

### Immunisation schedule

Refer to [CHAPTER 9](#) and <[www.immunise.health.gov.au](http://www.immunise.health.gov.au)> for updates.

### Diagnostic triads for children

The following is a selection of childhood disorders. The arrow represents a pointer to a possible diagnosis and is of course not conclusive.

## Acute–subacute onset

**DxT** Arthralgia (lower limbs) + rash (buttocks, legs) ± abdominal pain → Henoch–Schönlein purpura  
**DxT** Pallor + drowsiness + fever → meningitis  
**DxT** Pallor + abdominal pain (severe and intermittent) + inactivity → intussusception  
**DxT** (<12 months): drowsiness + cough + wheezing → bronchiolitis  
**DxT** (<3 months, usually male): weakness + weight loss + vomiting (severe, intermittent) → pyloric stenosis  
**DxT** (Neonate): vomiting (after first feeds) + drooling + abdominal distension → oesophageal or duodenal atresia  
**DxT** Malaise + pallor + bone pain → acute lymphatic leukaemia  
**DxT** Malaise + pallor + oral problems (gingival hypertrophy, bleeding, ulceration) → acute myeloid leukaemia  
**DxT** Abdominal pain + pallor + a/n/v → acute appendicitis  
**DxT** Abdominal pain + malar flush + fever ± URTI → mesenteric adenitis  
**DxT** Drowsiness + tachypnoea + chest wall recession → pneumonia  
**DxT** Drowsiness + fever + purpuric rash → meningococcal infection  
**DxT** URTI + brassy cough + inspiratory stridor → croup  
**DxT** Coughing + wheezing + chest wall recession → asthma or aspirated foreign body  
**DxT** Fever + conjunctivitis + skin changes (cracked red lips, maculopapular rash, erythema of palms/soles, desquamation of fingertips) → Kawasaki syndrome

90

## Congenital syndromes

**DxT** Large ears + long narrow face + large genitals → fragile X syndrome  
**DxT** Small extremities (hands, feet, genitals) + narrow forehead + eating disorder → Prader–Willi syndrome  
**DxT** ‘Elfin’ face + low-set ears + cardiac murmur → Williams syndrome  
**DxT** (Female): short + webbed neck + pigmented naevi ± cardiac disorder → Turner syndrome  
**DxT** Short + webbed neck + facial disproportion (broad forehead, ptosis, low-set ears, etc.) ± cardiac disorder → Noonan syndrome

## Chronic

**DxT** Malaise + abdominal pain (vague) + abnormal behaviour → lead poisoning  
**DxT** (<2 years): lethargy + irritability + pallor → iron deficiency anaemia  
**DxT** Fever + malaise (extreme) + a/n/v ± anaemia → neuroblastoma  
**DxT** Headache + a/n/v + ataxia → medulloblastoma  
**DxT** Speech communication skills + poor socialisation + repetitive/obsessive behaviour/restriction of interests → autism spectrum disorder

## Older children

**DxT** (Male): snorting, blinking, etc. + oral noises (e.g. grunts, hisses) ± loud expletives → Tourette syndrome  
**DxT** Mid to low back pain/discomfort + inability to touch toes + kyphosis → Scheuermann disorder  
**DxT** Knee pain (after activity) + tender knee ‘lump’ + pain on kneeling → Osgood–Schlatter disorder  
**DxT** (Adolescent): limp + knee pain + hip pain → slipped capital femoral epiphysis

## Patient education resources

Hand-out sheets from *Murtagh’s Patient Education* 6th edition:

- Feeding your baby
- Normal development in children
- Toilet training your child

*Children are not simply micro-adults, but have their own specific problems.*

Bel a Schick (1877–1967)

The family doctor usually treats children for common minor complaints such as non-serious viral respiratory infections and minor skin problems, offering parental advice and reassurance. Many of these everyday problems are discussed in this chapter, while immunisations (**CHAPTER 9**) and more complicated problems such as anaemia, diarrhoea and chronic cough are covered elsewhere (see Part 3, Problem solving in general practice).

### Crying and fussing in infants

Crying and fussing is a very common concern in the infant in the first few months. The term ‘colic’ (which is still widely used) needs to be used with caution, as it infers something is wrong with the gut of the infant, when most of the time this is not the case.<sup>1</sup>

The normal pattern is for crying to start increasing around two weeks of age, to peak around two months, and then settle down around three to four months of age, perhaps five. The amount of crying varies from baby to baby, but all babies cry—and not just human babies; in the early months babies of other mammal species cry as well. This is a survival instinct, to get the full attention of the carer and to establish attachment. It can also cause a great deal of distress for a mother or other carer, so active listening, careful assessment to exclude other causes and advice and reassurance are important.

### Management

- History—crying pattern and duration, assessment of the child’s temperament and parents’ coping abilities.
- Perform careful physical examination, including growth parameters, feeding and settling pattern, and development.
- Reassure parents that extra attention will not affect the baby but overstimulation should be avoided.
- Give parental reassurance and education (including advice on soothing techniques and coping strategies).

### Practice tip—the period of purple crying<sup>1</sup>

A useful term developed by specialists in this area is ‘the period of PURPLE crying’ <[www.purplecrying.org](http://www.purplecrying.org)>. The letters of the word ‘purple’ stand for characteristics of this period of crying, namely:

- P** = **Peak**—your baby may cry more each week, the most at 2 months, then less at 3–5 months
- U** = **Unexpected**—crying can come and go and you won’t know why
- R** = **Resists soothing**—your baby may not stop crying no matter what you try
- P** = **Pain-like face**—babies may look like they are in pain, even when they’re not
- L** = **Long-lasting**—crying can last as much as 5 hours a day, or more
- E** = **Evening cluster**—your baby may cry more in the late afternoon or evening

### Causes (to exclude)

- Cow’s milk intolerance
- Lactose intolerance
- Gastro-oesophageal reflux
- Pain from UTIs and other infections, bowel obstruction/hernias, other causes

### Soothing techniques

- Gentle stroking and cuddling
- Providing close contact or skin-to-skin contact
- Talking to them, singing to them, smiling at them and rocking them
- Repetitive rocking movements helps calm an overstimulated baby’s brain

### Coping strategies<sup>1</sup>

- Increase carry, comfort, walk and talk responses—the baby may still continue to cry, but there is a reasonable chance the parents may be able to soothe him or her.
- It’s okay to walk away—it’s important for parents to calm themselves before trying to calm their baby.

- Never shake or hurt a baby—advise that shaking a baby is a critically dangerous thing to do.

It is also useful to advise a parent to try and learn their baby's signals and body language, which are unique for every infant. Some typical body language patterns include:

- tired—stiff, jerky movements, being quiet or still, blank faced, rubbing eyes, moodiness, droopy eyelids or slow blinking and crying
- hungry—open mouth, eager expression and crying
- ready for action—wide open eyes, alert expression and kicking legs
- upset—jerky movements, turning away and crying

## § Teething

### Baby teeth (milk or deciduous teeth)

- Babies usually cut their teeth from age 6 months until 2–3 years.
- The first teeth to appear (which seldom cause discomfort) are usually the lower incisors (during the first year).
- The first and second molars (ages 1–3) tend to cause problems.
- Usually the first set (20 teeth) is complete soon after the second birthday (see FIG. 91.1).

### Symptoms

- The gum is slightly swollen and red
- This may cause little or no discomfort but may be quite tender
- The child may be more clingy and fretful, and dribbling more than usual
- Chews and mouths (though mouthing fingers, hands and other objects is a normal infant behaviour, especially from 4 months onwards)
- Irritability and crying (on and off for no more than a few days)

### Treatment

Parents are often misinformed about the importance and consequences of teething pain. Reassure parents that teething rarely results in anything more than minor distress, that it does not cause fever, rashes or diarrhoea, and that it will usually settle quickly.

### Soothing methods

- Gentle massaging of the gum with the parent's forefinger wrapped in a soft cloth or gauze pad is comforting.  
*or*
- Allow the baby to chew on a clean, cold, lightly moistened facewasher (a piece of apple can be placed inside the facewasher).  
*or*
- Give the baby a teething ring (kept cold in the refrigerator) or a teething biscuit.

### Medication

Medicine is usually not necessary for teething. Paracetamol should be used only for significant discomfort. Teething gels are salicylate-based and are not recommended.

### Pitted dark teeth and bruised teeth

Some children who are breastfed for long periods (e.g. 3 years) may develop unsightly pitting of the front surface of their teeth. This will not go away but parents should be reassured that the adult teeth will be normal when they appear.

Bruised teeth can result from minor trauma, with the tooth appearing a grey-brown colour. While a cosmetic issue for some parents, these too are not a concern and the adult tooth will appear and develop normally.

FIGURE 91.1 The lower set of primary teeth with average times of eruption

## § Thumb sucking

Thumb sucking involves placing the thumb or finger on the roof of the mouth behind the teeth (hard palate) and sucking with the mouth closed. Sucking is a normal and soothing behaviour for the infant, but it can become an entrenched habit. It occurs in children up to the age of 12 years but is most common under the age of 4 years. It usually settles by the early primary school years, and will sometimes stop if the child becomes self-conscious because other children notice. It can cause problems with the child's bite, especially as the adult teeth appear, at about age 7. One effect is that the pressure on the front teeth may cause protrusion of the front teeth (i.e. buck teeth); another is a narrowing of the bite with a gap between the top and bottom incisors, referred to as an open anterior bite. This can also happen with pacifiers. The best approach is for parents to notice when the child is doing it less, and to comment on how grown up the child is becoming, rather than scolding or overly drawing attention to the behaviour.

### Advice to parents

- No special diet or medication is necessary. Unpleasant-tasting topical applications to the pacifier or thumb are counter-productive.
- For a child over 6 years, carefully observe trigger factors and find ways of avoiding them. Provide distractions.
- Help the child explore other solutions to sooth themselves.
- Give praise and rewards for efforts to stop.

## § Snuffling infants

Snuffling frequently occurs in normal babies in the few weeks after birth and is not a problem unless it affects feeding. Infants and small children have particularly small noses, which block easily.

Snuffling in older infants is usually caused by rhinitis due to an intercurrent viral infection. The presence of yellow or green mucus should not be a cause for concern and is not an indication for antibiotics. Give reassurance, and advise that using a saline nasal solution to clear congestion is reasonable.

## § Blocked nasolacrimal duct

About 20% of infants develop watery eyes, but most resolve by 12 months. Excessive eye watering in infants is the key sign that there is inherited narrowing of the nasolacrimal ducts (see FIG. 91.2). It usually becomes obvious in infants between 3 and

FIGURE 91.2 Blocked nasolacrimal duct

12 weeks and affects one or both eyes. Mucus and mucopus may appear in the tears. The discharge is worse on waking. In some infants, watering and discharge soon after birth indicate that the ducts have failed to open. Infection may intervene (refer to CHAPTER 51) and conjunctivitis can be problematic.

### Outcome

In most cases the problem improves spontaneously. Self-correction usually occurs from 6 months of age onwards or even earlier. It remains a matter of controversy whether massage helps or not.

Minor infection can be treated with warm cotton-wool soaks. For more severe blockage, recurrent conjunctivitis or when eye watering has not settled by 12 months, referral to an ophthalmologist for consideration of probing is warranted.

## § Failure to thrive (FTT)<sup>2,3</sup>

It is essential to monitor growth of children, particularly infants (see CHAPTER 90). The sequential plotting of the weight, length and head circumference (anthropometric criteria) on growth charts (see Appendices I–IV) in the personal health record (PHR) and/or the doctor's medical file on the child enables appropriate monitoring of this growth. The growth charts mean little without considering the context of the baby's growth (e.g. premature babies, children of small parents). Correcting for prematurity (under 37 weeks) should be done until the age of 24 months.

Also, growth charts themselves have reliability issues. They are based on Caucasian children and are not fully representative for some other groups (e.g. Asian children tend to be smaller). Growth charts can also vary depending on whether they use data based on populations of exclusively breastfed infants or include formula-fed infants (who tend to grow faster).

Classically, failure to thrive (FTT) has been defined as children whose weight <3rd percentile on  $\geq 2$  occasions, or whose weight crosses two centile lines over time. These criteria, however, are met by 5% of infants at some stage, many of whom do not have concerning growth progression; they will also fail to pick up all children who may not be growing adequately. It is therefore important to consider the contextual issues of measurement mentioned above, as well as taking into account the overall clinical picture of the growth over time (e.g. how quickly is the percentile change happening) and the general health and development of the child. While FTT is a useful term to help identify and describe infants and children that may have growth issues, it is not a diagnosis in itself.

Average weight gain/week:

0–3 months	180 g/week
3–6 months	120 g/week
6–9 months	80 g/week
9–12 months	70 g/week

Weight gain slows further after 12 months of age.

## Causes

Traditionally, FTT was divided into organic and non-organic causes. It is becoming increasingly recognised that in many cases the cause is multifactorial, including biological, psychosocial and environmental contributors. A practical way of considering potential causes is looking at caloric intake, absorption and expenditure. In many cases (>80%) no cause is found.

## History

- Antenatal/birth/postnatal history—including growth parameters
- Feeding history (most important aspect)
  - Infants—BF/attachment, formula feeding, timing, volumes (e.g. weigh infant before and after, mother expressing and measuring breast milk), vomiting?, solids introduction (see CHAPTER 90)
  - Toddlers—types and amounts of foods/liquids (see CHAPTER 90), especially iron-containing foods, food intake inside and outside home, mealtime battles, distractions, food refusal, milk volume, parental food attitudes
- Medical history
- Developmental history (e.g. regression, syndromes)
- Family history (e.g. mid-parental height, parents' or siblings' childhood weight gain)
- Social history (e.g. finance, supports)

**Table 91.1** Failure to thrive: causes to consider<sup>2</sup>

Inadequate caloric intake/retention (most common)

- Inadequate amount of food provided
- Breastfeeding issues
- Physical reasons baby can't feed well (e.g. cleft palate)
- Persistent vomiting
- Chronic disease causing anorexia

Inadequate absorption

- Coeliac disease
- Chronic liver disease
- Pancreatic insufficiency (e.g. CF)
- Chronic diarrhoea (e.g. protein-losing enteropathy)

Excessive caloric utilisation

- UTIs
- Chronic respiratory disease (e.g. severe asthma, bronchiectasis)
- Congenital heart disease
- Diabetes mellitus
- Hyperthyroidism

Other medical causes

- Genetic disorders
- Inborn errors of metabolism

Psychosocial factors

- Parental depression
- Coercive feeding (feeding becomes a battle)
- Distractions at meal times
- Poverty (the single biggest risk factor in both developed and developing countries)
- Behavioural disorders
- Poor social support
- Neglect and abuse (risk of child abuse is 4x higher in children with FTT)

## Examination

- Growth charts (refer to FIGURE 91.3)
- General appearance (does the child look sick/irritable/lethargic? dehydration? loss of subcutaneous fat? pallor? inappropriate bruising or affect)
- Observation of infant feeding and child–parent interaction (a home visit, or assessment by a lactation consultant/early childhood nurse may be useful here)
- Dysmorphic features
- Developmental assessment
- Jaundice/bruising/scratches
- Skin, hair and nails
- ENT
- Cardiac/respiratory

FIGURE 91.3 Example of growth chart with FTT from inadequate calorie intake (the red dots indicate FTT). Note how the weight drop is more marked than the length drop.

- Abdomen (e.g. distention, organomegaly)
- Endocrine (e.g. goitre, urinalysis, finger prick glucose)
- Lymphadenopathy

### Investigations

In a healthy infant with no concerns found on history and examination, no investigations are required, and reassuring the family and further monitoring is appropriate. If concerns are found, targeted investigation for these should be done. Simple first-line investigations may include:

- FBC, CRP
- iron studies
- UEC/LFTs
- urine MC&S
- coeliac screen
- stool fat globules/fatty acid crystals

### Other issues to consider

Frequent weighing of children may exacerbate parental anxiety. Babies under 3 months of age should not be weighed more than weekly, and not more than fortnightly after that. A paediatric review may be required in more significant FTT situations, and occasionally admission to hospital to further assess feeding, psychosocial aspects and other medical causes. In difficult cases, a team-based approach potentially using paediatricians, lactation consultants, dietitians, early childhood nurses, speech pathologists or psychologists as well as the family doctor can be utilised.

### § Short stature<sup>4,5,6</sup>

Short stature is considered to be below the 3rd percentile. In general, it is important to differentiate between normal physiological variants of growth and pathological causes.

#### Causes

- 1 Familial short stature—this follows the family trend of a genetically small family.
- 2 Constitutional delay in maturation—a common and normal variant in which the growth spurt is later than average. Bone age is delayed.
- 3 Pathological causes—of the many causes, some are rare but serious conditions, such as coeliac disease, Crohn disease and chronic kidney failure. These may present with slow growth as the only abnormal sign.

### Rough rule for expected adult height based on parental height

- Boys—mean of parents' heights + 5 cm
- Girls—mean – 5 cm

Recombinant human growth hormone treatment for those children with idiopathic short stature (ISS, a diagnosis of exclusion) increases height in some children, with the range of benefit usually between 3 cm and 7 cm. It is expensive, and while considered safe in the short term, long-term safety is lacking. Specialist advice is recommended.

### § Tall stature

Tall stature is considered to be above the 97th percentile. It is not a common presenting childhood problem in general practice.

#### Causes

- familial (predicted final height should roughly match mid-parental height)
- precocious puberty
- growth hormone excess (pituitary gigantism)
- hyperthyroidism
- syndromic: Marfan, Klinefelter, homocystinuria

#### Management

As tall stature is generally socially acceptable, reassurance, counselling and education may alleviate the family's concerns. If treatment is considered appropriate, high-dose oestrogen is used in very tall girls (accelerates epiphyseal maturation and reduces final height) while high-dose testosterone is used for boys. The management should be undertaken by endocrinologists. The ideal time to commence hormone therapy is just after the appearance of the first pubertal changes.

### Overweight and obese children

Approximately a quarter of Australian children are overweight or obese.<sup>7</sup> A recent national nutrition survey showed that children eat too much saturated fat and sugar and regularly exceed the recommended maximum times spent watching screens.<sup>8</sup> Obesity in childhood increases the risk of adult obesity. Nutritional obesity is associated with growth acceleration and advancement of bone age, while endocrine obesity has the opposite effect. Refer to CHAPTER 78.

## § Delayed puberty<sup>9</sup>

This is the absence of pubertal development (testicular enlargement in boys or breast development in girls) in:

- girls >13 years
- boys >14 years

Significant causes include:

- constitutional delay of growth and puberty (CDGP) is usually familial and the commonest cause. It is associated with delayed growth and bone age
- chronic illness (e.g. severe asthma, cystic fibrosis, kidney failure)
- poor nutrition and exercise
- anorexia nervosa

Other less common causes include chromosomal abnormalities (e.g. Turner syndrome) and gonadal hormone deficiency (e.g. Kallman syndrome, post-chemotherapy). Consider referral to a paediatric endocrinologist for investigation and management, which can include testosterone for boys and oestrogen for girls.

## § Precocious puberty<sup>10</sup>

Puberty is trending earlier than in previous generations, known as the 'secular trend', and is presumed to be due to improved nutrition and absence of chronic disease. True precocious puberty is considered to be:

- girls <8 years
- boys <9 years

Growth spurts will be earlier and bone growth will be advanced, though final adult height may be reduced from what would otherwise be expected due to premature fusion of the long bones (height issues may determine the need for treatment). True precocious puberty is 20 times more common in girls than boys. It is usually idiopathic, though pituitary adenomas are a rare cause and more common as a cause in boys (boys always require brain imaging). Treatments are often not required, but may include gonadotrophin releasing hormone (GnRH) analogues and cyproterone.

## § Premature thelarche<sup>10</sup>

This is breast development in girls under 8 years old without other pubertal signs. It usually occurs in girls under 3 years and spontaneous regression can be expected. It may present at birth. Observation

with reassurance for this benign condition is appropriate.

## § Premature adrenarche<sup>10</sup>

This is the isolated appearance of pubic hair in boys or girls aged 6–9 years old. There are no other features of virilisation or oestrogenisation, and the hair remains until other signs of puberty appear at the normal time. It is usually a normal variant (no specific treatment necessary) but may rarely signify atypical congenital adrenal hyperplasia. Referral is indicated if any concerns.

## § Pubertal gynaecomastia<sup>10</sup>

This is a normal variant of male puberty, with a prevalence of about 40–50% and is usually a transient phenomenon, subsiding in 2–3 years.

There is a palpable and/or visible disc of breast tissue, which in boys may feel quite firm and needs to be distinguished from adipose tissue in overweight boys. There is no hormonal or medical treatment and surgical removal is rarely necessary. Advice regarding clothes (e.g. loose T-shirts for social activities or swimming) or explanatory letters to school can be helpful.

## § Asymmetrical breast development<sup>10</sup>

This may occur in both sexes—in males being a variant of pubertal gynaecomastia and in females part of a normal development process—and reassurance that the breast sizes will usually normalise in time is all that is required. If the discrepancy persists and is causing psychological problems, further strategies, such as prostheses or reconstructive surgery, may be advised by specialists.

## § Infant breast hyperplasia

A breast 'bud' is common in most term babies and may enlarge with breastfeeding (see FIG. 91.4). Milk may discharge from some ('witches' milk) but reassurance is all that is required (see CHAPTER 101).

## § Growing pains<sup>11,12</sup>

Growing pains are real and common (around 1 in 5 children).

### Features

- Typical age 3–12 years
- Positive family history
- Usually bilateral and non-articular

FIGURE 91.4 Breast hyperplasia in a 15-week-old child

- Poorly localised in leg—typical sites include shins, calves, thighs, popliteal fossa (see FIG. 91.5)
- Episodic, with pain-free intervals from weeks to months
- Last minutes to hours, regardless of treatments, and usually gone by the morning
- Usually occur late in the day or during the night
- Normal examination
- No associated symptoms
- No pain or disability next morning (runs okay)
- Very active days or being moody may lead to a 'bad' night

### Management

- Problem resolves spontaneously in time
- Reassurance
- Consider analgesic and heat packs (usually unsuccessful)
- Massage is a reasonable option—appears to help
- Check ESR if in doubt

FIGURE 91.5 Growing pains: typical sites of pain

## Childhood cardiac murmurs

Many children and infants will be found to have systolic murmurs on routine examination, especially in the presence of a fever, anxiety or fear. The majority, which will be innocent or physiological, are found in asymptomatic children and due to normal turbulence of flow within the heart and great vessels.

### § Innocent murmurs<sup>13</sup>

An innocent murmur can be diagnosed in children over 12 months of age if the following 4 criteria are met:

- there are no other abnormal physical findings
- the child is asymptomatic (e.g. no dyspnoea, palpitations, fatigue, nausea/vomiting, ongoing cough)
- no history of risk factors for structural heart disease (e.g. family history, maternal gestational DM/alcohol abuse, previous Kawasaki disease/rheumatic fever, genetic disorders, prematurity)
- auscultatory features typical of an innocent murmur (see 7 Ss below)

In murmurs heard in infants under 12 months of age, the risk of asymptomatic structural heart disease is higher, and further assessment is warranted.

The 7 Ss of innocent murmurs:

- 1 Sensitive (changes with child's position or with respiration)

- 2 Short duration (not holosystolic)
- 3 Single (no associated clicks or gallops)
- 4 Small (murmur limited to a small area and non-radiating)
- 5 Soft (low amplitude)
- 6 Sweet (not harsh sounding)
- 7 Systolic (occurs during and is limited to systole)

### Investigation

Chest X-rays and ECGs rarely assist in the diagnosis, and can give false reassurance. When a murmur cannot be definitively diagnosed as innocent, the child should be referred for echocardiography, paediatric cardiologist review or both.

### § Nocturnal enuresis<sup>14,15</sup>

Nocturnal enuresis (NE), or bedwetting, is urinary incontinence occurring during sleep in a child with a developmental age of 5 or older. An absence of other urinary symptoms (e.g. frequency, urgency, straining or daytime wetting) is referred to as monosymptomatic NE, but if present then the term non-monosymptomatic NE is used. Primary enuresis (80% of cases) occurs in a child who has never had urinary continence for 6 months, and secondary enuresis (20%) occurs after 6 months or more of day and night dryness, and is more commonly associated with organic or psychological causes.

### What is normal?

Prevalence:

- 15–20% of 5 year olds
- 5% of 10 year olds
- 1–2% of 15 year olds

The spontaneous resolution of NE is 15% per year. Boys are affected 3 times as much as girls, and there is a strong familial tendency (75% have an affected first degree relative, with maternal enuresis a greater risk factor than paternal enuresis). Twenty per cent of children with NE will also have daytime symptoms.

### Aetiology

The causes of NE are not fully understood, but are thought to be multifactorial, including:

- disturbance in arousal—children with NE often do not wake adequately in response to a full bladder
- overactive bladder—which leads to a reduced bladder capacity. Children in this situation will often have daytime symptoms or other urinary symptoms (e.g. urgency, frequency)
- nocturnal polyuria—this is caused by reduced nocturnal vasopressin (which normally reduces nocturnal urine production)

Other common contributing factors include constipation (more than a third of patients) and obstructive sleep apnoea. Both of these should be carefully enquired about in the history. UTIs, diabetes and psychopathology (e.g. behavioural problems, ADHD, stress or trauma, depression, anxiety) can also contribute to and/or are associated with NE.

### Assessment

As well as assessing for the above contributing factors, a detailed history of the urinary symptoms and pattern should be taken. This is greatly assisted by getting the parents (and child if old enough) to complete a 48-hour time and volume chart of fluids and urine (including urine symptoms).

Physical examination should include ENT examination (looking for large tonsils or nasal obstruction causing OSA), abdominal examination (large bladder, faecal loading) and a focused neurological examination.

Urinalysis and culture can help detect infection. Blood tests, imaging and urodynamics are not usually required for uncomplicated primary NE. If there are daytime symptoms, significant other urinary symptoms, history or diagnosis of UTIs, structural abnormalities of the urinary system or genitals, secondary enuresis or refractory problems, then further investigations and/or specialist review is warranted.

### Advice for parents/child: 'they/you will very likely grow out of it'

Both the parents and child should be reassured that primary NE is common, unlikely to be a medical concern, not the child's fault and will nearly always resolve by itself with time. If the issue is not bothering the child then treatment is not needed. If conducted, treatment should be delayed until the child is able and willing to comply, which is generally around age 7 years.

### Tips to help the family deal with the situation

- Do not scold or punish the child.
- Praise the child if achieving dryness.
- Use a night light to help the child who wakes.
- Use absorbent 'pyjama pants' or mattress protectors, which can help reduce distress for parents and child, and will not contribute to the enuresis.

- Make sure the child has a shower or bath before going to kindergarten or school (to avoid teasing).

### Treatment

The treatment of primary monosymptomatic NE requires educated and motivated child and parents. Guilt, shame and punishment need to be avoided. The child should be involved in the treatment (even though the child didn't cause the problem, he or she has a role in treating it).

### Urotherapy

Urotherapy, or improving urination habits, includes increasing daytime fluid intake (to increase bladder capacity and awareness of bladder fullness). Six to eight reasonable-sized drinks spaced throughout the day (not just after school) are recommended (50 ml/kg/day). Regular voiding every 2–3 hours will help the child become more cognitively aware of the bladder sensations.

Promptly and aggressively treating constipation will help bladder capacity and control.

### Alarm therapy

Alarms can be obtained through enuresis clinics, pharmacies and community health clinics. They can be body-worn, or bed alarms, and work on operant conditioning. The buzzer goes off and wakes the child when urine is passed.

Alarms take effort and commitment. It takes around 3 weeks for the child to recognise the sensation of a full bladder, and around 12 weeks to achieve dryness (success is measured as 14 consecutive dry nights). If dryness is achieved it is either through the child waking to urinate (a third of children) or sleeping through dry (two-thirds).

The success rate is around two-thirds of children, and half of these remain dry. 'Overlearning' (giving additional fluids at bedtime to those who achieve dryness) can improve the child's response to a full bladder signal and reduce the risk of relapse, especially in those who are sleeping through dry. If bedwetting restarts after stopping treatment, alarm training can be retried.

### Medications

*Desmopressin acetate*: while this vasopressin analogue is very effective, it has a high relapse rate. It comes in tablets, melts and nasal spray, with the tablets and melts preferable as they have a lower risk of hyponatraemia. Fluids need to be restricted from 1 hour before taking to 8 hours after the dose. It is

very useful for children in school camps or having sleepovers.

Other treatment options include using anticholinergics, tricyclic antidepressants, combinations of alarms and medications, or combinations of medications. These options should be undertaken by a specialist or through an enuresis clinic.

## § Constipation in children<sup>16,17</sup>

Constipation usually appears between 2–4 years of age, and up to a third of primary school-aged children will report constipation over a 12-month period. In toddlers, the gender distribution is equal, but by age 5 boys are more likely to get constipation than girls, with the frequency of faecal incontinence 3 times higher in boys.

Constipation is defined as having 2 or more of the following over the previous 2 months:

- <3 bowel motions per week
- >1 episode of faecal incontinence per week (previously referred to as encopresis)
- large stools in rectum or palpable on abdominal examination
- retentive posturing (e.g. 'stiff as a board' standing/lying, tip toes, crossed legs, braces against furniture) and withholding behaviour (e.g. refuses, hides, requests nappy, denies need to go)
- painful defecation

Constipation is nearly always functional (>95%), though the GP should check for any red flags for a pathological cause (see below). The key feature in functional constipation is chronic faecal retention leading to rectal dilatation and insensitivity to the normal defecation reflex (see FIG. 91.6)

Normally the rectum is empty just prior to defecation; with faecal retention, the rectum is stretched, weak and numb and it can leak.

### Advice to parents and child

- Educate them on 'the vicious cycle of constipation'.
- Remove blame for child and parent (e.g. while considering increasing dietary fibre and fluids to help constipation may be reasonable, it is usually retention behaviour driven by anxiety or fear).
- Explain stretched bowel (it is numb and weak).
- Outline need for softening stools (aiming for 'wet cement') and prolonged treatment (months) to restore the normal defecation reflex.
- All poos are to be celebrated.

FIGURE 91.6 The vicious cycle of constipation

- Advice on correct posture and position—‘how to do a poo’:<sup>18</sup>
  - feet supported (e.g. with a foot stool)
  - knees higher than bottom and apart
  - leaning forward with elbows on knees
  - encourage child to push out stomach
  - ensure privacy (including at preschool/school)

### Assessment

- History
  - check hardness, frequency, duration of constipation
  - Red flags for organic cause (e.g. blood in stools, perianal disease, fever, weight loss/delayed growth, delayed meconium/thin strip-like stools, vomiting, urinary symptoms, abnormal neurological findings in legs, medications used for children with behavioural/developmental issues)
- Examination:
  - abdominal exam for faecal loading
  - growth and development
  - lower back, neurological examination of legs
  - rectal examination not normally required
- Abdominal X-ray (not normally required)—may show a loaded colon.

### Management

(See CHAPTER 41)

- Education and advice (as above)
- Behaviour modification:

- regular toileting (where possible), 3 times/day for 3–5 minutes
- reinforce desired behaviour with stickers on an age-appropriate chart.
- Laxatives—if constipation has been brief in duration, treat for 3 months, but for chronic constipation, treat for 6 months minimum
- Can use macrogol 3350 (Movicol), paraffin oil or lactulose<sup>18</sup>
- For acute faecal impaction, high-dose laxatives can be used until liquid stools are achieved, and then revert back to maintenance treatment.<sup>18</sup> Enemas are suitable only for children with acute severe rectal pain or distress and are rarely required

### COMMON SKIN PROBLEMS<sup>19,20,21</sup>

Many of the common problems (e.g. acne, psoriasis, atopic dermatitis, seborrhoeic dermatitis) are covered in more detail in CHAPTER 123. The following are specifically (or usually) disorders of the neonatal period and early infancy.

#### § Toxic erythema of newborn

This benign condition occurs in around half of babies, usually 1–2 days after birth (but may appear up to 2 weeks later) with 2–3 mm erythematous macules and papules developing into pustules, with a surrounding blotchy area of erythema, described as a ‘flea-bitten’ appearance. The rash starts on the face and spreads to the torso and proximal limbs, and spares the palms and soles. The rash usually fades over a week, but may recur for a few weeks. No treatment is required.

#### § Salmon patch (naevus flammeus nuchae)

These are flat patches of pink or red skin with poorly defined borders. They occur in 40% of all newborns, and are seen at the nape of the neck (‘stork bite’) or between the eyebrows/on the eyelids (‘angel’s kiss’) (see FIG. 91.7). They are more prominent when the child is crying. They fade over 6–12 months but neck patches may persist into adult life. No treatment is required.

#### § Infantile haemangioma

Infantile haemangiomas can be superficial (‘strawberry haemangioma’, flat or lumpy, resembling strawberry jam splashed on the skin, see FIG. 91.8) or deep (‘cavernous haemangioma’, a bluish swelling). They usually appear after birth, and occur in 10% of infants.

**FIGURE 91.7** Salmon patch on the upper eyelid: called an 'angel's kiss'

**FIGURE 91.8** Strawberry haemangioma on the face of a child

Some 80% occur on the head and neck and 80% of their growth occurs in the first 3 months (most stop by 5 months, though some continue until 18 months). They usually involute and disappear (50% by 5 years, 70% by 7, 90% by 10), though regression of bulky ones tends to be incomplete, and they

often leave an atrophic 'dented' scar. Large, deep or multiple haemangiomas can be associated with malformations of organs, and referral of these, those causing cosmetic issues (such as being prominent on the face), those that impair vision/hearing/breathing or feeding, or in other important locations (e.g. perineum or sacrum) is recommended. Propanolol is a very promising new treatment for more significant lesions, especially if used early in the growth phase, and is now usually preferred over oral steroids.

### § Capillary vascular malformation ('port wine stain')

These dark red to purple lesions (a type of naevus flammeus) are present from birth and affect 3 in 1000 neonates. They are usually flat at birth, though they can become lumpy. There is an association with vascular syndromes, including Sturge-Weber syndrome, where a port wine stain on the skin supplied by the ophthalmic division of the trigeminal nerve is accompanied by glaucoma and seizures, and patients are at increased risk of developmental delay and hemiplegia. Port wine stains will often respond well to pulse dye laser (the treatment of choice). Cosmetic camouflage is useful.

### § Lymphatic malformation (lymphangioma)

These are present at birth but can subsequently grow. They can vary from large fluid-filled spaces (cystic hygromas) down to clusters of small firm blisters resembling frogspawn. They can be skin-coloured, red or purple (if associated vascular involvement) or brown or black. Surgical excision may be required.

### § Dermal melanocytosis ('Mongolian spot')

This condition presents as blue-grey discolouration of the skin over the lower back and sacrum in babies of east Asian and other dark-skinned ethnic backgrounds. These are of no clinical significance but may be mistaken for bruising or non-accidental injury. They usually disappear by 4 years of age.

### § Sebaceous hyperplasia

Hyperplastic sebaceous glands appear as tiny yellow-white papules on the nose or forehead. They disappear in several weeks.

FIGURE 91.9 Milia on the face of a 2-week-old infant

### § Milia

Blocked sebaceous glands, leading to pearly-white lumps under the skin, especially on the face, are present in 50% of neonates. The firm, white papules are about 1–2 mm in diameter and differ from the yellowish papules of sebaceous hyperplasia. These also disappear after several weeks, and usually no treatment is required (see FIG. 91.9).

### § Miliaria ('sweat rash')

This is related to overheating and occurs in skin folds such as around the neck and armpits, but also on the face. It appears as two types:

- 'crystallina'—beads of sweat trapped under the epidermis with surrounding erythema
- 'rubia'—itchy red papules

It is a benign condition that disappears after a few weeks.

If problematic:

- keep skin dry and cool (e.g. fan, air-conditioner)
- dress in loose-fitting cotton clothing
- avoid frequent bathing and overuse of soap

- mild topical steroids (e.g. hydrocortisone) can help if inflamed

### § Suckling 'blisters'

These are a hyperplastic response to suckling, and are common on the upper lip. Reassure that these will settle.

### § Umbilical discharge

When the umbilical stump first separates, some granulation and mild exudate can be present until healing occurs. If the umbilicus is discharging pus and there is surrounding erythema in the neonate, infection should be considered, and a bacterial swab taken and appropriate antibiotics given.

### Bleeding umbilical cord

Small amounts of bleeding may occur as the cord is separating and requires no treatment unless it is more profuse (if so, consider infection or a bleeding disorder).

### § Umbilical granuloma

These common fleshy pink-red growths can cause a persisting seropurulent discharge after the separation of the umbilical stump. The granuloma is often seen only by carefully examining the base of an 'innie' umbilicus. Drying out of the granulomatous tissue and healing can be achieved by the parent airing regularly, applying salt twice a day at home for a week or two (followed by irrigation), or the GP using a silver nitrate stick or copper sulphate crystals every few days until healing occurs. Large pedunculated and persistent granulomas may be helped by applying a double ligature to the neck of the granuloma.

### § Pityriasis alba

- These are round or oval pale skin patches usually on the face of children and adolescents, and are more visible in tanned or dark-skinned patients.
- They can occur on the neck and upper limbs, occasionally on the trunk.
- Full repigmentation occurs after a couple of years
- They may start out pale pink then fade to white, and can leave slight depigmentation.

### Treatment

- Reassurance
- Simple emollients
- Restrict use of soap and washing
- Mild steroids if scaly and itchy (rarely necessary)

## § Atopic dermatitis (eczema)

See FIGURE 91.10.

This common condition may appear typically in infants on the cheeks of the face, the folds of the neck and scalp and extensor surface of the limbs. For further information on its manifestation in children and management refer to CHAPTER 123.

## § Seborrhoeic dermatitis

See FIGURE 91.11.

This is quite different from adult seborrhoeic dermatitis and appears in the first 2 to 3 months.

Refer to CHAPTER 123.

## § Nappy rash

Nappy rash occurs under the nappy in response to wetness. The most common cause is contact dermatitis from urine and faeces, which will

FIGURE 91.10 Atopic dermatitis (eczema) in a 3-year-old child with widespread distribution and severe pruritus

FIGURE 91.11 Seborrhoeic dermatitis in a 10-week-old child, showing a red, scaly rash affecting the scalp, forehead, face, axillae and nappy area. Both cradle cap and nappy rash are present.

inevitably cause a rash if left on the skin for long enough. This will lead to the dull red rash being most prominent where the nappy contacts the skin, and sparing the folds. Sometimes ammonia is formed, resulting in a chemical burn (hence the alternative term ammoniacal dermatitis).

Nappy rash in the folds is more commonly found in infants with cradle cap and seborrhoeic dermatitis. Thrush can also coexist, with the rash appearing more bright red, and often having satellite lesions or pustules around the main rash. Bacterial superinfection (impetigo, see later in this chapter) can occur, with crusting, pustules and irregular blisters. Swabs should be taken for this if suspected. Other conditions such as psoriasis and atopic dermatitis also need to be considered, especially for resistant or recurrent nappy rash.

### Advice to parents

- Keep the area dry. Air dry when possible (e.g. lying on towel without a nappy).
- Do not use powder, which can irritate the skin.
- Change wet or soiled napkins promptly—disposable ones with their absorbent hydrocellulose gel are very effective.
- If using cloth nappies, nappy liners can help keep the skin dry. Do not use plastic pants around them.
- Give evening fluids early to reduce night-time wetting, and change the nappy before parents go to bed.
- Wash gently with warm water and pat dry (do not rub).
- Avoid excessive bathing and soap.
- Use moisturisers to keep skin lubricated (e.g. zinc oxide and castor oil cream). Silicone barrier creams can also help.

### Treatment

- Hydrocortisone and/or antifungal cream while rash is present.
- Antifungal can be continued for a few more days if thrush suspected.
- Do not use strong steroid creams on baby's bottom.

### § Cradle cap

Cradle cap is infantile seborrhoeic dermatitis confined to the scalp. The seborrhoeic dermatitis may also involve other areas (see CHAPTER 123). Cradle cap is very common, usually occurring in the first 6 weeks of life and settling over the next few weeks to months, but it sometimes takes much longer.

Greasy yellow scales are formed in response to sebum combining with old skin cells as they try to dry and fall off. The yeast *Malassezia furfur* may be involved. It is not usually itchy or distressing to the child.

### Treatment

- Reassurance and watchful waiting (if not too bad, given the natural history is to improve with time)
- Use vegetable oil overnight to soften scales and then gently brush off (not olive oil; this encourages *Malassezia*)
- Baby shampoos and then gentle brushing off of scales
- 2% ketoconazole shampoo (Nizoral) twice weekly

- Apply hydrocortisone cream to red and inflamed areas

### § Molluscum contagiosum in children<sup>22,23</sup>

Molluscum is usually diagnosed by its distinct pink pearly appearance and central punctum (see CHAPTER 126). It is very common in children (up to 10% of the paediatric population have it at any given time), and is usually spread by direct contact, sharing towels and bath toys, or through water (e.g. sharing baths or swimming).

The rash lasts weeks to months, or occasionally a couple of years. Molluscum rarely leaves tiny pit-like scars. It can have a reactive dermatitis surrounding the lesions (especially in children prone to atopic dermatitis) and hydrocortisone cream can be used to help this.

### Advice to parents

- Give the child a shower instead of a bath (the child can spread the virus to other parts of the body).
- Don't share baths.
- Wash and dry bath toys after use.
- After showers/baths/swimming, dry areas with molluscum last and don't share/re-use towels.
- Wash hands after touching molluscum.
- Don't exclude children from school or playing together.
- If swimming, reasonable precautions include covering the lesions with waterproof tape and having personal kick-boards.

### Treatment

The most common approach in children is to leave the rash alone and wait for it to clear. Treatments designed to irritate the lesion can make the rash clear more quickly (see CHAPTER 126) but can be distressing to the child and so are not normally done.

### § Warts in children<sup>24</sup>

Warts affect about 10% of children. Even without treatment, 50% of them will go in 6 months, and 90% in 2 years. It is therefore best to avoid painful treatments unless the parent and child are motivated (e.g. for cosmetic reasons, or uncomfortable plantar

warts). A reasonable option that can help the wart disappear faster is to cover with occlusive tape (e.g. duct tape) 24 hours a day.

Refer to **CHAPTER 68** (plantar warts) or **CHAPTER 126** (general warts) for more active treatment options.

## § Hair problems in children

Refer to **CHAPTER 128**.

## § Lead poisoning<sup>25</sup>

- Young children are susceptible to lead poisoning. They are more likely than adults to be exposed to lead because of their exploratory and mouthing behaviour and because they absorb more of any ingested dose. The most common source seen in general practice is home renovation, involving paint removal in houses built before the 1980s.
- All Australians should have a blood lead level below 10 mcg/dL (though there is no known safe level of lead).
- Some communities are more susceptible to lead exposure due to industrial or mining activity, and some occupations and hobbies can also increase risk to household members. These include home and furniture restoration, soldering, burning of plastics and paints and cigarette smoking. Other potential sources include imported toys containing lead or coated with lead-based paints, some 'traditional' medicines and improperly fired ceramic cookware (e.g. imported tagines).
- Levels of lead have increased in the biosphere 1000-fold in the past 300 years, especially during the second half of the twentieth century, but the elimination of lead in petrol has helped reduce the exposure risk.
- Levels above 10 mcg/dL are associated with adverse neurocognitive effects including decreased IQ levels and behavioural issues, and it is uncertain whether levels below this also cause problems.
- When symptoms appear, they are usually non-specific and may include lethargy, intermittent abdominal pain, irritability, headache, abnormal behaviour and, in acute high-level exposure (rare), encephalopathy.
- High blood lead levels should be considered in the presence of unexplained iron-deficiency anaemia.
- Advise parents or parents-to-be to reduce exposure to lead by testing paint (particularly

old or peeling paint) in houses (testing kits are readily available in paint shops), painting over old paint, being careful with old furniture and imported toys, and avoiding exposure to smoking or other sources.

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Bed wetting (enuresis)
- Crying baby
- Dyslexia and other SLDs
- Encopresis
- Growing pains
- Infant colic
- Nappy rash
- Seborrhoea in infants
- Snuffling infant
- Tear duct blocking
- Teething
- Thumb sucking

*A surgeon should have three diverse properties in his person. That is to saie, a harte as the harte of a lyon. His eyes like the eyes of a hawke, and the handes of a woman.*

John Halle (1529–68)

An imperative task for the GP is not only to diagnose surgical conditions in infancy and children as early as possible, but to be aware of the degree of urgency and the optimal times for intervention. In many instances the emphasis should be placed on a non-surgical solution using natural resolution with time and simple ‘tricks of the trade’.

## HEAD DEFORMITY

The neonate’s head may become distorted because of the position in utero or after the passage through the birth canal. The head shape can recover to a normal shape within about 8 weeks following birth. If the abnormal shape persists consider deformational plagiocephaly or craniostenosis.

### § Plagiocephaly

This is asymmetry of the skull with a normal head circumference. The shape can be likened to a tilted parallelogram (see FIG. 92.1); it is the most common cause of an abnormal head shape. On the side with the flat frontal area the ear and the parietal eminence sit more posteriorly. It is either congenital or acquired and often results from the infant sleeping in one position. There is no impairment of cerebral development or intellect. If the sutures are ridged or the sleeping position causation is ruled out, a skull X-ray should be performed. Management involves initially changing the side to which the child usually faces for sleeping, then regularly changing sides and encouraging time in the prone position while awake. If not responsive, a cranial remodelling helmet can be tried—best from 4 to 8 months.<sup>1</sup>

### § Craniostenosis

This is premature fusion of one or more sutures of the cranial vault and base, which act as lines of growth. The abnormality of head shape depends on the sutures involved. The diagnosis is confirmed by radiography. Prompt referral to a paediatric craniofacial surgeon is necessary as planning for possible complex surgery, best at 5 to 10 months, is required.

**FIGURE 92.1** Plagiocephaly, congenital or acquired. The long axis is deflected from the sagittal plane. In this case the right ear is more posterior.

### § Hydrocephalus

This condition, which is due to an imbalance between the production and absorption of CSF, usually caused by obstruction to circulation, requires early referral for diversion of ventricular fluid. Prognosis is generally good with early intervention and regular supervision.

## Macrocephaly and microcephaly

Macrocephaly and microcephaly are defined as a head circumference greater than the 97th percentile and less than the 3rd percentile respectively. Infants whose head circumference measurements cross these percentile lines require expert assessment and investigation. It is appropriate to undertake regular head circumference measurements in the early childhood years.

## EARS, NOSE, FACE AND ORAL CAVITY

### § Prominent bat/shell ears

The ears are almost adult size and firmness by 5 to 6 years of age but the ear cartilage is not strong enough to cope with surgery under 3 years. For this

reason, and because it is best to correct the problem when the child is in a position to support a decision to operate, the optimal time for surgical correction is after 5 to 6 years. It may be possible to correct an ear deformity by moulding the ear with tape or splinting within the first 6 months of life.<sup>1</sup>

### § Facial deformity

It is best to refer any facial deformity as soon as it is detected.

### § External angular dermoid

This dermoid cyst, which has a readily identifiable constant position, lies in the outer aspect of the eyebrow. It is noticed in infancy as it progressively enlarges. Excision is advisable.

### § Cleft lip and cleft palate

Congenital clefts of the lip and palate occur in approximately 1:600 of all births. It is very important that the simplest and least obvious form should be recognised in time for adequate repair. This is the submucous cleft, frequently not recognised in infancy because the palate appears to be intact.<sup>2</sup> The submucous cleft can be diagnosed on close inspection as the uvula is bifid and there is a deep groove in the midline of the palate covered only by mucous membrane. The ideal age for repair of the cleft lip is under 3 months of age. Secondary surgery can then be performed at various ages. The repair of the palate, which requires preliminary diagnostic ultrasound, is best performed before the child begins to speak. The optimal time is 6 to 12 months of age.

### § Nasal disorders

Rhinoplasty is best deferred to late adolescence. If performed early there is a higher incidence of secondary surgery.

Choanal atresia may be unilateral, leading to delayed diagnosis, or bilateral, where there is no instinctive reaction to breathe through the mouth, leading to asphyxia. Since the obstruction is usually by a very thin membrane one side can be perforated with a urethral sound as an emergency procedure.

Septoplasty can be considered if the problem is symptomatic.

### § Tongue tie (ankyloglossia)

Early signs:

- tongue may appear heart-shaped

- infants unable to protrude the tongue over the lower lip
- breastfeeding problems

The ideal time to release the 'tie' is in infancy, under 4 months.<sup>3</sup> As the frenulum is thin and avascular, simple frenulotomy by snipping with sterile scissors (with care) is advisable (see FIG. 92.2). Otherwise surgery should be left until after 2 years of age. The conditions may not be noticed until later in life. A useful guideline is a strong family history of speech problems corrected by tongue tie surgery.

FIGURE 92.2 Tongue tie release in infant

### § Pre-auricular sinus

This common condition can get recurrently infected with pus discharge from a small opening immediately anterior to the ear at the level of the meatus in front of the upper crus of the helix. It also causes cosmetic problems. It is not a branchial sinus. Refer when diagnosed for surgical excision although it can be left alone if it is causing no problems.

### § Branchial sinus/cyst/fistula

This is a rare condition and is located inferior to the external auditory meatus or anterior to the sternomastoid muscle. The opening may discharge mucopus. A skin tag or cartilage remnant may be present. Refer when diagnosed for excision.

### § Strabismus (squint)

A squint is rarely obvious in the first weeks of life, but tends to show up when the baby learns to use the eyes, from about 2 weeks to 3 or 4 months of age.

FIGURE 92.3 Types of squint

However, it may appear late, even as an adult. Vision, which is present at birth, continues to develop until 7–8 years of age.

### Main types of squint

See FIGURE 92.3.

- *Constant or true squint* is one that is permanent—always present.
- *Latent squint* is one that only appears under stressful conditions such as fatigue.
- *Transient squint* is one that is noticeable for short periods and then the eye appears normal.
- *Alternating squint* is one that changes between the eyes so the child can use either eye to fix vision.
- *Pseudosquint* is not a true squint but only appears to be one because of the shape of the eyelids, i.e. broad epicanthic folds.

A useful way to differentiate a true squint from a pseudosquint is to observe the position of the light in the eyes (corneal reflections) when a torch is shone into them from about 40 cm away. This light reflex will be in exactly the same position in both eyes in the pseudosquint but in different spots with the true squint.

- If one eye is 'lazy' (that is, not being used), it is standard practice to wear a patch (maybe on glasses) over the good eye for long periods in order to use the inactive eye and have both eyes eventually capable of vision.

- The two serious squints are the constant and alternating ones, which require early referral. Transient squint and latent squint usually are not a problem.
- Always refer children with strabismus (squint) when first seen to exclude ocular pathology such as retinoblastoma, congenital cataract and glaucoma, which would require emergency surgery.
- Children with strabismus (even if the ocular examination is normal) need specialist management because the deviating eye will become amblyopic (a lazy eye with reduced vision, i.e. 'blind', if not functioning by 7 years of age). The younger the child, the easier it is to treat amblyopia; it may be irreversible if first detected later than school age. Surgical correction of a true squint is preferred at 1–2 years of age.

### Blocked nasolacrimal duct

Refer CHAPTER 91.

### NECK LUMPS

#### 💰 Sternomastoid tumour/fibrosis

Features in infants:

- hard painless lump (2–3 cm long) within sternomastoid muscle
- tight and shortened sternomastoid muscle
- usually not observed at birth
- appears at 20–30 days of age
- associated torticollis—head turned away from but tilted towards the tumour
- restricted head rotation to side of tumour

Most tumours resolve spontaneously within 1 year. The mother or baby's carer should be reassured and the child referred to a physiotherapist early. The mother or carer should frequently gently massage the lump, rotate the head to the side of the lesion and then side-flex (stretch) away from that side. Repeat several times twice daily. Encourage the baby to look towards the affected side. If surgery for a persistent fibrotic shortened muscle is required it is best before 12 months.

Older children can present with torticollis and a tight, short fibrous sternomastoid muscle. It is associated with rotation of the head to the affected side, hemihypoplasia of the face and a wasted ipsilateral trapezius muscle. It requires surgical repair.

### § Thyroglossal cyst

This is the most common childhood midline neck swelling. It moves with swallowing and tongue protrusion. It is prone to infection, including abscess formation. The cyst and its tract are best excised before it becomes infected.

### § Lymphatic malformation/lymphangioma/cystic hygroma

These usually present as soft cystic tumours of the neck, face or oral cavity. They resemble clusters of vesicles and are often poorly localised. Some have visible red dots due to haemangiomatous inclusions. If located in the floor of the mouth or peripharyngeal area they endanger the airway and can precipitate an emergency requiring surgery. Surgery is advisable in the early years.

### Cervical lymphadenopathy

Refer to CHAPTER 61.

## BIRTHMARKS AND SKIN TUMOURS

### § Infantile haemangioma (strawberry naevus)

See CHAPTER 91. These start soon after birth as a red pinpoint lesion and grow rapidly for the first 6 months, then involute and become pale. Full resolution may take several years. Reassure parents and demonstrate how to stop any bleeding by applying pressure. Possible treatment options include oral or intralesional steroids, vascular laser, interferon and surgery. Surgical intervention is usually not necessary. Exceptions are locations in critical areas such as periorbital, nose, lips and face. Refer lesions on the eyelid early since visual obstruction can lead to amblyopia. Stridor accompanying a haemangioma on the face is suggestive of laryngeal haemorrhage, so refer urgently.

### § Capillary vascular malformation (port wine stain)

These are present from birth and surgical intervention is inadvisable. They may be treated by pulsed dye laser, which is best initiated as early as possible as the response is best in the first 2 years<sup>4</sup> (see CHAPTER 91).

### § Venous malformations

These are aggregations of abnormal subcutaneous veins that may infiltrate deeper tissues. In the past

these lesions were treated surgically, but now the emphasis is on specialised sclerosant agents injected under fluoroscopic guidance and specialised laser techniques. Referral to Vascular Malformation Clinics in larger centres is worthy of enquiry.

### § Lymphatic malformation

These appear sometimes as skin lesions because of the red discolouration on the surface of the tumour. Management is as described above.

### § Congenital naevi

These have to be treated on an individual basis. If giant naevi they can be dermabraded at ideally less than 6 weeks.

### § Benign juvenile melanoma (Spitz naevus)

These pigmented lesions, which typically appear on the face, are usually surgically excised because of their rapid growth and family concerns.

## CHEST AND BREAST DISORDERS

### § Breast asymmetry

If necessary surgery should be performed in late adolescence after breast development is complete. It can take the form of a unilateral implant, different-sized bilateral implants or unilateral breast reduction.

### § Macromastia

Reduction surgery should also be delayed until breast growth is complete, at late adolescence.

### § Gynaecomastia

This is not to be confused with pseudogynaecomastia due to fat in obese preadolescents. However, gynaecomastia in thin boys does occur and requires referral for assessment if it cannot be attributed to drugs such as oestrogen. If it develops in the pubertal stage, gynaecomastia may resolve spontaneously within 1 or 2 years. If necessary, simple mastectomy can be performed, if no cause can be found.

### § Subareolar hyperplasia in boys

This presents as a firm discoid subareolar lesion similar to premature breast hyperplasia of girls. It typically occurs at about 12–14 years. There is no indication for surgical treatment. Give an explanation with reassurance that the problem will dissipate.

## § Chest wall skeletal deformity

Surgical correction is best performed in adolescence.

## § Poland syndrome

This syndrome is an absent sternal head of pectoralis major with associated chest wall deformity plus a hypoplastic or absent breast and nipple–areolar complex. Surgical correction can be undertaken from 10 to 20 years.

## CONGENITAL HEART DISORDERS

GPs have an important role in the diagnosis of congenital heart disorders as many of the affected infants develop cyanosis, murmurs or congestive heart failure. Early diagnosis and intervention helps prevent serious problems such as bacterial endocarditis and paradoxical emboli.

## § Ventricular septal defect (VSD)

VSD is the commonest congenital heart lesion (1:500 births).

The defect connects the two ventricles with a L → R shunt (see FIG. 92.4).

FIGURE 92.4 Ventricular septal defect: defect in muscle wall

Symptoms and signs depend on size of hole. All have a palpable thrill at the left sternal edge and a pansystolic murmur down right sternal edge.

Small VSD ('maladie de Roger'): harsh murmur, usually asymptomatic and closes spontaneously.

Larger VSD: symptoms appear in infancy.

- Breathlessness on feeding and crying (i.e. early CHF)
- Recurrent chest infections
- Failure to thrive
- Heart failure from about 3 months with large defects

Refer early, especially if failure—early surgery performed by 6 months but can be performed at any age from the newborn period. A patch can close the defect through open-heart surgery. Some may be closed by sealing with an occlusive device through a percutaneous cardiac catheter. A cardiologist will make the appropriate decision. As a general rule about 50% of all VSDs will close spontaneously. The membranous type, unlike the muscular type, is less likely to close spontaneously.

## § Atrial septal defect (ASD)

In ASD the defect connects the two atria with two distinct types—ostium secundum with holes higher in the septum (most common) and ostium primum with holes lower in the septum (more serious) (see FIG. 92.5). Signs are a mid-systolic murmur in the pulmonary area, a split 2nd sound and a loud P2. An echocardiogram is diagnostic.

FIGURE 92.5 Atrial septal defect: primum defect

Symptoms are uncommon in infancy and childhood with ostium secundum but heart failure with pulmonary hypertension develops early with ostium primum.

Refer these patients early. Prophylactic antibiotics are needed for patients with ostium primum. Follow other cases with regular echocardiograms and growth/development monitoring. Closure is advisable where there is evidence of a troublesome shunt. Options are repair by direct surgical suture or an insertion of a patch or a device closure using a self-expanding 'double umbrella device' manipulated into the defect via cardiac catheterisation.

All patients require prophylactic antibiotics before procedures.

## § Patent ductus arteriosus

The ductus fails to close after birth. A loud, continuous machinery murmur is heard. Symptoms relate to

shunt size. The child presents with a murmur with possible respiratory infections, failure to thrive and heart failure. Refer for possible surgical closure by ligation. Alternatives include device closure with placement of an occlusive device or by embolisation coils.

### § Coarctation of the aorta

This usually presents in infancy with heart failure. Refer for early surgery to remove the narrowed portion of the aorta.

## HERNIAS AND GENITAL DISORDERS

### § Inguinal hernias

These usually present in the first 3 to 4 months with an incidence of 1 in 50 males and 1 in 500 females (see FIG. 92.6).

FIGURE 92.6 Sites of common hernias

They and femoral hernias should be referred urgently as early surgery is advisable to avoid the high risk of bowel incarceration or strangulation and ovarian entrapment and ischaemia in females. It is useful to follow the '6-2' rule (see CHAPTER 114).

### § Hydroceles

Scrotal hydroceles are painless cystic swellings around the testis. The opening of the processus vaginalis is narrow and often closes spontaneously. Two types can be identified—slack, often bilateral, which disappear within 12 months, and tense, often unilateral, which often persist after the first year. Ninety per cent resolve by 18 months of age; for those that persist, referral is recommended with a view to surgical intervention if present for longer than 2 years.

### § Undescended testes

Testes can still descend up to 3 months after birth. Refer by 6 months with a view to correction between 9 and 12 months but definitely before 2 years (see CHAPTER 114).

### § Hypospadias

Refer to disorders of the penis (see CHAPTER 115). Look for other abnormalities. Refer as soon as possible if the child is not producing a good urinary stream. Non-urgent cases should be evaluated by 6 months with a view to surgery at around 12 months; these patients should not be circumcised.

### The foreskin and circumcision

For more detail refer to penile problems (see CHAPTER 115). If not circumcised in the neonatal period it is best performed under general anaesthetic after 6 months of age following consultation, counselling and with the consent of both parents.

### § Phimosis

Real phimosis is uncommon and almost all cases of tight foreskin with narrowing of the preputial orifice resolve naturally. Treatment with corticosteroid creams should be considered (see CHAPTER 115). Probably the only indication for circumcision is persistent difficulty in passing urine.

### § Paraphimosis

Management of this painful condition is outlined in CHAPTER 115.

### § Umbilical hernia

Surgery is not usually required for umbilical herniae as most close naturally by 4 years of age (95% resolve spontaneously by 2–3 years). Refer for possible repair if still present at 4 years of age. A good guideline is that if the hernial orifice is greater than 1 cm at 12 months then surgical intervention is a possibility. It is usual to operate at 4–5 years.

### § Umbilical granuloma

Refer CHAPTER 91.

### § Para-umbilical hernia

This is due to a defect in the linea alba adjacent to the umbilicus proper. Most lie just above the umbilicus. The defect is felt like an elliptical slit with firm edges.

Spontaneous closure rarely occurs and they are more likely to incarcerate. Refer for operation at any age preferably after 6–12 months.

### § Epigastric hernia

An epigastric hernia (not to be confused with divarification of the rectus muscles) lies between the umbilicus and the xiphisternum. It is unlikely to close naturally, is likely to incarcerate and causes pain by strangulation of herniated fat. Indications for repair are pain (reproducible on palpation of the hernia) and cosmetic.

### § Anal fissure

Anal fissures are often seen in infants and toddlers with uncomfortable defecation and minimal bright bleeding. The anal mucosa is split in the midline either anterior or posterior. It is caused by the passage of hard stool. The fissure usually heals within a few days.

### § Fused labia (labial agglutination)

Labial fusion is caused by adhesions considered to be acquired from perineal inflammation (see CHAPTER 107). They are certainly not present at birth. Most authorities recommend no treatment if the child can void readily and allow natural healing to occur.

### § Penile problems

Refer CHAPTER 115.

## CHILDHOOD LEG AND FOOT DEFORMITIES

### § Developmental dysplasia of hip

- Detected by clinical examination (Ortolani and Barlow tests) and ultrasound examination (see CHAPTER 65).
- Infants are usually treated successfully by abduction splinting (e.g. Pavlik harness).
- Open reduction may be required, especially in older babies and toddlers.

### § Bow legs (genu varum)

- Most are physiological (which are symmetrical) and improve with age.
- Consider rickets in children at risk.
- Toddlers are usually bow-legged until 3 years of age.

- Resolve spontaneously by 3 years except in severe cases.
- Monitor intercondylar separation (ICS): distance between medial femoral condyles.
- Refer when ICS >6 cm at 4 years, not improving or asymmetric (see FIG. 92.7).

### § Knock knees (genu valgum)

- Most are physiological and children are usually knock-kneed from 2–8 years (maximal 3–4 years).
- Running is awkward, but improves with time.
- Reassure parents about spontaneous improvement.
- Monitor intermalleolar separation (IMS): distance between medial malleoli.
- Refer if IMS >8 cm (see FIG. 92.7).

FIGURE 92.7 Postural variance of lower limbs

### § In-toeing (pigeon toes)

In-toeing does not cause pain or affect mobility.

Causes of in-toeing (see FIG. 92.8) are metatarsus varus, internal tibial torsion and medial femoral torsion. Children with femoral torsion tend to sit in a characteristic 'W' sitting position (see FIG. 92.9). These features are compared in TABLE 92.1.<sup>5</sup>

### § Out-toeing

#### Infants

- Have restricted internal rotation of hip due to an external rotation contracture
- Exhibit a 'Charlie Chaplin' posture between 3 and 12 months—up to 2 years

FIGURE 92.8 Causes of in-toeing

FIGURE 92.9 The classic 'W' position of femoral torsion (inset hips)

- Child weight-bears and walks normally
  - No treatment required as spontaneous resolution occurs
- Surgery may be necessary in older children.

§ Club foot (congenital talipes equinovarus)

Most abnormal-looking feet in infants are not a true club foot deformity; the majority have postural problems referred to as 'postural talipes' such as talipes calcaneovalgus, metatarsus varus and postural talipes equinovarus. Such conditions are usually quite mobile and mild, and all resolve spontaneously without treatment. True club foot deformity is usually stiff and severe, and requires orthopaedic correction.<sup>5</sup>

§ Inset hips (medial femoral torsion)

In children with inset hips, the femur tends to rotate inwards especially when the child is about 5–6 years old and is normal up to 12 years. The children tend to sit in a 'W' position (see FIG. 92.9). Fortunately, most children outgrow this condition before the age of 12.

Table 92.1 In-toeing in childhood

	Metatarsus varus	Internal tibial torsion	Medial femoral torsion
Synonyms	Metatarsus adductus		Inset hips
Age at presentation	Birth	Toddler	Child
Site of problem	Foot	Tibia	Femur
Examination	Sole of foot bean-shaped	Thigh–foot angle is inwards	Arc of hip rotation favours internal rotation
Management	Observe or cast	Observe and measure	Observe, rarely surgery
Resolution (usually by)	3 years	3–4 years	8–9 years
When to refer if not resolved	3 months after presentation	6 months after presentation	8 years after presentation

Source: Reprinted from D Efron. *Paediatric Handbook*. Melbourne: Blackwell Science, 1996 with permission

## § Flat feet (pes plano valgus)

The majority are physiological and are usually hereditary. All newborns have flat feet but 80% develop a medial arch by their sixth birthday and most by 11 years.<sup>5</sup> The presence of the arch can be demonstrated to parents by the tiptoe test. The arch can be seen better when the feet are hanging in the air and even better still when the child is standing on tiptoes (see FIG. 92.10). Flat feet are present in about 10% of teenagers. No treatment is required unless painful and stiff. Good roomy footwear is important. Studies in California have shown no benefit from wearing orthoses or other form of arch supports. Arches develop naturally.

FIGURE 92.10 The tiptoe test for flat feet

## § Curly toes

Usually the third toe curls inward under the second toe so that the second toe lies above the level of the first and third toes. The toes can usually be straightened if necessary, so ignore the problem until 2 years. Refer if necessary to have a severe deformity corrected by flexor tenotomy.

A summary of optimal signs for surgical intervention in children's surgical disorders is presented in TABLE 92.2.

## Appendicitis in children

Refer to CHAPTER 34.

## Surgical causes of vomiting in children

Refer to CHAPTER 60.

### NEONATAL SURGICAL EMERGENCIES

It is worthwhile knowing those non-traumatic conditions that demand immediate attention. Danger signs include excessive drooling of frothy secretions, bile-stained vomiting and delayed passage of meconium.

Neonatal gut obstruction—consider meconium ileus, volvulus, small bowel atresia.

## § Neonatal emergencies<sup>6,7</sup>

- Oesophageal atresia: rattling respiratory distress + excessive drooling and secretions + choking with feeding (passage of 10F catheter stops about 10 cm)  
*Action:* nil orally, oropharyngeal suction, IV fluids
- Diaphragmatic hernia: severe respiratory distress + barrel-shaped chest + scaphoid abdomen (X-rays of chest/abdomen show loops of bowel in chest)  
*Action:* Give O<sub>2</sub>, nasogastric tube (avoid bag and mask)
- Bilious (green vomiting) = bowel obstruction or malrotation (abdominal X-ray)  
*Action:* nasogastric drainage and refer (do not feed)
- Neonatal intestinal obstruction including volvulus, Hirschsprung disorder, atresia and meconium ileus: bilious vomiting (green bile) + distension + delayed stools  
*Action:* nasogastric tube, IV fluids, refer
- Imperforate anus and rectum  
*Action:* refer for surgery on day of birth, anoplasty for low lesions; complex surgery for high lesions
- Bile duct atresia: neonatal jaundice (conjugated bilirubin) (usually 4–6 weeks) → white stools  
*Action:* refer early for precise diagnosis and surgical correction
- Congenital lobar emphysema: respiratory distress + cyanosis + signs of emphysema  
*Action:* refer early for urgent assessment and surgery to remove diseased lung
- Congenital cystic disease of the lungs: respiratory distress soon after birth  
*Action:* as above
- Congenital heart disease (severe forms)  
*Action:* refer early for medical treatment and assessment

**Table 92.2** Optimal times for surgery/intervention in children's surgical disorders

Disorder	Surgery/intervention
Squint (fixed or alternating)	12–24 months: absolutely before 7 years
Tongue tie	3–4 months or 2–6 years
Ear deformity	After 6 years
Cleft lip	Less than 3 months
Cleft palate	6–12 months
Inguinoscrotal lumps:	Best assessed before 6 months
• undescended testes	Surgery best at 6–12 months Don't leave >12 months
• inguinal hernia	ASAP, especially infants and irreducible hernias Reducible hernias: the '6–2' rule Birth–6 weeks: surgery within 2 days 6 weeks–6 months: surgery within 2 weeks Over 6 months: surgery within 2 months
• femoral hernia	ASAP
• torsion of testicle	Surgery within 4 hours (absolutely 6 hours)
• hydrocele	Leave to 12 months, then review (often resolve; if not, repair by 2 years)
• varicocele	Leave and review
Other hernias:	
• umbilical hernia	Leave to age 4 Surgery after 4 if persistent (tend to strangulate) Never tape down
• para-umbilical hernia	Any age—best after 6 months
• epigastric hernia	Any age—best after 6 months
Leg and foot development problems:	
• developmental dysplasia hip	Most treated successfully by abductor splinting (e.g. Pavlik harness)
• bow legs (genu varum)	Normal up to 3 years Usually improve with age: refer if ICS > 6 cm
• knock knees	Normal 3–8 years, then refer if IMS > 8 cm
• flat feet	No treatment unless stiff and painful
• internal tibial torsion	Refer 6 months after presentation if unresolved
• medial femoral torsion	Leave to 8 years, then refer if unresolved
• metatarsus varus	Refer 3 months after presentation if unresolved
• Exomphalos (intestinal contents in a sac) <i>Action:</i> nasogastric tube, IV dextrose drip, temperature control, refer	<i>Action:</i> early referral
• Gastroschisis (exposed bowel contents through anterior wall defect) <i>Action:</i> as for exomphalos; cover with plastic wrap	• Tension pneumothorax <i>Action:</i> intercostal needle/catheter with aspiration
• Pierre–Robin syndrome: micrognathia + cleft palate + respiratory obstruction from tongue	• Myelomeningocele and meningocele <i>Action:</i> early neurosurgical referral  <i>Note the importance of plain X-rays as urgent first-line investigations and early surgical referral.</i>

## Other important childhood emergencies

- Pyloric stenosis: projectile vomiting weeks 2–6, epigastric ‘tumour’
- Torsion of testis: severe groin/low abdominal pain + vomiting
- Intussusception: pallor + abdominal pain (severe and intermittent) + inactivity
- Acute appendicitis: abdominal pain + a/n/v + guarding
- Peritonitis
- Intestinal obstruction: colicky pain + vomiting + distension
- Irreducible inguinal hernia
- Paraphimosis
- Cerebral abscess
- Meckel diverticulum—diverticulitis or haemorrhage
- Various neoplasias

## § Chickenpox (varicella)

### Epidemiology

Chickenpox has become much less common since the introduction of the varicella vaccine in 2000 and its inclusion on the National Immunisation Program in 2005, because of both individual and herd immunity.<sup>1</sup> Prior to this, nearly all children acquired it (<80% of the Australian population were seropositive by their teens). Chickenpox has a complication of only 1%, and is often thought of as not being a serious disease—which mostly it isn't—but because it was so common prior to the vaccine's introduction it resulted in 1500 hospital admissions and 7–8 deaths a year.<sup>1</sup>

Chickenpox is a highly contagious infection caused by the varicella zoster virus, a DNA virus within the herpes virus family. Primary infection causes chickenpox (varicella), with the virus establishing latency in the dorsal root ganglia. Reactivation leads to herpes zoster (shingles), which is relatively uncommon in children and can be more difficult to diagnose as it often presents with only a few lesions.

Note: shingles *can* happen in childhood.

See CHAPTER 124.

### Clinical features

The clinical features of varicella are shown in TABLE 93.1 and the complications in TABLE 93.2. Children are not normally very sick but tend to be lethargic and have a mild fever. Adults have an influenza-like illness. The typical distribution is shown in FIGURES 93.1 and 93.2.

Congenital varicella syndrome can occur from varicella in pregnancy, and may result in skin scarring, limb defects, ocular anomalies and neurological malformations, with the risk highest in the second trimester. Intrauterine exposure also increases the risk of shingles in infancy. Severe neonatal varicella infection can result from perinatal varicella in the mother (especially if contracted from 5 days before the birth to 2 days after).

Table 93.1 Clinical features of varicella

#### Onset

Children: no prodrome

Adults: prodrome (myalgia, fever, headaches) for 2–3 days

#### Rash

Centripetal distribution, including oral mucosa (see FIG. 93.1)

Lesions can become infected

'Cropping' phenomenon: vesicles, papules, crusting lesions present together

#### Pruritic

#### Degrees of severity

Number of vesicles can vary from fewer than 10 to thousands (usually 200–500)<sup>1</sup>

Mild cases can be missed

More severe in adults and the immunocompromised

Viral pneumonia rare in children, uncommon in adults

Death rare except in the immunocompromised and neonates with congenital varicella

### Treatment

Treatment is symptomatic and usually no specific therapy is required. Antiviral therapy is used in patients with complications or those at high risk (e.g. immunocompromised people). Many people, especially parents, worry about scarring but the lesions invariably heal, leaving normal skin, unless they become infected.

### Advice to parents

- The patient should rest until feeling well.
- Give paracetamol for the fever (avoid aspirin in children due to the possibility of Reye syndrome).

**Table 93.2** Complications of varicella**Common**

Bacterial infection of cutaneous lesions (usually staphylococcal or streptococcal); can take form of cellulitis or bullous impetigo

Can leave pitted scars

**Uncommon**

Viral pneumonia

Eczema herpeticum

Thrombocytopenia

Birth defects with neonatal infection

Acute cerebellitis (ataxia, normal mental state)

**Rare**

Meningoencephalitis

Purpura fulminans

**FIGURE 93.1** Varicella (chickenpox) in a 12-year-old girl showing a maculopapular vesicular rash with a centripetal distribution

**FIGURE 93.2** Chickenpox: typical distribution

- Daub calamine or a similar soothing lotion to relieve itching, although the itch is usually not severe.
- Avoid scratching; clean and keep the fingernails short. Provide cotton mittens if necessary.
- Daily bathing is advisable, with the addition of mild antiseptic or sodium bicarbonate if pruritic (add half a cup to the bath water). Pat dry with a clean, soft towel; do not rub.

### Medication

Antihistamines can be prescribed for itching. Aciclovir or similar agents can be life-saving in the immunocompromised host. Antibiotics (e.g. flucloxacillin/dicloxacillin) are reserved for bacterial skin infection. Use hydrogel for sore wounds.

### Exclusion from school<sup>2</sup>

Exclusion is recommended until the blisters have dried, usually at least 5 days in unimmunised children but possibly shorter in those immunised. Except for immunocompromised children, contacts should not be excluded from school.

Exclusion and incubation times for chickenpox (and other basic childhood infectious diseases) are given in **TABLE 93.3**.

### Prevention

Prevention in contacts who are immunocompromised or at high risk (e.g. neonates) and in contact with varicella, is possible with zoster immune globulin (ZIG). An attenuated live virus vaccine is available and suitable for healthy children from the age of 12 months up to and including 13 years. It is given routinely at 18 months with the immunisation schedule. Vaccination of household contacts and post-exposure vaccination will reduce risk and also result in less serious disease if it does occur.

### Measles

Measles (rubeola) is a highly contagious disease caused by an RNA paramyxovirus. It presents as an

acute febrile exanthematous illness with characteristic lesions on the buccal mucosa called Koplik spots (tiny white spots like grains of salt, opposite the molars).

The disease is endemic throughout the world and complications are usually respiratory in nature. If an acute exanthematous illness is not accompanied by a dry cough and red eyes, it is unlikely to be measles. Laboratory diagnosis is by serology, with IgM rising 3–5 days after the onset of the rash.

### Epidemiology

Measles is transmitted by patient-to-patient contact through oropharyngeal and nasopharyngeal droplets expelled during coughing and sneezing.

The incubation period is 10–14 days and the patient is infectious until about 4 days after the onset of the rash, but especially just before the appearance of the rash. Morbidity and mortality are high in countries with substandard living conditions and poor nutrition.

**Table 93.3** Basic childhood infectious diseases: incubation periods, minimum exclusion periods from school, preschool and child care centres (times in days)<sup>1,2</sup>

	Incubation period (days)	Patient exclusion (least time from onset of rash or symptoms) (days)	Contact exclusion (days)
<b>Measles</b>	10–14	4	14 in non-immunised
<b>Glandular fever</b>	? 30–50	Nil	Nil
<b>Mumps</b>	12–25	9	Nil
<b>Pertussis</b>	7–20	5 (after starting antibiotics) or 21 from onset of cough	Non-immunised household contacts—until have had 5 days of antibiotics or 21 days after exposure finishes
<b>Parvovirus B19 (erythema infectiosum)</b>	4–20	Nil	Nil
<b>Roseola infantum</b>	7–17	Nil	Nil
<b>Rubella</b>	14–21	4	Nil
<b>Scarlet fever</b>	1–7	24 hours (after starting antibiotics and feeling well)	Nil
<b>Impetigo</b>	1–3 for strep, 4–10 for staph	Until treatment commenced (cover sores)	Nil
<b>Meningococcus</b>	1–10 (commonly 3–4)	Until antibiotic therapy complete	Check with consultant
<b>Varicella and zoster</b>	10–21	Until blisters have dried	Only those immune deficient
<b>Hepatitis</b>			
A	15–50	7 or recovery	Nil
B	45–180	Nil	Nil
C	14–180	Nil	Nil
<b>Infective diarrhoea</b>	Varies	24 hours after cessation of diarrhoea	Nil

Immunity appears to be lifelong after infection. Measles, like smallpox, could be eradicated with public health measures. While vaccination programs have been very successful worldwide, there has been a recent resurgence of measles in developed countries due to falling vaccination rates in some areas.

### Clinical features

The clinical presentation can be considered in three stages.

- 1 *Prodromal stage*. This usually lasts 3–4 days. It is marked by fever, malaise, anorexia, diarrhoea and 'the three Cs': cough, coryza and conjunctivitis (see FIG. 93.3). Sometimes a non-specific rash appears a day before the Koplik spots.
- 2 *Exanthema (rash) stage*. Identified by a typically blotchy, bright red maculopapular eruption; this stage lasts 4–5 days. The rash begins behind

**FIGURE 93.3** Measles showing the typical blotchy, bright red maculopapular rash on the face of a miserable child with the three Cs (cough, coryza and conjunctivitis)

the ears; on the first day it spreads to the face (see FIG. 93.4), the next day to the trunk and later to the limbs. It may become confluent and blanches under pressure. The patient's fever usually subsides within 5 days of the onset of the rash.

- 3 *Convalescent stage*. The rash fades, leaving a temporary brownish 'staining'. The patient's cough may persist for days, but usually good health and appetite return quickly.

**FIGURE 93.4** Measles typical symptoms. Note the 3Cs: cough, coryza, conjunctivitis.

### Complications

Measles is often a serious disease, and complications are common.<sup>1</sup> These include otitis media (9%), pneumonia (6%) and diarrhoea (8%). Children under 5 and adults and patients with chronic disease are more prone to complications. For every 1000 children who get measles, 1 to 2 will die,<sup>3</sup> with the majority of deaths occurring from pneumonia. Infection during pregnancy can lead to miscarriage or premature delivery, but is not associated with congenital malformation.

### Central nervous system

Encephalitis has an incidence of 1 in 1000, and has a mortality of 10–15% and also a high rate of permanent brain damage. Subacute sclerosing panencephalitis (SSPE) is a late complication, occurring on average 7 years after infection in 0.5–1/100 000 cases, and is manifested by universally fatal progressive brain damage.

Treatment

There is no specific treatment although some symptoms can be relieved (e.g. a linctus for the cough, paracetamol for fever). The patient should rest quietly, avoid bright lights and stay in bed until the fever subsides.

Prevention

Vaccination should be given to any child over 12 months, or any teenager or adult born since 1966 who does not have a documented record of 2 MMR-containing vaccines (or serological evidence of protection for measles, mumps and rubella).<sup>1</sup> Live attenuated measles virus vaccinations combined with mumps and rubella (MMR) are recommended at the age of 12 months and then MMRV (with varicella) at 18 months. Consider normal immunoglobulin for infants under 12 months and the immunocompromised when MMR is contraindicated, given as soon as possible after exposure.

Rubella

Rubella (German measles) is a viral exanthema caused by a togavirus. It is a minor illness in children and adults, but devastating when transmitted in utero. Congenital rubella syndrome (CRS) occurs in up to 90% of infants born to mothers contracting rubella in the first trimester. Multiple features of CRS are usually evident, which include intellectual disabilities, cataracts, deafness, cardiac abnormalities, intrauterine growth disorders (IUGR) and inflammatory lesions of the brain, liver, lungs and bone marrow. It is completely preventable. The risk declines rapidly after the first trimester.

All women of child-bearing age should have 2 documented doses of rubella-containing vaccines and if not their immune status should be assessed serologically. If not immune, they should be vaccinated and retested 6–8 weeks later and revaccinated if they have negative or low levels. No antibody response to 2 doses may represent a false negative result. Rubella-containing vaccinations are contraindicated in pregnant woman and pregnancy should be avoided for 28 days after vaccination.<sup>1</sup> Once the baby arrives, postpartum vaccination of those mothers not fully immune should be done immediately (breastfeeding is not a contraindication).

Epidemiology

CRS is rare in Australia due to vaccination. Only 2.5% of women of child-bearing age are seronegative,

though the risk is higher in women born overseas. Intra-uterine infection occurs via the placenta.

Approximately one-third of infections are asymptomatic (subclinical). Infection usually confers lifelong immunity. Incubation period is 14–21 days.

Clinical features

The clinical features of rubella are presented in TABLE 93.4 and FIGURE 93.5 and the complications in TABLE 93.5.

Table 93.4 Clinical features of rubella

There is no prodrome.
A generalised, maculopapular rash, sometimes pruritic, may be the only evidence of infection.
Other symptoms are usually mild and short-lived.
There is often a reddened pharynx but sore throats are unusual. An exudate may be seen as well as palatal exanthem.
Fever is usually absent or low-grade.
Other features: headache, myalgia, conjunctivitis and polyarthrititis (small joints).
Lymphadenopathy may be noted; usually postauricular, suboccipital and postcervical.
The patient is infectious for a week before and at least 4 days after the onset of the rash.
The rash
A discrete pale pink maculopapular rash (not confluent as in measles).
Starts on the face and neck—spreads to the trunk and extremities.
Variable severity: may be absent in subclinical infection.
Exaggerated on skin exposed to sun.
Brief duration—usually fades on the third day.
No staining or desquamation.

Treatment

Treatment is symptomatic, especially as rubella is a mild disease. Patients should rest quietly until they feel well and take paracetamol for fever and aching joints. Prevention is by vaccination, recommended at 12 and 18 months.

School exclusion

The child is usually excluded until fully recovered or for at least 4 days from the onset of the rash.

FIGURE 93.5 Rubella: typical symptoms

Table 93.5 Complications of rubella

Encephalitis (rare)

Polyarthrits, especially in adult women (this complication abates spontaneously)

Thrombocytopenia (rare)

Congenital rubella syndrome

### § Viral exanthema (fourth syndrome)

This mild childhood infection may be caused by a number of viruses, especially the enteroviruses, and produces a rubella-like rash that may be misdiagnosed as rubella. The rash, which is usually non-pruritic and mainly confined to the trunk, does not desquamate and often fades within 48 hours (see FIG. 93.6). The child may appear quite well or can have mild constitutional symptoms, including diarrhoea.

### § Parvovirus B19 (erythema infectiosum, fifth disease)

Parvovirus, also known as 'slapped cheek' syndrome, is a childhood exanthem caused by parvovirus strain B19. It occurs typically in young school-aged children. The incubation period is 4–20 days. Non-specific prodromal symptoms (fever, runny nose, headache,

FIGURE 93.6 Viral exanthema (fourth syndrome). This mild rubella-like maculopapular rash, which may be caused by a number of viruses, is usually non-pruritic

nausea) are followed 2–5 days later by the rash. The bright macular rash erupts on the face first (see FIG. 93.7) then, after a day or so, a maculopapular rash appears on the limbs.<sup>1</sup> The rash lasts for only a few days but may recur for several weeks. By the time the rash appears the individual usually is no longer infective.

### Clinical features

- Mild fever (30%) and malaise
- Runny nose, headache, nausea
- Possible lymphadenopathy (especially cervical)

The rash (see FIG. 93.8):

- bright red flushed cheeks with circumoral pallor for 2–3 days
- maculopapular rash on limbs (especially) and trunk (sparse)
- reticular appearance on fading
- may be pruritic

**FIGURE 93.7** Parvovirus, showing the typical slapped cheek appearance

**FIGURE 93.8** Parvovirus: typical distribution of rash

Typically, the cheeks become reddened again for the next few weeks on exposure to sunlight or wind or after a hot bath. Adults can be infected and the side effects, especially arthritis, can be quite severe.

## Parvovirus in pregnancy<sup>4</sup>

Erythema infectiosum is a mild illness but, if the parvovirus infection occurs during pregnancy, fetal complications including miscarriage can occur. It is advisable to avoid close contact with pregnant women (see **CHAPTER 109**). Some 50% of young adult females are susceptible to parvovirus infection. About 50% of susceptible household contacts will become infected, and around 20% of classroom contacts.

Pregnant women should be tested for parvovirus IgM and IgG if:

- in the same room as the infected person for >15 minutes
- face-to-face contact
- household contact

The results are interpreted as:

- IgG alone detected—immune
- IgM detected—false positive or early infection. Repeat in 2 weeks to see if rising IgG levels
- IgM and IgG not present—susceptible. If susceptible and becomes unwell, repeat test

If infection occurs in the first half of pregnancy, the fetus may become anaemic (the virus replicates in erythroid progenitor cells) and hydrops fetalis and miscarriage can occur. Women in this situation should be reassured that <5% of women will miscarry, though ultrasound monitoring is recommended. Parvovirus in pregnancy is not associated with fetal anomalies. If exposure or infection is suspected in the second half of pregnancy, investigation is still warranted as there may be errors in the gestational age and the risk to other pregnant women in health settings needs to be managed.

## Treatment

Treatment is symptomatic.

- Ample fluid intake
- Paracetamol for fever
- If itchy, daub a soothing anti-itch lotion such as Pinetarsol or calamine lotion
- Wear a broad-brimmed hat when outside

Adults may need stronger analgesics or NSAIDs for arthralgia (more common in adult women).

## § Roseola (roseola infantum, exanthema subitum or sixth disease)

Roseola is a viral infection (human herpes virus 6) of infancy, affecting children at the age of 6 months and 2 years; 95% of children have had it by this time,

and it is rare after this. Constitutional symptoms are generally mild.

### Clinical features

- Sudden high fever (up to 40°C)
- Runny nose
- Temperature falls after 3 days (or so) *then*
- Red macular or maculopapular rash appears

The rash:

- largely confined to the trunk and limbs (see FIG. 93.9)
- usually spares face
- appears as fever subsides
- blanches on pressing
- disappears within 2 days
- no desquamation
- mild cervical lymphadenopathy

FIGURE 93.9 Roseola: typical distribution of rash

The infection runs a benign course, although a febrile convulsion can occur. The child will no longer be infectious by the time the symptoms appear. Treatment is symptomatic. Encourage high fluid intake.

### § Hand, foot and mouth (HFV) disease

This is a mild vesicular eruption caused by enteroviruses, the most common being Coxsackie A-16, with EV-71 being less common. HFV disease affects both children and adults but typically children under the age of 10. Sometimes referred to as 'crèche disease', it often occurs among groups of children in child care centres. Transmission is through respiratory

secretions, touch contact with the blistered areas or faeco-oral transmission (hand washing after changing nappies is important to reduce transmission).

### Clinical features

- Incubation period 3–5 days
- Initial fever, headache and malaise
- Sore mouth and throat
- The rash appears after 1 or 2 days
- Starts as a red macule, then progresses to vesicles
- Vesicles lead to shallow ulcers on buccal mucosa, gums and tongue
- Greyish vesicle with surrounding erythema
- On hands, palms and soles (usually lateral borders)
- May appear on limbs especially buttocks and genitals
- Lesions resolve in 3–5 days
- Healing without scarring
- Virus excreted in faeces and saliva for several weeks
- Children are infectious until the blisters have disappeared
- Diagnosis is clinical, investigations usually unnecessary

### Management

- Reassurance and explanation
- Symptomatic treatment
- Careful hygiene
- Exclusion until blisters have dried up

### § Scarlet fever

Scarlet fever results when a Group A *Streptococcus pyogenes* organism produces erythrogenic toxin. The prodromal symptoms prior to the acute exanthem comprise malaise, sore throat, fever (may be rigors) and vomiting. A throat swab should be taken.

### Features of the rash

- Appears 12–24 hours after the start of the fever
- First appears on neck
- Rapidly generalised
- Punctate and red, a 'boiled lobster' or sunburnt appearance
- Blanching on pressure
- Prominent on neck, in axillae, cubital fossa (Pastia lines), groin, skinfolds (see FIG. 93.10)
- Absent or sparse on face, palms and soles
- Circumoral pallor
- Feels like fine sandpaper
- Lasts about 5 days
- Fine desquamation

FIGURE 93.10 Scarlet fever: typical presentation of rash

93

### Treatment

Phenoxymethylpenicillin (dose according to age) for 10 days with rapid resolution of symptoms. Children can return to school 24 hours after taking antibiotics and feeling well.

### § Kawasaki disease<sup>5,6</sup>

This is an uncommon but important systemic vasculitis, usually in children under 5 years of age, likely caused by an infection, though the presumed agent remains unknown. It is characterised by an acute onset of fever  $>39^{\circ}\text{C}$  of 5 days or more and accompanied by 4 out of 5 of the following features:

- polymorphous rash
- bilateral (non-purulent) conjunctival infection
- mucous membrane changes, e.g. reddened or dry cracked lips, strawberry tongue, diffuse redness of oral or pharyngeal mucosa
- peripheral changes, e.g. erythema of the palms or soles, oedema of the hands or feet (and in convalescence desquamation)

- cervical lymphadenopathy ( $>15$  mm diameter, usually unilateral, single, non-purulent and painful)

Other diseases with similar signs should be excluded (e.g. staph or strep infections, measles, viral exanthems, drug reactions or JRA).

Kawasaki disease can be elusive as there are variations with atypical or incomplete manifestations. Think of it in a miserable child with a high fever  $\geq 5$  days and arrange for paediatric review if suspicious. Blood results will also help contribute to the diagnosis and management decisions (e.g. ESR and CRP usually raised, thrombocytosis often raised in second week, neutrophilia, normochromic normocytic anaemia, hypoalbuminuria, abnormal LFTs).

The disease is generally benign and self-limiting but it is important to make an early diagnosis because early treatment may prevent complications (which also occur in the atypical cases). The major complication is vasculitis, which causes coronary aneurysms and ectasia in 15–25% of untreated cases, and which can lead to ischaemic heart disease and sudden death either at the time or years later. The aneurysms usually develop between the second week and the second month of the illness. Early treatment with immunoglobulin and aspirin has been shown to be effective in reducing the prevalence of coronary artery abnormalities. Echocardiography is used to detect the aneurysms and determine prognosis.

### § Mumps<sup>1</sup>

Mumps is an acute infectious disease caused by a paramyxovirus with an affinity for the salivary glands and meninges. It is usually transmitted by respiratory secretions or saliva. A third of infections are asymptomatic, and most of the others have non-specific symptoms, such as fever, headache, malaise, myalgia and anorexia. The classic parotitis occurs in only two-thirds of clinical cases and is usually bilateral. The submandibular and sublingual glands are less commonly involved. About 6% of patients will have presternal oedema resembling cellulitis of the neck.

Mumps can result in spontaneous abortion if contracted in the first trimester of pregnancy. Maternal infection is not associated with an increased risk of congenital malformations.

Prior to vaccination, cases peaked in the 5–9-year age group; however, since 2000 it is now most commonly seen in adolescents and young adults. Recent outbreaks have occurred in the developed world in areas of declining vaccination rates.

### Clinical diagnosis

Enlargement of the cervical lymph glands can be mistaken for parotitis but the correct diagnosis is indicated by the anatomy of this area. Lymph nodes are posteroinferior to the ear lobe; the parotid gland is anterior and, when enlarged, obscures the angle of the mandible.

Bacterial (suppurative) parotitis is associated with toxæmia and results in a high leucocyte count. The skin over the parotid gland is tense and shiny and the Stensen duct might discharge pus.

Rare disorders such as Sjögren syndrome can be misdiagnosed as mumps.

### Complications

The complications are summarised in [TABLE 93.6](#).

Orchitis, usually unilateral, occurs in 15–30% of postpubertal males, developing 3–4 days after parotitis. Subsequent sterility is rare, even if both testes are affected.

Aseptic meningitis is common but benign. Many patients suffer transient abdominal pain and vomiting.

**Table 93.6** Complications of mumps

Common
Orchitis
Meningeal symptoms (10%)
Abdominal pain (transient)
Rare
Oophoritis
Encephalitis
Arthritis (one or several joints)
Deafness (usually transient)
Pancreatitis

### Management

Treatment is symptomatic. Paracetamol may be prescribed for fever, meningitis and orchitis. The patient with orchitis should use supportive underwear. Children should be excluded until 9 days after the onset of the parotitis.

### § Epstein–Barr mononucleosis

Although glandular fever is more common in adolescents and young adults, it can occur in young children but is often asymptomatic or atypical. The differential diagnosis includes cytomegalovirus

infection and acute lymphatic leukaemia. Diagnosis is confirmed by specific antibody tests. Refer to [CHAPTER 28](#).

### § Pertussis<sup>1,7</sup>

Pertussis (whooping cough) is a respiratory infection (a bronchitis) caused by *Bordetella pertussis* and occurs worldwide. Other organisms (*Bordetella parapertussis*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*) can cause a pertussis-like syndrome. Despite vaccination, pertussis remains prevalent in Australia, and is the least well-controlled vaccine-preventable disease. Between 2000 and 2010 multiple epidemics caused over 139 000 confirmed cases.

The greatest risk of severe infection and complications is to infants with their soft and easily damaged airways, especially before the first 2 vaccine doses are administered. Adolescents and adults with waning immunity (both from vaccination and previous infection) are often the source of infection, in particular the parents (>50% of identified primary cases).

### Clinical features

Pertussis is highly infectious, with *B. pertussis* spreading to >90% of household contacts. The incubation period is 7 to 20 days. The classical paroxysmal cough followed by an inspiratory whoop is less common in older children and adults, or children who have partial immunity from vaccination. A prolonged cough may be the only presenting feature, and in local epidemics every cough needs to be approached with a suspicion for pertussis.

*B. pertussis* accounts for 7% of cough illnesses in adults, and given that each year 25% of adults have a cough  $\geq 5$  days duration, many cases go undiagnosed. The primary goal of preventing complications and deaths is centred on protecting children, particularly infants (see Prevention below). The fatality rate in unvaccinated infants less than 6 months is 8 per 1000 cases. The most common cause of death is pertussis pneumonia, sometimes complicated by seizures and hypoxic encephalopathy. Apnoea and cyanosis from coughing spasms are also common in the very young.

Even in adults the cough can be very distressing and prolonged. Pertussis is also referred to as the ‘100 day cough’. This can lead to issues with sleep disturbance, work performance (especially when dealing with machinery or driving) and rarely rib fractures.

Classic whooping cough is characterised by cough and coryza for 1 week (catarrhal phase) followed by

paroxysms of a more pronounced cough (paroxysmal phase). Fever is uncommon, there are often no other clinical signs, and children are well between coughing paroxysms. Vomiting may follow a coughing spasm (a 'cough-vomit').

## Diagnosis

As well as having a high index of suspicion with coughing patients (both immunised and non-immunised), particularly in outbreaks, any suspicion should lead to PCR testing of nasopharyngeal aspirate/swab.

## Complications

- Neurological: asphyxia, hypoxia, seizures, cerebral haemorrhages
- Pulmonary: atelectasis, pneumonia, pneumothorax, bronchiectasis

## Treatment<sup>7,8</sup>

Treatment during the catarrhal phase or early in the paroxysmal stage may ameliorate symptoms. Treatment early in the disease will help reduce infectiousness; however, once the cough has been present for 3 weeks there is little risk of infectiousness. Options include:

- azithromycin
  - <6 months: 10 mg/kg daily for 5 days
  - >6 months: 10 mg/kg on day 1 (up to 500 mg) then 5 mg/kg (up to 250 mg) for a further 4 days
- clarithromycin
  - >1 month: 7.5 mg/kg (up to 500 mg) bd for 7 days
- erythromycin
  - >1 month: 10 mg/kg (up to 250 mg, or 400 mg if ethyl succinate) qid for 7 days

Cough mixtures are ineffective. Good ventilation is important: avoid dust and smoke, and also emotional excitement and overfeeding during the paroxysmal phase.

All infants under 6 months and older children with complications (e.g. apnoea, cyanosis, pneumonia, encephalopathy) require admission to hospital.

## Treatment of contacts<sup>8</sup>

High-risk contacts of a pertussis case (those with close/household contact and who may be vulnerable to complications, or transmit to others who are vulnerable) should be treated with the same medications, dosage and duration as above. There is

little evidence that prophylactic antibiotic treatment of contacts reduces secondary transmission outside of household settings (i.e. not in child-care centres, preschools, schools or workplaces). State public health officers should be contacted to determine which contacts require prophylaxis.

## Prevention<sup>8</sup>

Other strategies to reduce the incidence of pertussis and its complications, particularly in infants, include:

- a 'cocoon' strategy of vaccinating any adults who are or will be in close contact with an infant. Fathers and other adult contacts can be vaccinated before the birth
- mothers should be vaccinated in pre-pregnancy planning or straight after delivery. Alternatively, if more than 5 years has elapsed since their last previous dose, a pertussis vaccine should be given in their third trimester (which will boost maternal antibodies that are transmitted in utero to the about-to-be-newborn)
- a single booster dose of pertussis-containing vaccine is recommended in health care workers and other adults in regular contact with young children (booster required after 10 years)

## § Herpes simplex<sup>9</sup>

Herpes simplex virus (HSV) infection is common and widespread. Primary HSV infection is usually a disease of childhood readily transmitted through direct contact, with the majority of the population being infected in early childhood. Many cases are asymptomatic or non-specific. The specific gingivostomatitis occurs in 25–30% of cases and can be severe and acute.

## Clinical features

Typical clinical features of the primary infection:

- children 1–3 years
- fever and refusal to feed
- ulcers on gums, tongue and palate
- prone to dehydration
- may be lesions on face and conjunctivae
- resolution over 7–14 days

Pushing fluids and monitoring for dehydration is important. Topical lignocaine preparations can help. Paracetamol is often not useful, though if the child is very distressed codeine-containing compounds (Painstop) can be considered. Topical antivirals usually do not contribute and are not recommended.

Serious complications (seek specialist advice):

- encephalitis can develop in otherwise healthy children (see CHAPTER 30)
- eczema herpeticum—children with eczema can get widespread severe herpetic lesions
- disseminated HSV infection in neonates (avoid contact until recovered)
- HSV can be a serious issue in the immunocompromised patient

### § Impetigo<sup>10</sup>

Impetigo (school sores) is a contagious superficial bacterial skin infection caused by *Streptococcus pyogenes* or *Staphylococcus aureus* or a combination of these two virulent organisms.

There are two common forms:

- 1 vesiculopustular with honey-coloured crusts (either strep or staph)
- 2 bullous type, usually *S. aureus*

### Treatment

If mild with small lesions and a limited area:

- soak a clean cloth in a mixture of ½ cup white vinegar and 1 L of tepid water. Apply the compress to moist areas for 10 minutes several times a day then wipe off crusts (alternatively just use soap and water)
- antiseptic (povidone iodine, chlorhexadine) or mupirocin (Bactroban), a small amount tds for 10 days. Topical antibiotics other than mupirocin 2% (Bactroban) are not recommended
- general measures while still oozing or crusted:
  - cover the sores
  - avoid close contact with others (especially touch and bathing contact)
  - regular hand washing
  - use separate towels and cloths
  - change and launder clothes and linen daily

If extensive and causing systemic symptoms:

flucloxacillin/dicloxacillin 12.5 mg/kg up to 500 mg) 6 hourly for 10 days

or

cephalexin 25 mg/kg up to 1 g 12 hourly for 10 days

Boils (furunculosis) and carbuncles can use the same treatment as impetigo.

The child should be excluded from child-care settings until antibiotic treatment has commenced. Any sores on exposed skin should be covered with a watertight dressing.<sup>2</sup>

### § Head lice<sup>10</sup>

Head lice is an infestation caused by the louse *Pediculus humanus capitis* (see FIG. 93.11). The head louse is about 1–3 mm in length, white to grey, wingless and has a flat elongated body. They spread through close contact, and do not jump or fly. The female louse lays eggs (or 'nits'), which are glued to the hairs a few millimeters from the scalp. The nit moves away from the scalp as the hair grows. They hatch at around 8 days, mature into adults in about 10 days and live for about a month.

Head lice spread from person to person by direct contact, such as sitting and working very close to one another. They can also spread by the sharing of combs, brushes and headwear, especially within the family. Children are the ones usually affected, but people of all ages and from all walks of life can be infested. It is more common in overcrowded living conditions but is not a reflection of poor hygiene. Resistance to the usual agents is becoming a problem.

FIGURE 93.11 Louse (enlarged)

### Clinical features

Infestations can vary from a few dozen to hundreds of lice and eggs.

- Asymptomatic or itching of scalp
- White spots of nits can be mistaken for dandruff
- Unlike dandruff, the nits cannot be brushed off
- Diagnosis by finding lice (or 'nits')
- Occasionally the eyelashes can be affected (use physical removal methods outlined below)
- 'Wet combing' (see below) improves detection rate

### Treatment

Treatment can be based on physical methods, chemical methods or both (the most effective).

### Physical methods

Wet combing:

- Inspection—look for both lice and nits behind and above the ears and at the back of the scalp.
- Treat all members of family at the same time.

- Have ready a metal nit comb (available at pharmacies), a good light, some paper towels or tissues and lots of cheap hair conditioner. Sitting a child in front of the TV will help them keep still (it takes around 30 minutes).
- Wet the hair with a handful or two of conditioner.
- Work through the hair in sections, removing resistant nits by combing down the hair towards the shaft.
- Wipe the conditioner onto tissues or paper towels, where the lice and nits will be visible.

Repeat the combing routine for at least 2 more consecutive nights. Repeat weekly until no lice are found on 3 consecutive nights (nits may persist but do not necessarily mean active infection—they may be empty or dead eggs). Other physical measures include:

- machine wash bed-linen, clothes, towels in hot water
- items that can't be washed such as soft toys/helmets should be placed in an airtight plastic bag for two weeks
- vacuum pillows
- spray hairbrushes and combs with fly spray

### Chemical treatments

Insecticides used to treat head lice include:

- malathion
- permethrin
- phenothrin

These applications can be irritating to the scalp, so use caution in children prone to atopic dermatitis; following the manufacturer's instructions carefully is important. A second application 7 days after the first may be required.

Many other methods are used and recommended for head lice, both commercially available or 'home remedies', which may or may not be useful. These include suffocating agents (e.g. mayonnaise, olive oil, petroleum jelly), natural oils and cutting the hair short (especially in boys e.g. a No. 1 cut).

Treatment failure and/or reinfestation is common. The former can be from inappropriately applied treatments, resistance to chemical treatments or misdiagnosis of old nits as active infection.

Community or school-wide education programs can also keep infestation rates down.

### Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Chickenpox (varicella)
- Hand, foot and mouth disease
- Head lice
- Herpes simplex (cold sores)
- Impetigo
- Measles
- Mumps
- Roseola
- Rubella
- Slapped cheek disease
- Whooping cough (pertussis)

*Although the world is full of suffering, it is also of the overcoming of it.*

Helen Keller 1903

Many behavioural issues in children arise because of (and in the context of) factors such as the child's temperament, parental schema and child–parent attachment. These factors determine, in the beginning, how the parent–child relationship will evolve, and also strongly affect the psychological development of the child.

## Temperament

Temperament refers to the personality characteristics you are born with—what is innate rather than learned. An awareness of the fact that children are born with characteristics over which parents have no control can be liberating, especially for parents of children with challenging temperaments.

The best-known description of temperament is based on the work of Thomas and Chess from the 1970s.<sup>1</sup> They found that about two-thirds of children can be classified into one of three categories: easy, difficult and slow to warm up. Of these, about 15% were considered easy, 70% slow to warm up and 15% difficult. A child with a difficult temperament will be emotionally labile and have difficulty coping with new experiences. A child with a slow-to-settle temperament will have some difficulty coping with new experiences, but will eventually manage after repeated exposures. A child with an easy temperament will cope easily with new experiences and will have a calm nature.

Easy doesn't mean good, and difficult doesn't mean bad. These children may just require more patience and a thoughtful and paced approach to parenting. Further, the characteristics that can make a child 'difficult' can be the flipside of other characteristics that lead them to achieve success (if appropriately nurtured and guided). A stubborn child may have good persistence, and a distractible child may be artistic and expressive.

Of course, most children will have a few 'difficult' characteristics, but some will have more than others.

**Table 94.1**

Easy and difficult temperament characteristics

Easy temperament characteristic	Difficult temperament characteristic
Generally happy	Generally serious
Goes with the flow	Inflexible
Laid-back	In-your-face
Patient	Impulsive
Flexible	Stubborn
Friendly	Shy
Calm body movements	Restless
Persistent	Gives up easily
Calm nature	Hot-tempered
Expressive	Reserved
'Even' mood	Up and down mood
Thick-skinned	Over-sensitive
Good concentration	Distractible
Regular body clock	Chaotic body clock
Tolerates sensations well	'Sensory defensiveness' (light, sounds, tastes, textures)

Raising parents' awareness of this, getting them to think about the innate characteristics of their child (which may or may not be similar to their siblings or one or both of the biological parents) and to adjust their parenting style accordingly will help them deal more effectively with the challenges of raising their child.

## Parental schema

Schema is the view you have of the world based on your own experiences; it is the 'soup in your head'. Parental schema is how parents view how they should parent, and is often based on how they were brought up themselves. Parental schemas may not match, and

this can cause relationship issues. Parental attitudes to issues such as communication, emotion sharing and discipline can fundamentally affect the behaviour and psychological health of a child. Parental schema can also commonly be influenced by cultural factors.

## Child–parent attachment

Rather than nature versus nurture, for human beings, nurture is nature. While we do not start with a blank slate (we have our innate temperament), the most essential nutrient for a child's mind, the thing that makes it grow, is a meaningful connection with other minds, particularly those of their parents. The way we end up is not predetermined, like Michelangelo 'finding' the David within the marble; we, as human beings, are built up, constructed out of the clay that comes largely from the relationship between parent and child.

However, an infant first has to learn how to connect with other minds. A child does this in their first relationship, usually with their mother. This is attachment.

If we were a tree, our attachment would be our trunk. Just like a tree trunk's fastening to the ground, everything else flows from it. It is how a child orientates to the rest of the social world. It's important to note that attachment is an ongoing phenomenon, even into adulthood. Children attach not only to their mother, but to other people from whom they can 'gather strength'. Children's attachment to their two parents may differ and can also change over time.

A secure attachment is achieved if a parent responds to a child's cries *promptly, consistently* and *appropriately*. The three main ways in which attachment can go wrong are:

- Carer not responding—this can result in a lack of emotional depth in the child. People who are raised in this way can even develop what is called 'learnt unresponsiveness' and be emotionally barren. They are also more likely to parent this way themselves (so it can become 'heritable').
- Carer responding inconsistently—this can lead to uncertainty and anxiety in the child.
- Carer responding inappropriately—such as with aggression or anger. This is obviously very damaging, and happens in situations of emotional abuse, particularly with mental health or drug and alcohol issues in the carer. It creates a terrible and *unsolvable paradox* for children, where the person on whom they are completely reliant to teach them how to relate to the world is also a threat.

Observing how carers, particularly mothers, respond and interact to their child can give the family doctor insight into this relationship. Gently advising and encouraging appropriate responses to the child's needs can be beneficial, particularly in a mother with poor parenting capabilities and/or difficult circumstances (e.g. very young mothers, socially isolated, postnatal depression, drug using or alcoholic parents, violence in the household). In high-risk situations, further referral to support services or even protective agencies may be required (see CHAPTER 95).

## Child behaviour and discipline<sup>2,3</sup>

Issues around child behaviour and how to deal with unwanted behaviours commonly arise and are often a source of conflict and angst. It is normal for children, especially toddlers, to have resistant and oppositional behaviour. The word 'discipline' comes from the Latin *disciplina*, which means 'to teach'. The purpose of disciplining a child is to guide and teach, so they know what is allowed and what is not allowed, what 'works' in the world and what will not.

Parents can teach children in a variety of ways. The most effective forms of discipline are actually praise and encouragement—of wanted behaviours. However, when children are doing something that they should not—an unwanted behaviour—they need to learn that this is the case. The challenge for parents is to get this message across to them clearly and effectively.

A simple equation sums up the best way to deliver this message:

$$\text{unwanted behaviour} = \text{unwanted (by your child) outcome}$$

Educating parents to recognise that the thing a child desires most in the world is the attention (this is a survival instinct) and approval of their parents will help them understand how to reinforce desired behaviours, and extinguish unwanted behaviours. That is, pay attention to when the child is behaving, and even praise particularly wanted behaviours, and ignore unwanted behaviours.

## Consequences<sup>3</sup>

Consequences work only with children >3 years of age, and should be used solely in response to a small fraction of a child's behaviour, regardless of the child's temperament. If consequences are overused, their effectiveness diminishes and family relationships can be damaged.

There are three types of consequences that work (in decreasing order of usefulness):

- *Natural consequences*: where there is a natural flow from the misdemeanour to the consequence. For example, if a child refuses to have dinner, he or she goes to bed hungry. Natural consequences have a momentum of their own and, assuming they do not result in harm, can provide many valuable lessons.
- *Related consequences*: where there is some link between the unwanted behaviour and the result. This is also sometimes called a 'logical consequence'. For example, if a child makes a mess, he or she must clean it up. Or, if two children are fighting over a toy, the toy gets taken away for a while. Related and natural consequences allow a child to link the unwanted behaviour with the consequence.
- *Losing a privilege*: This can be a very powerful technique as it focuses the child's attention but is more punitive than natural and related consequences. Also, there is no logical link between behaviour and consequence. Parents should only withdraw a privilege with care as it can cause resentment, and the child should be warned beforehand that he or she is going to lose a particular privilege for a particular unwanted behaviour.

*Time-outs*<sup>4</sup> are another response to unwanted behaviours. Time-outs are useful from 2–3 years of age, and can take the heat out of a situation, for both the parent and child. Time-outs should be consistent, enforced promptly and calmly, even with empathy, and short—a good rule of thumb is a minute per year of age.

Responses that don't work when disciplining children include: screaming, constantly explaining, repeatedly warning, threatening, pleading, arguing, bribing and giving in, as well as smacking.<sup>5</sup> Most parents who are struggling with behaviour and discipline issues respond with relief when provided with a set of alternative responses for disciplining children, though care needs to be used when raising these issues, as they can be highly emotional and confronting topics for parents.

## § Tantrums<sup>6</sup>

Tantrums are when we lose control of our feelings and behaviour. Everyone, including adults, is capable of tantrums. Tantrums are what we use to deal with an emotionally confronting situation when we have no

other option—the emotional response of last resort. They are more common in toddlers (particularly between 18 months and 3 years of age) because they have not learned any or many other emotional responses to challenging situations, such as ignoring, negotiating, reconsidering or reframing a situation. There is a lot of misinformation about tantrums, frequently over-emphasising control rather than guidance.

Diverting a child from predictable tantrum triggers, 'scaffolding' (giving necessary support) to handle the event (e.g. a 5-minute warning), distraction or active listening in the build-up to a tantrum can be useful strategies to employ.

Once a child is mid-tantrum, any attempts at negotiation will be ineffective. Afterwards, an unemotional and calm response from the parent will tell the child that tantrums don't work (though, of course, this can be difficult for a stressed parent). Skill-building toddlers in how to handle emotionally challenging situations (i.e. expanding their repertoire beyond tantrums) is best done either before or after ('What else could you have done?'). Rousing at a child is counter-productive; they are still learning to control their emotions, and this will just increase the risk of them becoming demoralised and losing self-esteem.

## § Breath-holding attacks<sup>7</sup>

Breath-holding is common (around 5% of children do so at some stage), and occurs between 6 months and 6 years (peak at age 2). While frightening to watch, such attacks are harmless, and no treatment or action is required. There are two types:

- blue spells (more common)—these happen in response to being upset or angry. The child cries loudly then holds his or her breath at the end of expiration
- pale spells—these happen in response to pain or a fright

They can last from 10–60 seconds, and can cause the child to faint or, rarely, fit. They cause no harm, and parents should be reassured. Approaches to discipline should not change because of them. There is no need to blow air or splash water in the child's face, and the child should be treated as if they have not occurred (i.e. no discussion or punishment).

## § Head banging and rocking<sup>8</sup>

Head banging and rocking, which usually occur before the child goes to sleep, are common. Head banging occurs in up to 30% of normal infants and toddlers,

and rocking is even more prevalent. They are more frequent in children with developmental disability and autism, where these behaviours may be more pervasive through the day.

### Features

- Usually starts after 8–9 months, and is rare after 2 years of age
- Usually prior to going to sleep
- Child usually not distressed and rarely self-injurious

### Management

There is no need to try to stop the behaviour, and attempting to do so is often not successful.

- Reassure parents that it's a self-limiting behaviour and usually settles by 2 years.
- Avoid reinforcing behaviour by excessive attention or punishment.
- Ignore the behaviour.
- Place the bed or cot in the middle of the room away from a wall (reduces disruption from noise).
- Monitor the condition of the cot, to ensure screws and hinges are not being loosened.

### § Sibling rivalry

Sibling rivalry is very common and can cause a lot of disruption in the family. A toddler may pinch, prod and even attempt to smother a new baby, so providing the toddler with attention from the mother and encouraging the child to see that it is his or her baby too can ease the jealousy. In school-age children the following tips are useful:<sup>9</sup>

- Be fair.
- Avoid making comparisons between your children.
- Encourage the children to work out their own differences.
- Avoid taking sides in sibling conflicts. Set guidelines on how children can disagree and resolve conflicts.
- Discourage telling tales on each other.
- When it is necessary to punish or reprimand, do it with the child alone in a quiet, private place.
- Use regular family meetings to establish family rules and negotiating conflicts.

### § Stutters

Stuttering<sup>10</sup> usually begins at age 2–4 years, as children start to use more words and longer sentences.

It can start suddenly or develop slowly. Up to 12% of children will stutter by the age of 4.

Stutters can be repetitions (of a sound, word or phrase), prolongations of a sound (e.g. 'aaaand'), a block (where no sounds comes out) or combinations of these. There is no known cause, though it can run in families. Stutters are not associated with other disabilities, though they may cause psychological distress for the child. They are not caused by anxiety or stress, but can be more prominent when the child is excited.

A child developing a stutter should see a speech pathologist as soon as possible, as early treatment is more successful. The most common program used in Australia to treat stuttering is the Lidcombe Program, which is often successful and can even sometimes stop the stutter.

### § Habit cough

This is a common problem usually affecting school-age children and occurs in the absence of underlying disease. It occurs only when the child is awake—not during sleep.

There are two common types of habit cough:

- 1 A honking-type cough (heard from the waiting room) in teenage girls. There is no dyspnoea or sputum production.
- 2 A throat-clearing cough commonly seen in boys aged 7–10. This is related to a transient tic disorder.

Habit cough is a diagnosis of exclusion and there should be a careful assessment to exclude other causes such as respiratory disorders or pertussis. Underlying triggers include inter-family problems and bullying or other perceived stress or anxiety. Management includes explanation, reassurance and CBT.

Referral for resistant cases is appropriate.

Other functional respiratory problems:

- hyperventilation
- sighing dyspnoea
- vocal cord dysfunction (see CHAPTER 57)

### § Sleep disorders in children

See CHAPTER 71.

### § Bullying<sup>11,12</sup>

There are varying figures on how common bullying is, but most suggest more than a quarter of children are significantly bullied at some stage. It is more common

in the early school years, but can happen at any age. Bullying differs from conflict, in that there is an imbalance of power between the perpetrator and the victim. It is a deliberate behaviour repeatedly done and intended to harm the victim. It is a power play, constructed on contempt, not anger, and this is what can make it so damaging.

Types of bullying include physical harm, verbal assaults, hidden bullying (e.g. exclusion or spreading rumours) and cyberbullying (now the most common form of bullying). The latter is particularly insidious as it is difficult to detect and follows the victim home and even into their bedroom via social media or phones. Bullying can lead to physical, psychological and social consequences, and in extreme cases depression and even suicide. Despite this, less than half of bullying is reported (with boys reporting less than girls) due to fear of retaliation or not being believed.

Bullies themselves tend to be assertive, impulsive and aggressive, with little empathy for their victims or remorse for their actions. They often come from dysfunctional backgrounds, and their bullying tendency may have been learned from being modelled by parents or peers.

If bullying is raised, the child should be believed, and a history carefully, gently and non-judgmentally extracted. Parents should be encouraged to stay calm, involve other adults in the environment (e.g. teachers at school) and to formally address the issue after educating themselves on the best approach. There are many good resources available for this, such as the National Centre Against Bullying at <[www.ncab.org.au](http://www.ncab.org.au)>. A vigilant approach to this common and serious problem by GPs and parents should be employed, especially in those particularly vulnerable to bullying, such as children who are shy, lacking in confidence, children with disabilities or who physically or socially stand out in some way (e.g. children with speech disorders). Indicative signs to watch out for include:

- school phobia: sham sickness and other excuses
- being tense, tearful and miserable after school
- reluctance to talk about happenings at school
- poor appetite
- functional symptoms (e.g. habit cough)
- repeated abdominal pains/headache
- unexplained bruises, injuries, torn clothing, damaged books
- lack of a close friend; not bringing peers home
- crying during sleep
- restless sleep with bad dreams

- appearing unhappy or depressed
- unexpected irritability and moods; temper outbursts

Referral to a psychologist should be considered in severe cases, in those that fail to be resolved, or if there are other psychological or family issues. If child abuse is suspected, appropriate action should be taken (see **CHAPTER 95**).

## BEHAVIOURAL AND DEVELOPMENTAL DISORDERS

### Developmental disability and delay

The family doctor is in an ideal position to recognise and initiate evaluation of the child with a developmental disability, whether it is a physical disability or delay, an intellectual disability or a learning disability. All children with a suspected developmental delay should be promptly evaluated by a paediatrician or a multidisciplinary developmental assessment team, and the family doctor should remain a key player in the long-term management both of the child and the family.

Many developmental problems will be obvious but others are subtle. Several disabilities may evade a diagnosis. Transient developmental delay may be associated with factors such as prematurity, family stress, physical illness and learning opportunities, while persistent delay can be caused by intellectual disability, cerebral palsy, autism and hearing and visual impairment.

Many rare dysmorphic syndromes are becoming more recognised and defined with the rapid advances in genetics, and referral to genetic disorder units will help in getting an appropriate evaluation.

### Evaluation

An appropriate history includes a careful look at developmental milestones, social and behavioural issues, and family history (see **CHAPTER 9**). A new diagnosis of developmental delay of any sort can have a massive impact on family members, especially parents, and the family doctor should keep a watchful eye on how they are coping and reacting to the diagnostic process.

The physical examination includes growth parameters, assessment of all developmental domains, looking for dysmorphic features, testing of hearing and vision, examining for neurocutaneous stigmata (e.g. café-au-lait spots, neurofibromas, hypopigmented macules) and careful systems examination, including cardiac and neurological

examination. Eyes, ears, mouths (including teeth), hands and feet, and genitals should all be examined.

Investigations are usually coordinated via specialist services, but often include bloods (including karyotyping and genetic tests), urinary metabolic screening, and imaging such as cerebral MRI (which may require a general anaesthetic).

## Intellectual disability

Intellectual disability (ID) is a neurodevelopmental disorder characterised by deficits in intellectual and adaptive functioning that present before 18 years of age.<sup>13</sup> The term replaces and improves upon the older term 'mental retardation'. The term 'global developmental delay' (GDD) is usually used to describe children <5 years of age who fail to meet expected developmental milestones in several areas of development. Not all children with GDD will meet criteria for ID as they grow older.

Presentations include learning difficulties, language delay and behavioural problems.

The two most common causes are trisomy 21 (see CHAPTER 18) and fragile X syndrome.

Fragile X syndrome, Prader-Willi syndrome and Williams syndrome are presented in CHAPTER 18.

## Cerebral palsy<sup>14</sup>

Cerebral palsy (CP) is a physical disability that affects movement and posture, and is the most common physical disability in childhood (2 in 1000 live births). Its cause is usually unknown, but CP is associated with numerous antenatal and perinatal factors, including antenatal infections (e.g. rubella, CMV), birth defects, preterm birth, IUGR, multiple pregnancy, perinatal hypoxia and postnatal head trauma or cerebral infection. It is more common with low birth weight or low socioeconomic status. It can vary from minimal to profound disability.

### Definition

There are 5 key elements:

- 1 It is an umbrella term for a group of disorders.
- 2 It is permanent, but not unchanging.
- 3 It involves a disorder of movement and/or posture and of motor function.
- 4 It is due to a non-progressive interference, lesion or abnormality.
- 5 The interference, lesion or abnormality originates in the immature brain.

## Associated impairments

- 3 in 4 are in pain
- 1 in 2 has an intellectual disability
- 1 in 3 cannot walk
- 1 in 3 requires a hip replacement
- 1 in 4 cannot talk
- 1 in 4 has epilepsy
- 1 in 4 has a behavioural disorder
- 1 in 4 has bladder control problems
- 1 in 5 has a sleep disorder
- 2 in 5 dribble
- 1 in 10 is blind
- 1 in 15 is tube fed
- 1 in 25 is deaf

## Classification

Many different classification systems are used for CP. These include those based on:

- *severity*—mild (no restriction of activities and mobile without aids), moderate (some assistance/aids required), severe (wheelchair and marked restriction of activities)
- *topographic location*:
  - paresis (weakened) vs plegia (paralysis)
  - terms include: mono- (one limb), di- (two, usually legs), hemi- (arm and leg), para- (lower body), quadri- (4 limbs) and penta- (4 limbs and also head and neck/breathing issues)
- *motor function*—spastic (pyramidal) versus non-spastic (extra-pyramidal)
- *muscle tone*—hypertonic or hypotonic

Other terms used include 'ataxic', 'dyskinetic' and 'athetoid'.

## Diagnosis

Severely affected children are often picked up soon after birth, but mildly affected cases may not be diagnosed for years. A family doctor who has any suspicion of a disorder in movement or posture should refer the child for specialist assessment, which may include a paediatrician, a paediatric physiotherapist or a multidisciplinary team assessment.

Depending on the clinical presentation, multiple investigations may be undertaken, including visual and hearing tests, pathology tests (e.g. karyotyping, genetic testing, urine metabolic screening) or imaging such as a cerebral MRI.

## Management

Management of motor and posture issues is largely the domain of specialist clinics and therapists. Multiple

team members may be involved, and the family doctor may be required to take a team management and coordination role. Other responsibilities that may be met by the family doctor include:

- facilitating access to funding streams and services
- diet and growth monitoring
- monitoring and treating bladder issues, including UTIs
- managing constipation issues
- dealing with pressure sores
- addressing sleep issues
- helping with behaviour issues
- looking at pain management
- addressing family issues, such as parents coping or sibling dynamics
- dealing with normal paediatric issues in general practice (e.g. immunisations, treating commonplace infections and injuries). These may present special challenges, depending on the level and type of CP

## § Autism spectrum disorder

In May 2013, the DSM-5<sup>13</sup> made significant changes to autism terminology and classification that reflected recent research. Autism spectrum disorder (ASD) superseded autistic disorder, pervasive developmental disorder not otherwise specified (PDD-NOS) and Asperger disorder, though the latter term is also still widely used by clinicians and the public. This resulted in a change in the way autism was diagnosed, with three domains (social deficits, communication deficits and repetitive behaviour) reducing to two (social-communication deficits and repetitive behaviour). Another change is a 'severity' criterion that is designed to better capture the 'spectrum' nature of the disorder: level 3 (very substantial support), level 2 (substantial support) and level 1 (some support).

ASDs are common, with the latest Australian data putting the incidence at 1 in 160 children.<sup>15</sup> While autism diagnoses are much more common in recent decades compared to previously (it was first described as a disorder only in 1944), whether there has been a true increase in incidence is unknown, as increasing awareness and widened diagnostic criteria make comparison with previous prevalence data unreliable.

### Identification

When an autism spectrum disorder (ASD) is suspected, a GP is likely to face one of three different scenarios:

- A A family member presents with his or her own concerns about their child's development.
- B A family member reports that a third party, such as a child-care worker or teacher, has expressed concerns about their child's development.
- C The GP himself/herself identifies concerns with a child's social and language development through routine developmental screening or general observation.

Scenario A should always be taken seriously, as the concerns of parents are commonly justified. Many parents present to their GP during the second to third year of their child's life when it becomes apparent that the child's development has stalled compared with his or her peers. While social deficits of ASD (such as delayed or absent joint attention—see below) often present earlier, they frequently go unrecognised by parents and it is usually speech delay that prompts a visit to the doctor.

Other parents may request a hearing assessment, thinking their child is deaf because he or she doesn't respond to their name. In about 25–30% of cases there may be actual regression, with the child beginning to say words but stopping, commonly between the ages of 15 and 24 months. Parents may also report loss of eye contact and gestures such as waving or pointing.

### When to suspect ASD

A typically developing child should smile in response to a familiar caregiver's smile or 'baby talk' by 2–4 months. At 8 months, an infant will follow a parent's gaze, that is, look in the same direction as the parent is looking. Children should be able to follow their parent's point by 10–12 months and start pointing themselves by 12–14 months. They then begin to point to share ('look at this') by 16 months. As they point, children will look back and forth between the object and their parent—it's the shared social experience, not the tangible object, the child seeks. These joint attention behaviours are often absent or reduced in a child with ASD.

### Social deficits

Younger children with ASD often appear to have little desire to connect with others. They may have problems imitating actions (such as clapping). As they get older, individuals may have difficulty understanding the perspective of others, commonly called theory-of-mind, which in turn leads to difficulties with empathy and sharing. Affected children will often have few or no friends; higher-functioning children may desire friendship but approach peers in an inappropriate way.

Inappropriate social behaviours (e.g. commenting loudly on someone’s physical appearance) can lead to problems at school. Frequently, individuals become overwhelmed by social or sensory stimulation, such as loud sounds.

Communication deficits

Communication deficits in autism include deficits in both non-verbal and verbal communication, and expressive and receptive language. Some individuals remain mute throughout life. Although present, language may not be functional—children may be able to rote learn shapes and numbers, but not follow one-step commands. Stereotyped and repetitive language, including echolalia (‘parroting’ of learned phrases or scripts) is common. Other signs include unusual vocal qualities, such as tone or speed, and pronoun reversal (e.g. saying ‘you’ instead of ‘I’).

Affected individuals frequently have a very concrete and literal understanding of language, such as not understanding idioms, lies or jokes, and miss social cues such as body language and tone of voice. Even relatively mildly affected children (and adults) may have difficulty initiating and sustaining two-way conversations.

Children with ASD tend not to play imaginatively (e.g. pushing the car along and saying ‘brrrm’) and instead will engage in unusual repetitive play, such as lining up toys, or spinning the wheels of a car. They frequently show little interest in social play (e.g. peek-a-boo or pattycake) and their play is often object-focused (e.g. computer games) rather than people-focused.

The following red flags<sup>16</sup> are absolute indications for referral for an autism-specific assessment:

94

Red flags for autism

- Lack of babbling or pointing by 12 months
- No sharing of interest in objects or activities with another person
- No single words by 16 months, or no two-word (non-echoed) phrases by 24 months
- Any loss of language or social skills at any age

A GP-friendly screening tool for ASD is the Checklist for Autism in Toddlers (CHAT)—abbreviated version (see TABLE 94.2).<sup>17</sup> This can be administered at approximately 18 months of age and takes only a couple of minutes.

If a child fails all three items, referral is indicated, as the chances of *autism* are high. If a child fails only

Table 94.2 Checklist for Autism in Toddlers (CHAT—abbreviated version)

Section A: Ask the parent	Section B: GP’s observation
1 Does your child ever pretend, for example, to make a cup of tea using a toy cup and teapot, or pretend to do other things?	Get the child’s attention, then give the child a miniature toy cup and teapot and say, ‘Can you make a cup of tea?’ Does the child pretend to pour out tea, drink it, etc.? (If you can elicit an example of pretending in some other game, score a YES for this item.)
2 Does your child ever use his/her index finger to point, to ask for something?	Get the child’s attention, then point across the room at an interesting object and say ‘Oh look! There’s a (name of toy)!’ Watch the child’s face. Does the child look across to see what you are pointing at? (To record a YES for this item, ensure the child has not simply looked at your hand, but has actually looked at the object at which you are pointing.)  Say to the child, ‘Where’s the light?’, or ‘Show me the light’. Does the child point with his or her index finger at the light? (If the child does not understand ‘light’, repeat this with ‘Where’s the teddy?’ or other unreachable object.) (To record a YES for this item, the child must have looked up at your face around the time of pointing.)

1 or 2 items, still refer as the chances of *developmental delay* are high.

Further assessment

If there are concerns that a child may have ASD, it is essential that the child is promptly referred to a general or developmental paediatrician, or to a developmental assessment unit, for an autism-specific diagnostic assessment. Taking a ‘wait and see’ approach, or saying ‘come back in 6 months and we’ll reassess’, is not acceptable. Getting hearing checked or assessments from speech therapists, OTs or psychologists may also be done in this work-up phase.

## Management

Intensive early intervention for ASD, which is what guidelines<sup>18</sup> recommend as gold standard and does improve long-term outcomes, involves intensive and often expensive behavioural/developmental therapies, and the earlier it commences the better. However, this type of therapy may be beyond the organisational and financial capability of the family, so care should be taken in what is recommended. Parents should be directed to reliable information sources<sup>17,18</sup> on these options, which they may find daunting. There is also a lot of misinformation on autism, particularly regarding complementary and alternative therapies, for which there is no evidence of efficacy.<sup>18</sup> State-based autism associations can also help with advice. If the waiting times for diagnostic assessment are long (as is often the case), families should be referred to early intervention services while they wait.

## The role of the GP in management

A child being diagnosed with ASD can have a massive impact on the family. GPs should monitor how family members are coping, and provide a 'medical home' for reliable advice on management options. Children with autism also have particular vulnerability to certain medical issues, and the GP will be involved in the management of these. These include:

- minor traumas and injuries
- restricted diet (due to sensory issues or special diets used by some families)
- behavioural issues
- constipation (due to sensory issues causing voluntary faecal retention, or from medications used for co-diagnoses)
- dental issues (sensory issues making brushing difficult, or grinding)

When consulting children with autism, special tactics can be employed to help things run smoother. Alerting front desk staff so they are aware of potential behavioural issues, allowing easier access for families in stress (e.g. calling the patient from the car if behaviour in the waiting room is problematic) and reassuring parents that challenging behaviour by the child is not an issue will help. The decreased eye contact and interaction means that the GP needs to work harder to engage these children, but it can be done, and parents will appreciate any effort made. Adjusting for sensory issues, for example, letting children hold and examine equipment before it is used, can also help.

## § Dyspraxia

Dyspraxia (from the Greek, meaning 'disorder of practising') is a disorder of the planning, organising and carrying out of motor tasks. It can affect articulation and speech, perception and thought, though it is not associated with decreased intelligence. It can vary from difficulties with simple motor movements, such as waving goodbye or clapping, to more complex issues such as handwriting or riding a bike. It is more common in males. Another term that is used is developmental coordination disorder (DCD).

If there is an issue with motor skills being delayed (without associated social and communication delay beyond motor skills) then referral to physiotherapists, occupational therapists and speech therapists, depending on the type of motor issues involved, is advisable. A delay in fine and gross motor skills can become a barrier to socialisation (e.g. not being able to play or perform in team sports) or academic achievement (e.g. writing) and can have flow-on effects on self-esteem and mood.

## Specific learning disorders

A specific learning disorder (SLD) is characterised by persistent difficulties in reading, writing, arithmetic and mathematical reasoning skills during school years.<sup>13</sup> The difficulties must result in abilities well below what is expected in culturally and linguistically appropriate testing. The learning issues should not be explained by other developmental, neurological, sensory (such as vision or hearing problems) or motor disorders and must significantly interfere with academic achievement, occupational performance, or activities of daily living. Dyslexia and dyscalculia are examples of SLDs.

## § Dyslexia

Dyslexia (from the Greek, meaning 'disorder of words') is an SLD of reading and spelling, while still having otherwise normal learning abilities. The condition was originally called 'word blindness'. Also referred to as developmental reading disorder, it is not a problem of comprehension, but of the speed and accuracy of decoding (converting letters and words to sounds) and spelling (converting sounds to their correct written symbols). It can run in families. Individuals with dyslexia can have different or compensatory learning styles, but may also be helped with input from an occupational therapist or speech therapist.

## § Attention deficit hyperactivity disorder

Attention deficit hyperactivity disorder (ADHD) is a disorder affecting attention, hyperactivity and impulse control.<sup>19</sup> It can also affect children's learning, social skills and family functioning. It is very common, affecting 3–5% of Australian children. It is much more common in boys. There are 3 types: predominantly hyperactive/impulsive; predominantly inattentive; and mixed, with the latter being the most common. To meet DSM-5 criteria, symptoms must be present before the age of 12, and often persist into adulthood.

### Criteria<sup>13</sup>

Hyperactive/impulsive—6 out of 9 of the following:

- often fidgets with hands or feet or squirms in a seat
- often leaves seat in classroom or in other situations in which remaining seated is expected
- often runs about or climbs excessively during inappropriate situations (in adolescents or adults, may be limited to subjective feelings of restlessness)
- often has difficulty playing or engaging in leisure activities quietly
- is often on the go
- often talks excessively
- often blurts out answers before questions have been completed
- often has difficulty awaiting turn
- often interrupts or intrudes on others (e.g. butts into conversations or games)

Inattentive—6 out of 9 of the following:

- often fails to pay close attention to detail or makes careless mistakes in schoolwork, work or other activities
- often has difficulty sustaining attention in tasks or play activities
- often does not seem to listen when spoken to directly
- often does not follow through on instructions and fails to finish schoolwork, chores or duties in the workplace (not due to oppositional behaviour or failure to understand instructions)
- often has difficulty organising tasks and activities
- often avoids, dislikes or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework)
- often loses things necessary for tasks or activities

- is often easily distracted by extraneous stimuli
- is often forgetful in daily activities

Mixed—meets both hyperactive/impulsive and inattentive criteria.

### Diagnosis

While most young children have short attention spans and are impulsive, children who meet the above criteria will stand out, and the symptoms should be displayed in more than one environment (e.g. home and school). The issue is usually raised by the parents to the GP, and a query may have been raised by an early childhood worker or teacher. Symptoms often become apparent when the child starts school, or as academic expectations start to rise around age 7–8 years. The diagnosis should be made only by appropriately experienced psychologists, paediatricians or child psychiatrists, and will require information gathered from parents, teachers or other important adults in the child's life.<sup>19</sup>

### Treatment

Children with ADHD often find their condition distressing and demoralising, and need support and understanding from family and teachers. Behavioural strategies (see TABLE 94.3) should be offered to all children, even those who do not strictly meet the diagnostic criteria but have these types of behaviours.

### Medication<sup>20</sup>

Stimulants are the single most effective treatment for ADHD, and became the standard treatment in the 1980s. Controversy remains in the media, and the public are often wary, with concerns about addiction and other safety issues often raised by parents, but these fears are unfounded. While there are potential side effects, these are mostly not serious. Stimulants are often useful, and 1–2% of Australian children are put on them at some stage. Parents (and children) will frequently report a positive experience, reflecting that their previous concerns were unfounded. Eight out of ten children will find a significant improvement in their concentration, impulse control and overactivity.

Medications:

- methylphenidate (Ritalin, short acting, effect duration 3–4 hours)
- slow-release methylphenidate (Ritalin LA 6–8 hours, Concerta 10 hours)
- dexamphetamine
- atomoxetine (Strattera)

**Table 94.3** Behavioural strategies for ADHD<sup>20</sup>

<b>Verbal instructions</b>	<ul style="list-style-type: none"> <li>Keep brief and clear</li> <li>State name or tap on shoulder before giving</li> <li>Keep eye contact</li> </ul>
<b>Written work</b>	<ul style="list-style-type: none"> <li>Use highlighters</li> <li>Use *asterisks*, UPPER CASE, or <b>bold</b> layout techniques</li> </ul>
<b>Other learning strategies</b>	<ul style="list-style-type: none"> <li>Use one-on-one teaching where possible</li> <li>Use class 'buddies' to help</li> <li>Use activities with 'hands-on' involvement</li> <li>Most important learning is done when concentrating best (usually morning)</li> <li>Use checklists</li> <li>Sit front and centre in class, not near friends</li> <li>Homework done in clutter-free environment (no distractions, no unnecessary screens nearby or available)</li> <li>Organised bag, organised diary, organised desk, organised locker</li> <li>Regular scheduled homework time</li> </ul>
<b>Reduce overactivity/fatigue</b>	<ul style="list-style-type: none"> <li>Regular rest breaks</li> <li>Physically active breaks (e.g. delivering notes, taking lunch orders)</li> </ul>
<b>Keeping structure</b>	<ul style="list-style-type: none"> <li>Fixed routine</li> <li>Activities predictable (home and school)</li> <li>Display schedules and rules (home and school, in multiple places)</li> <li>Tell about changes to activities/schedules/rules in advance</li> <li>Use countdowns (e.g. 5-minute warnings)</li> <li>Keep choices to a minimum</li> </ul>
<b>Self-esteem</b>	<ul style="list-style-type: none"> <li>Set up for success (i.e. achievable goals)</li> <li>Acknowledge achievements (by written and verbal means) and regularly review achievements</li> <li>Acknowledge effort</li> <li>Ensure participation in classroom and positive feedback for effort</li> <li>Address any specific learning difficulties promptly</li> </ul>
<b>Social skills</b>	<ul style="list-style-type: none"> <li>Expose to small groups rather than large</li> <li>Reward appropriate social behaviour (e.g. sharing)</li> <li>Teach problem-solving skills when provoked</li> <li>Encourage 'supervised socialisation' (e.g. sport, Scouts/Girl Guides)</li> <li>Regularly discuss consequences of his or her actions</li> <li>Use visual prompts to think before acting (e.g. STOP, THINK, DO)</li> </ul>
<b>Communication between home and school</b>	<ul style="list-style-type: none"> <li>Have formal communication portal (e.g. diary, online parent forum) and use regularly</li> <li>Communicate positive and negative behaviours</li> </ul>

### Issues related to medication

- Can normally be prescribed only by paediatricians, child psychiatrists or neurologists
- Mechanism of action—increases noradrenalin and/or dopamine at the synapse
- Common side effects:
  - decreased appetite
  - poor weight gain
- Uncommon side effects:
  - headache/dizziness
  - stomach aches
  - insomnia
  - irritable, withdrawn or highly emotional
- Slight growth stunting (rarely a problem clinically)
- Slight increase in heart rate/blood pressure (not an issue unless underlying cardiac issues)

### Fish oil

- Sometimes suggested for ADHD, but research is unclear about existence of and/or extent of benefit
- Contains high amounts of omega-3 fatty acids
- May help improve symptoms in some children

## § Oppositional defiant disorder

Oppositional defiant disorder (ODD) is defined as an ongoing pattern of anger-guided disobedience and hostile and defiant behaviour towards authority figures that goes beyond the bounds of normal childhood behavior.<sup>13</sup> In the DSM-5, symptoms are grouped into three types: angry/irritable mood, argumentative/defiant behaviour and vindictiveness, reflecting the disorder having emotional and behavioural symptomatology. While such behaviours are common in early childhood, ODD should be considered when they are consistently displayed, and are impacting the family and the child's social and educational functioning.

ODD is common (with an incidence estimated at 5–10%)<sup>21</sup> and often undiagnosed, and has a large incidence of co-diagnosis with ADHD, with many of the symptoms crossing over between the two conditions. The onset is usually gradual, becoming evident before the age of 8. Children with ODD have a higher incidence of child abuse, school dropout and long-term mental health problems. ODD is caused by a combination of difficult temperament traits (see earlier in this chapter) and environmental factors, such as poor attachment, parenting styles or family conflict/mental health issues in parents.

## Management<sup>21</sup>

For parents:

- improve positive parenting skills
- enhance skills in problem-solving, conflict resolution and communication

For the child:

- develop communication, problem-solving and anger management skills

For the family:

- counselling and support regarding relationships and home environment

In the classroom:

- teacher or school counsellor to provide social skills/conflict resolution skills training

There is strong evidence that psychological strategies and interventions reduce the impact of ODD on the child and family, and the earlier the better. They can also prevent progression to more serious disorders<sup>13</sup> such as:

- *Disruptive mood dysregulation disorder (DMDD)*—characterised by severe and recurrent temper outbursts greatly out of proportion in intensity or duration to the situation >3/week for >12 months
- *Conduct disorder*—where there is behaviour that violates the rights of others or societal norms, such as aggression directed towards people, animals or property, often with a callous manner and lack of empathy

## § Tic disorders<sup>22</sup>

Tics are sudden, rapid, recurrent involuntary vocalisations or movements usually appearing in bouts that wax and wane in intensity, frequency and type of tic. They include behaviours such as grunting, blinking, shrugging shoulders, humming, yelling out a word or phrase or clearing the throat. Tic disorders are classified into:<sup>13</sup>

- *Tourette syndrome*—motor and vocal tics for >1 year
- *persistent motor or vocal tic disorder*—motor or vocal tics for >1 year
- *provisional tic disorder*—motor and/or vocal tics for <1 year

Characteristics of tic disorders:

- average age of onset 5–6 years
- average of 5 years from onset to diagnosis
- associated with psychosocial distress and poor functioning

- strong genetic component (first-degree relatives have 10–100-fold increased risk of tics)
- associated with ADHD and OCD
- can be simple (one muscle group) or complex
- examples of complex tics (which are different from compulsions in OCD in that they are not cognitive, preplanned or anxiety reducing) include:
  - copropraxia (making obscene gestures)
  - echopraxia (copying others)
  - wounding oneself
  - echolalia (repeating others)
  - palilalia (repeating oneself)
  - coprolalia (uttering obscenities)
- unknown aetiology
- 80% decrease in adolescence and adulthood to no longer be an impairment
- 20% do not decrease, and may increase
- there is no treatment, other than psychosocial support and treating comorbidities

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Attention deficit hyperactivity disorder
- Autism
- Autism: Asperger syndrome
- Bullying of children
- Stuttering
- Tantrums

*It is customary, but I think it is a mistake, to speak of happy childhood. Children, however, are often overanxious and acutely sensitive. Man ought to be man and master of his fate; but children are at the mercy of those around them.*

Sir John Lubbock, Baron Avebury (1834–1913)

Public and medical awareness of child abuse has markedly increased in recent decades, and the possibility of child abuse and neglect has to be kept in mind by the family doctor. It may surface in families from all walks of life and where a good trustful relationship exists between parents or children and doctor.

While reporting rates continue to increase (at 34 per 1000 Australian children in 2012<sup>1</sup>), the true incidence of child abuse is much greater and also difficult to assess.

The various types of abuse<sup>1</sup> (and their estimated incidence<sup>2</sup>) shown in **FIGURE 95.1**.

**FIGURE 95.1** Percentage breakdown of primary substantiated harm types in Australia in 2011–12<sup>4</sup>

Source: Based on Australian Institute of Health and Welfare material.

### Facts on child abuse<sup>1,4,5</sup>

- The younger the child the greater the risk.
- The more disabled the more vulnerable.

- Indigenous children are 8 times more likely to be the subject of substantiated abuse than non-Aboriginal children.
- The number of children who are deemed at risk and placed in out-of-home care (OOHC) has increased in recent years, with the rate in 2012 at 7.7 per 1000 Australian children nationally. Roughly half of these are in foster care, and half in relative/kinship care, with a small (5%) proportion in residential (paid workers) care.

### Definitions<sup>6</sup>

Child abuse and neglect are collectively referred to as child maltreatment. This refers to any non-accidental behaviour by parents or other adults or adolescents that is outside the norms of conduct and entails a substantial risk of causing physical or emotional harm to a child or young person. Such behaviours may be intentional or unintentional, and can be through omission (i.e. neglect) or commission (i.e. abuse).

Deciding whether behaviour constitutes maltreatment can depend on:

- cultural issues (e.g. corporal punishment)
- developmental age of the child
- the severity, frequency and duration of the behaviour
- the behaviour itself, or the result of the behaviour (a definition issue)

### Physical abuse (non-accidental injury)

Physical abuse is defined as the non-accidental use of physical force against a child that results in harm to the child. It includes behaviours such as hitting, shoving, slapping, shaking, throwing, punching, kicking, biting, burning, strangling and poisoning. Munchausen syndrome by proxy (see below) is considered physical abuse.

## Neglect

Neglect is defined as the failure by a parent/caregiver to provide a child (when they are in a position to do so) with the conditions that are culturally accepted as being essential for the child's physical and emotional development and well-being.

## Emotional maltreatment

This is where a parent or caregiver conducts inappropriate verbal or symbolic acts towards a child, and/or there is a pattern or failure over time to provide a child with adequate non-physical nurture and emotional availability. This can take the form of rejecting, isolating, terrorising, ignoring or corrupting, and can damage the child's self-esteem and social functioning.

## Sexual abuse

Sexually abusive behaviour refers to any sexual activity between an adult and a child below the age of consent; non-consensual sexual activity between minors (e.g. a 14-year-old and a 10-year-old); or any sexual activity between a child under 18 years of age and a person in a position of power or authority (e.g. parent, teacher).<sup>2</sup> It is sometimes difficult to determine whether a behaviour constitutes sexual abuse, depending on variables such as age, development and cultural norms.

Behaviours can include fondling of genitals, masturbation, oral sex, vaginal or anal penetration by a penis, finger or any other object, fondling of breasts, voyeurism, exhibitionism or exposure to pornography. In contrast to other forms of maltreatment, the labelling of an act as sexual abuse also depends on the relationship between perpetrator and victim (e.g. age difference, being related).

## Other types of child maltreatment

- Munchausen syndrome by proxy—this is the term used when a parent or guardian creates an illness in a child so that the perpetrator can develop or maintain a relationship with medical staff or transfer his or her responsibilities. A 'devoted parent' may continually present a child for medical treatment yet deny the origin of the problem—namely, the parent. Often the mother is the abuser. The abuse may be of physical or medical neglect. The masquerade may be simple or very sophisticated. Children may be indirectly abused by the lengthy or invasive investigations. Be cautious where there has been unexplained illness or death of a sibling.

- Incest—defined as intercourse between biological family members.
- Fetal abuse behaviour, such as smoking, drinking or illicit drug use, during pregnancy that endangers a fetus.
- Bullying, or peer abuse (see CHAPTER 94)
- Sibling abuse
- Witnessing community violence
- Institutional abuse
- Organised exploitation (e.g. child sex rings, child prostitution)
- State-sanctioned abuse (e.g. female genital mutilation in parts of Africa, the Stolen Generations in Australia)

## Abuse: who and why?

The real cause seems to be a combination of several interrelated factors: personal, familial, social/cultural and societal stress. Abused children exist at all levels of society, although the majority of abused children who come to the attention of authorities are from families where there is high mobility, lack of education, loneliness, poverty, unemployment, inadequate housing and social isolation. Sexual abuse, occurring alone, does not follow these patterns and can occur under any socioeconomic circumstance.

Both men and women physically abuse their children. While women are the parents most responsible in cases of neglect and emotional abuse (probably because of a dominant role in child-care, social and economic disadvantage and being the only one responsible for the care of children in a single parent arrangement), men are more likely to abuse their own or other children sexually.

The child can be abused at any age (even adolescents can be victims of abuse and neglect). It is important to keep this in mind—it *does happen*.

## Underdiagnosing and under-reporting

Although the medical profession remains the foremost focus of child abuse reporting (they are the most likely to encounter injured children and are the most qualified to diagnose abuse), they still contribute only a small percentage of the total reporting to central registries.<sup>7</sup> This could be because there is underdiagnosis of the problem but it could also be because of under-reporting.

Reasons given<sup>7</sup> as to why GPs don't report more cases of child abuse include:

- concern about drain on time and finances
- breaching doctor–patient confidentiality

- lack of undergraduate education on the topic
- risk of alienation and stigmatisation to the family
- the feeling by some GPs that they can work on the problem with the family without outside intervention
- a breakdown of the doctor–patient relationship
- uncertainty about *what* to do
- personal and legal risks (e.g. fear of court, libel suits, irate parents), especially if they ‘get it wrong’
- reluctance until absolutely certain of diagnosis

It will always be difficult to take the first step but it is important and it can help, no matter how small that first step is.

## Interviewing parents or guardians

A skilled, sensitive, diplomatic interview is fundamental to management. Guidelines include:

- a relaxed, non-judgmental approach
- sensitivity to all people involved
- appropriate questions—open-ended, not leading
- using verbatim quotes from the child where possible and waiting silently for a reaction
- recording notes carefully

## Physical abuse<sup>8,9</sup>

Physical abuse should be suspected, especially in a child aged under 2 years, if certain physical or behavioural indicators in either the child or the parents are present. Inflammation, bruising, abrasions and lacerations are the most common presentations of the physically abused child, with equal incidence in boys and girls. As well as the consequences of the physical injuries, victims of physical abuse are more likely to develop a variety of behavioural and functional problems including conduct disorders, physically aggressive behaviour (e.g. become bullies), poor academic performance and decreased cognitive functioning. Children suffering traumatic brain injuries from physical abuse (e.g. hitting head or shaking) are at risk of disabilities including ADHD, seizures, spasticity, blindness, paralysis and developmental delay.

Parents and carers can tend to misinterpret normal child behaviours (e.g. crying and tantrums) and respond to them inappropriately. A vigilant GP can actually help prevent abuse by providing ‘anticipatory guidance’ to parents on normal child behaviour, educating them on appropriate responses to behaviours, and offering themselves as a resource to which they can turn if the child’s behaviour becomes unmanageable or overwhelming.

Risk factors:

- maternal smoking
- >2 siblings
- low infant birth weight
- unmarried mother
- poverty
- significant life stressors in parents
- caregiver role conflicts
- living in house with unrelated adult (50 times more likely to die from inflicted injuries)

## Physical abuse indicators

Accidental injuries such as bruises or fractures are common in children, but tend to follow certain patterns. A GP should be aware of cases where the injury or injuries suggest a non-accidental cause is possible, when the history doesn’t match up with the injury or developmental age of the child, or when the behaviour of the parent and/or child is suggestive of non-accidental injury.

## Bruises

Bruises are commonly found on the front of the body over bony prominences (e.g. forehead in toddlers, knees and shins in older children). Suspicious bruises include:

- finger-shaped bruises (e.g. thumb grip marks)
- multiple bruises/welts of different ages (the colour of a bruise doesn’t reliably indicate when it occurred)
- bruises in premobile children
- bruises away from bony prominences—face, scalp, neck, buttocks (see FIG. 95.2), genitalia, earlobes, behind the ears

FIGURE 95.2 Physical abuse: imprint of a boot on the buttock of a child

- abdominal bruising (consider damage to internal organs, including organ rupture)
- multiple bruises of uniform shape
- multiple bruises in clusters

### Scalds and burns

Beware of:

- a scald of uniform depth, sparing flexures, uniform burn line demarcation, bilateral and no splash marks (suggests forced immersion)
- unusual position (e.g. back of hand, genitals)
- cigarette butt-type burns

### Fractures

Look out for:

- metaphyseal fractures of the proximal humerus and proximal or distal tibia are highly suggestive
- other fractures commonly non-accidental: rib (especially posterior), clavicle, vertebral body, sternum, scapula
- multiple, especially bilateral
- complex or multiple skull fractures

### Shaking and brain injury

Shaking a baby is a critically dangerous thing to do, a danger often underestimated by perpetrators. The relatively large head size and weak neck muscles can easily lead to serious injury. Suspicion of traumatic brain injury should be raised when there is:

- unexplained encephalopathy
- unexplained vomiting, irritability and apnoeas
- altered states of consciousness
- neurological symptoms and signs
- torn frenulum or retinal damage

### History

- Unexplained injury
- Different explanations offered
- Vague or changing history
- Injury unlikely to have occurred in manner stated
- Unreasonable delays between injury and presentation
- Presentation inconsistent with child's developmental capabilities
- Evidence of neglect (clues include failure to thrive, dental caries, severe nappy rash, poor wound care)

Remember Munchausen syndrome by proxy.

### Behavioural indicators

- Wariness of adult contacts
- Inappropriate clothing (e.g. long sleeves on a hot day)

- Apprehension when other children cry or shout
- Behavioural extremes
- Fear of parents
- Afraid to go home
- Child reports injury by parents or gives inappropriate explanation of injury
- Excessive compliance
- Extreme wariness
- Attaches too readily to strangers

### Management

If suspected or disclosed, a thorough assessment, with detailed documentation (including measurement and photography of bruises/other injuries) of findings should be undertaken. A detailed history and thorough examination of all areas of the body is required. In a general practice setting, getting help with this difficult situation would often be useful. Discussing (immediately) with colleagues or child protection authorities is advisable, with the safety of the child (and other cohabiting children) being ensured at all stages. Verbatim comments should be written down and, if possible, information gathered from other sources or witnesses.

The family doctor should diplomatically confront the parents and/or carers and always act in the best interests of the child. Offer to help the family. An approach would be to say, 'I am very concerned about your child's injuries as they don't add up—these injuries are not usually caused by what I'm told has been the cause. I will therefore seek assistance—it is my legal obligation. My duty is to help you and, especially, your child.'

### Acquiring essential help

- Psychosocial assessment of child and family: involves social worker and multidisciplinary assessment
- Admission to hospital: for moderate and severe injuries
- Investigations done in conjunction with specialists
- Case conference (where appropriate)
- Mandatory reporting: notify child protection authorities

### § Emotional abuse

#### Physical indicators

- There are few physical indicators, but emotional abuse can cause delay in physical, emotional and mental development.

### Behavioural indicators

- Extremely low self-esteem.
- Compliant, passive, withdrawn, tearful and/or apathetic behaviour.
- Aggressive or demanding behaviour.
- Anxiety.
- Serious difficulties with peers and/or adult relations.
- Delayed or distorted speech.
- Regressive behaviour (e.g. soiling).

### § Neglect

#### Physical indicators

- Consistent hunger.
- Failure to thrive, or malnutrition.
- Poor hygiene.
- Inappropriate clothing.
- Consistent lack of supervision.
- Unattended physical problems or medical needs.
- Abandonment.
- Dangerous health or dietary practices.

#### Behavioural indicators

- Stealing food.
- Extending stays at school.
- Consistent fatigue, listlessness or falling asleep in class.
- Alcohol or drug abuse.
- Child states there is no caregiver.
- Aggressive or inappropriate behaviour.
- Isolation from peer group.

### § Sexual abuse<sup>3,5</sup>

- Only 6% of child sexual abuse is by strangers. Most are known by parents and child; that is, familiar people in familiar environments, especially within the family.
- A child may disclose up to 12 times before they are believed (listen for hints).
- Most (but not all) of the adults who sexually abuse are men.
- Boys are assaulted less commonly than girls, but are less likely to disclose if they are assaulted.
- Adolescents are perpetrators in at least 20% of cases.
- Child sexual abuse is usually about power rather than sexual gratification.

### Sexual abuse presents in three main ways:

- Allegations by the child or an adult
- Injuries to the genitalia or anus
- Suspicious presentations, especially:
  - genital infection (see FIG. 95.3)
  - recurrent urinary infection
  - unexplained behavioural changes/psychological disorders

FIGURE 95.3 Genital human papillomavirus infection—a sign of sexual abuse in a child

Clinical indicators that may suggest child sexual abuse are presented in TABLE 95.1.

### Clinical approach

Ideally, the child should be assessed by experienced medical officers at the regional sexual assault service, so the temptation for the inexperienced GP to have a quick look should be resisted. For the practitioner having to assess the problem, a complete medical and social history, including a behavioural history, should be obtained prior to examination.

The child's history must be obtained carefully, honestly, patiently and objectively, without leading the child. The history is more important than the physical findings as there are no abnormal physical findings in many confessed cases.

### Examination

A parent or legal guardian must give informed consent before the child is physically examined. It is

**Table 95.1** Clinical indicators that may suggest child sexual abuse

Child disclosing abuse (rarely invented, and the majority of presentations)
Parent or adult disclosing abuse allegation
Vaginal discharge
Sexually transmitted infections (acquired in 5% of sexually abused children)
Urinary tract infection
Unexplained genital trauma
Unexplained perianal trauma
Overt sexual play
Pregnancy in an adolescent
Deterioration in school work
Family disruption
Indiscriminate attachment
Abnormal sexualised behaviour (many abused children do not do this)
Poor self-esteem
Psychological disorders: <ul style="list-style-type: none"> <li>• behaviour disturbances</li> <li>• regression in behaviour</li> <li>• sleep disturbances</li> <li>• abnormal fears/reactions to specific places or persons</li> <li>• psychosomatic symptoms</li> <li>• anxiety</li> <li>• lack of trust</li> <li>• overcompliance</li> <li>• aggressive behaviour</li> </ul>
Depression: <ul style="list-style-type: none"> <li>• self-destructive behaviour</li> <li>• substance abuse</li> <li>• suicidal tendencies</li> </ul>
Non-specific physical problems: <ul style="list-style-type: none"> <li>• abdominal pain</li> <li>• enuresis (especially secondary)</li> <li>• encopresis</li> </ul>
Examination (abnormal findings uncommon)
Genital trauma
Perforated hymen/lax vagina
Perianal trauma
Vaginal discharge
Look for semen and STIs

recommended that the physical examination of any child suspected of being sexually abused is performed by a paediatrician or forensic physician experienced in the area of sexual abuse.

### Point of caution:

Perianal erythema due to streptococcal infection (GABHS) (see FIG 95.4) or threadworms and non-specific vulvovaginitis (see CHAPTER 107) can be misinterpreted as sexual abuse.

**FIGURE 95.4** Perianal dermatitis with erythema caused by group A beta-haemolytic streptococcal infection

### The crisis situation

It is important to realise that the child will be in *crisis*. Children are trapped into the secrecy of sexual abuse, often by a trusted adult, through powerful threats of the consequences of disclosure. They are given the great responsibility of keeping the secret and holding the family together or disclosing the secret and disrupting the family. A crisis occurs when these threats become reality.

### Management

It is important to act responsibly in the best interests of the child. When we encounter real or suspected child abuse, immediate action is necessary. The child needs an advocate to act on its behalf and our intervention actions may have to override our relationship with the family.

Some golden rules are:

- Never attempt to solve the problem alone.

- Do not attempt confrontation and counselling in isolation (unless under exceptional circumstances).
- Seek advice from experts (only a telephone call away).
- Avoid telling the alleged perpetrator what the child has said.
- Refer to a child sexual assault centre or Protective Services Unit where an experienced team can take the serious responsibility for the problem.

### Supporting the child

- Acknowledge the child's fear and perhaps guilt.
- Assure the child it is not his or her fault.
- Tell the child you will help.
- Obtain the child's trust.
- Tell the child it has happened to other children and you have helped them.

### Prevention of child abuse

Prevention of abuse, particularly self-perpetuating abuse, can be helped by creating awareness through media attention, programs in schools and the community in general, and increased knowledge and surveillance by all professionals involved with children. Clear guidelines on reporting and the accessibility of child abuse clinics are important for the strategies to be effective. Teaching children how to protect themselves offers the greatest potential for prevention.<sup>5</sup>

### Counselling the secondary victims

Non-offending parents, who are the secondary victims of the abused child, will require help and guidance from their family doctor on how to manage the crisis at home.<sup>3</sup> Parents should be advised to reassure the child of support and safety and to maintain usual routines. The child should be allowed to set the pace, without overattention and pressure from the parents. Siblings should be informed that something has happened but that the child is safe. Ensure that the child will inform if the perpetrator attempts further abuse. Parents need substantial support, including alleviation of any guilt.

An unhappy consequence of the crisis is the problem of broken relationships, which may involve the separation of the child from the family. At least one hitherto unsuspecting parent will be devastated if a parent is responsible for the abuse. The sexually abused child needs to be living with a protective parent or carer, with the abusive parent living separately.

### Support for doctors

The attending doctor also requires support, and sharing the problem with colleagues, mentors and family is recommended. Some helpful guidelines are as follows.

- Carefully record all examination findings (take copious notes).
- Always keep to the facts and be objective.
- Do not become emotionally involved.
- Work with (not for) the authorities.
- Avoid making inappropriate judgments to the authorities (e.g. do not state 'incest was committed', but rather say 'there is evidence (or no evidence) to support penetration of . . .').
- If called to court, be well prepared; rehearse presentation; be authoritative and keep calm without allowing yourself to be upset by personal affronts.

The main difficulty in diagnosing child abuse is denial that it could be possible.

### Adult survivors of child abuse<sup>10</sup>

All forms of child abuse can result in PTSD (from a single incident) or complex trauma (cumulative). Because of the high rate of child abuse, much of it unreported and hidden away for many years, adult survivors of child abuse are likely to be presenting to GPs on a frequent basis, often unknowingly.

Childhood trauma, especially in the first few years during formative brain development, can lead to lifelong problems with dealing with stress. Unresolved trauma restricts the capacity to respond flexibly to life challenges. Patients may present with diverse and puzzling symptoms, including medically unexplained symptoms. Substance abuse, mood disorders and other psychological impairments may result.

A GP should be aware of this possibility, and screen for trauma from child abuse in patients presenting with such issues. Take particular care with physical examination, particularly in sensitive areas or involving internal examination, and realise that many patients on whom we are doing Pap tests or rectal examinations may be survivors of child abuse. Procedures can also cause pain, and may re-traumatise such a patient. Practising in a 'trauma informed' manner involves paying attention to the way we perform a service or procedure, as well as what it comprises, and being sensitive to the context of what may have come before. Trauma from previous child abuse can often be helped by appropriately targeted psychological therapies.

## Basic rules

- Suspect child abuse.
- Recognise child abuse.
- Consult the child protection authorities.

### Mandatory reporting

In most states of Australia and in many areas throughout the world it is mandatory to notify the relevant statutory authorities about suspected child abuse. All family doctors should become familiar with the appropriate local legislation.

### Practice tips and guidelines

- A child's statement alleging abuse should be accepted as true until proved otherwise.
- Children rarely lie about sexual abuse.
- False allegations, however, are a sign of family disharmony and an indication that the child may need help.
- Do not insist that the child has 'got it wrong', even if you find the actions by the alleged perpetrator unbelievable.
- Do not procrastinate—move swiftly to solve the problem.
- The genitalia are normal in the majority of sexually abused children.
- Be supportive to the child by listening, believing, being kind and caring.

## When to refer

Unless there are exceptional circumstances, referral to an appropriate child abuse centre where an expert team is available is recommended. If doubtful, relatively urgent referral to a paediatrician is an alternative.

*We can say with some assurance that, although children may be the victims of fate, they will not be the victims of our neglect.*

John F Kennedy (1917–63)

Important serious emergencies in children include:

- trauma, especially head injuries and intra-abdominal injuries
- painful conditions
- swallowed foreign bodies (FB)
- respiratory problems:
  - bronchial asthma
  - epiglottitis
  - croup
  - inhaled FB
  - acute bronchiolitis
- severe gastroenteritis
- septicaemia (e.g. meningococcal septicaemia)
- myocarditis
- immersion
- poisoning
- bites and stings
- seizures
- febrile convulsions
- sudden infant death syndrome (SIDS) and apparent life-threatening episode (ALTE)
- child abuse:
  - emotional
  - physical
  - sexual
  - neglect
  - potential
- psychogenic disturbances
- anxiety/hyperventilation
- suicide/parasuicide

### Survey by age group

The author's study analysed emergencies into three groups:<sup>1</sup> preschool (0–5 years), primary school (6–12), adolescence (13–17).

The commonest emergency calls in the 0–5 years group were poisoning, accidents and violence, dyspnoea, fever/rigors, convulsions, abdominal pain, earache, vomiting.

In the 6–12 years age group: accidents and violence, dyspnoea, abdominal pain, vomiting, acute allergy, bites and stings, earache.

In the 13–17 years age group: accidents and violence, abdominal pain, psychogenic disorders, acute allergy, bites and stings, epistaxis.

### The signs and symptoms of a serious illness

Babies who are febrile, drowsy and pale are at very high risk and require hospital admission.

The busy GP will see many sick children in a day's work, especially in the winter months with the epidemic of URTIs. It is vital to be able to recognise the very sick child who requires special attention, including admission to hospital. It is unlikely that the commonplace robust, lustily crying, hot, red-faced child is seriously ill but the pale, quiet, whimpering child spells danger. These rules are particularly helpful in the assessment of babies under six months of age.<sup>2,3</sup> The presence of a fever in itself is not necessarily an indication of serious illness but rather that the baby has an infection.<sup>2</sup>

### The features of a very sick infant include:

- inactive, lying quietly, uninterested
- increased respiratory rate
- increased work of breathing
- noisy breathing:
  - chest wall or sternal retraction
  - wheezes, grunting, stridor
- tachycardia
- sunken eyes
- cold, pale skin
- cold extremities
- drowsiness
- poor perfusion (reduced capillary refill time)

A Melbourne study<sup>4</sup> of the sensitivity of clinical signs in detecting serious illness in infants identified five key signs or markers:

Marker	Risk to baby
Drowsiness	58%
Pallor	49%
Chest wall retraction	41%
Temperature >38.9°C or <36.4°C	42%
Lump >2 cm	42%

If sepsis suspected, investigate with:

- blood culture
- FBE/ESR/CRP
- lumbar puncture
- urine culture
- chest X-ray

Serious infectious illnesses to consider include:

- *Haemophilus influenza* type B (Hib) infection:
  - acute epiglottitis
  - meningitis
 (now uncommon since Hib immunisation)
- acute bacterial meningitis
- septicaemia:
  - meningococcaemia
  - toxic shock syndrome
  - other bacterial sepsis
- acute viral encephalitis
- acute myocarditis
- asthma/bronchitis/bronchiolitis
- pneumonia
- intussusception/bowel obstruction/appendicitis
- severe gastroenteritis

## Strategic approach<sup>5</sup>

It is useful to have a systematic mnemonic for appraisal of the sick child. One general pattern (ABCDEFG) for the primary survey is:

- Airway
- Breathing
- Circulation
- Disability (neurological assessment)
- Exposure
- Fluids: in and out
- Glucose

Another is the ABCD assessment (see below). Blood glucose should not be overlooked:

- normal random range
  - children 3.5–5.5 mmol/L
  - neonates 2.9–7 mmol/L

- hyperglycaemia >12 mmol/L
- hypoglycaemia <2.5 mmol/L

Two main groups of signs are good indicators of serious illness.<sup>2</sup>

## Group 1: common features with reasonable risk and indicator of toxicity

Here a useful mnemonic is ABCD:

A = poor Arousal, Alertness and Activity

B = Breathing difficulty

C = poor Circulation (persistent pallor, cold legs to knees)

D = Decreased fluid intake and/or urine output

*Note:* The more signs present, the greater the risk.

Children with any of these signs must be seen early, investigated and treated as a priority.

## Group 2: uncommon features with high risk requiring urgent referral

- Respiratory: apnoea, central cyanosis, respiratory grunt
- GIT: persistent bile-stained vomiting, mass >2 cm other than hydrocele or umbilical hernia, significant faecal blood
- CNS: convulsions
- Skin: petechial rash

## Airway and breathing<sup>5</sup>

Assessment of the airway and breathing is an important barometer of life-threatening illness and impending cardiac arrest due to hypoxia. The effort and efficacy of breathing must be assessed in the sick infant and child.

## Important signs to observe with indicators

- Inspiratory noises with obstruction
  - bubbly noises—partial obstruction with fluid
  - snoring—decreased level of consciousness
  - stridor—partial obstruction to larynx or trachea
- Apnoea—no respiratory effort for >20 seconds
- Bradypnoea—respiratory rate < normal for age
- Tachypnoea—rate > normal for age (indicates need to ↑ O<sub>2</sub> and ↓ CO<sub>2</sub>)
- Chest recession—on inspiration
- Tracheal tug—downward pull on inspiration
- Accessory muscle use
- Nasal flaring
- Gasping—severe hypoxia; impending arrest

- Grunting—expiration against obstructed glottis
- Oxygen saturation—efficacy of breathing; use oximetry only as an adjunct to clinical assessment
- Cyanosis

## Secondary signs of worsening obstruction

- Increased respiratory rate or effort
- Decreased oxygen saturation
- Increasing tachycardia
- Deterioration of colour
- Development of agitation or decreased level of consciousness

Indications for investigations are presented in **TABLE 96.1**.

**Table 96.1** Indications for investigations in the sick child<sup>2</sup>

Urine microscopy, culture and sensitivity	All with fever
Full blood examination	All <4 weeks Risk factors present Doctor uncertain
Blood microscopy, culture and sensitivity	All <3 months Risk factors present Doctor uncertain
Faecal microscopy, culture and sensitivity	All with diarrhoea
Chest X-ray	All with significant respiratory track symptoms and signs
C-reactive protein	Those on antibiotics Doctor uncertain
CSF examination (lumbar puncture contraindicated in the unresponsive febrile patient)	Suspected meningitis (infant drowsy, pale and febrile) Convulsion in febrile child and: <ul style="list-style-type: none"> <li>• source of fever unknown</li> <li>• receding drowsiness and pallor</li> <li>• infant &lt;6 months, child &gt;5 years</li> <li>• prolonged convulsion (&gt;10 minutes)</li> <li>• postictal phase longer than usual (&gt;30 minutes)</li> </ul>

## § Collapse in children

Collapse in children is a very dramatic emergency and often represents a life-threatening event. It is important to remember that the child's brain requires two vital factors: oxygen and glucose.

There is only a 2-minute reserve once cerebral blood flow stops. Bacterial meningitis should be considered as a cause.

Important causes of collapse are presented in **TABLE 96.2**. Keep in mind child abuse as a cause of collapse.

**Table 96.2** Collapse in children: causes to consider

Anaphylaxis	Penicillin injection Stings
Asphyxia	Near drowning Strangulation
Airways obstruction	Asthma Epiglottitis Croup Inhaled foreign body
CNS disorders	Convulsions Meningitis Encephalitis Head injury
Severe infection	Gastroenteritis → dehydration Septicaemia Myocarditis
Hypovolaemia	Dehydration (e.g. heat) Blood loss (e.g. ruptured Spleen)
Cardiac failure	Arrhythmias Cardiomyopathy
Metabolic	Acidosis (e.g. diabetic coma) Hypoglycaemia Hyponatraemia
Poisoning	Drug ingestion Envenomation
SIDS	Near miss
Functional	Breath-holding attacks Conversion reaction Vasovagal

*Note:* Consider child abuse.

## Initial basic management<sup>6</sup>

- 1 Lay child on side.
- 2 Suck out mouth and nasopharynx.
- 3 Rescue breaths.
- 4 Intubate or ventilate (if necessary).
- 5 Give oxygen 8–10 L/min by mask.
- 6 Pass a nasogastric tube:
  - 0–3 years 12 FG
  - 4–10 years 14 FG

- 7 Attend to circulation: IV access  
? give blood, Haemaccel or N saline.
- 8 Take blood for appropriate investigations.
- 9 Consider 'blind' administration of IV glucose.
- 10 A pulse oximeter is ideal.

### Cardiopulmonary resuscitation<sup>6</sup>

Sudden primary cardiac arrest is rare in children. Mostly due to hypoxia. Asystole or severe bradycardia is the usual rhythm at the time of arrest.

The following basic life support plan should be followed:

- Check breathing and pulse.
- Inspect oropharynx and clear any debris.
- Basic life support outside the hospital setting is 30:2 compression ventilation ratio, including two initial rescue breaths. The ratio of 30:2 is recommended for all ages regardless of the number of revivers present <[www.resus.org.au/policy/guidelines/index.asp](http://www.resus.org.au/policy/guidelines/index.asp)>.
- Tilt head backwards, lift chin and thrust jaw forwards (the sniffing position).
- Ventilate lungs at about 20 inflations/min with bag-valve-mask or mouth to mask or mouth to mouth. An Air-viva using 8–10 L/min of oxygen is ideal if available.
- Intubate via mouth and secure, if necessary (must pre-oxygenate).
- If intubation not possible, use a needle cricothyroidotomy as an emergency.
- Start external cardiac compression if pulseless or <60 beats/min (see TABLE 130.2 in CHAPTER 130). Use two fingers or thumbs for infants <1 year and heel of one hand for children 1–8 years.
- If >8 years use a two-handed technique. Avoid pressure over ribs and abdominal viscera. The compression ratio for children is 100 per minute (one per 0.6 seconds).

### Guidelines

Differences in children's airways for intubation:

- epiglottis longer and stiffer, more horizontal
- larynx more anterior → difficult to intubate 'blind'
- cricoid ring is narrowest position → cuffed tube not required
- shorter trachea → increased risk intubating right main bronchus
- narrow airway → increased airway resistance

### Rule for endotracheal tube (ETT) size (internal diameter in mm)

- ETT (mm) = (age in years ÷ 4) + 4  
or  
the size of the child's little finger or nares
- ETT length (cm) oral = (age in years ÷ 2) + 12;  
nasal—add 3 cm

For endotracheal size refer to TABLE 96.3 and for a basic schedule for CPR refer to TABLE 130.2.

**Table 96.3** Childhood intubation: endotracheal tube size and insertion distance<sup>6</sup>

Age	Internal diameter (mm)	Length to lip (cm)
Newborn	3.0	8.5
1–6 months	3.5	10
6–12 months	4.0	11
2 years	4.5	12
4	5.0	14
6	5.5	15
8	6.0	16
10	6.5	17
12	7.0	18
14	7.5	19
Adult	8.0	20

Drugs that can be administered through the ETT can be considered under the mnemonic NASALS:

N = Naloxone  
A = Atropine  
S = Salbutamol  
A = Adrenaline  
L = Lignocaine  
S = Surfactant

### Paediatric advanced life support

- Compression ventilation ratio of 30:2 for infants and children should be used in an advanced life support situation (i.e. in a hospital setting).
- Give a single shock instead of stacked shocks (single shock strategy) for ventricular fibrillation/pulseless ventricular tachycardia.

- Where the arrest is witnessed by a health care professional and a manual defibrillator is available, then up to three shocks may be given (stacked shock strategy) at the first defibrillation attempt.
- Monophasic or biphasic defibrillation: first shock—2 J/kg, subsequent shocks—4 J/kg.

## § Poisoning

Poisoning in children is a special problem in toddlers (accidental) and in adolescents (deliberate). Children 1–2 years old are most prone to accidental poisoning. The most common cause of death in comatose patients is respiratory failure.

The common dangerous poisons in the past were kerosene and aspirin. Excluding household chemicals, camphor/moth balls, pesticides, insecticides and opioids, the dangerous drugs or substances are:

- antidepressants, especially tricyclics
- antihistamines
- antihypertensives
- antipsychotics
- anxiolytics (e.g. benzodiazepines/barbiturates)
- beta blockers
- calcium-channel blockers
- chloral hydrate
- disc (button) batteries
- digoxin
- dishwashing powder
- iron tablets
- Lomotil (diphenoxylate)
- opiates/'designer' drugs
- paracetamol/acetaminophen (the most common in Australia)
- potassium tablets
- quinine/quinidine
- salicylates (e.g. aspirin)
- selective serotonin reuptake inhibitors
- tricyclic antidepressants

Be mindful of the serotonin syndrome (see CHAPTER 19).

In a UK study<sup>7</sup> the main cause of deaths from poisoning were (in order) tricyclics, salicylates, opioids including Lomotil, barbiturates, digoxin, orphenadrine, quinine, potassium and iron.

## Principles of treatment<sup>8,9</sup>

The use of activated charcoal has become the key to treatment and is the 'universal antidote'.

- Identify the poison
- Support vital functions—ABCD:

**Airway**—relieve obstruction

**Breathing**—ventilate with oxygen

**Circulation**—treat hypotension/arrhythmias

**Dextrose**—avoid severe hypoglycaemia

- Dilute the poison—give a cupful of milk or water to drink

*Note:* The modern trend is away from emesis, which includes not using syrup of ipecacuanha.<sup>7</sup>

- gastric lavage: within 1 hour (refer to TABLE 96.4 for guidelines) but also has a limited place in management
- Delay absorption:
  - activated charcoal (the preferred method):
    - 1 g/kg orally or via nasogastric tube (best) or gastric tube (refer to TABLES 96.5 and 96.6)
    - multiple dose charcoal, 5–10 g every 4 hours or 0.25 g/kg per hour for 12 hours, is effective
    - never administer activated charcoal in children with an altered conscious state without airway protection (use only where benefits outweigh the risks of aspiration)<sup>7</sup>
    - check with an emergency physician
    - evaporated milk
- Administer antidote early (see TABLE 96.7)

**Table 96.4** Guidelines for gastric lavage

- Do within 60 minutes of ingestion
- Ideally indicated for serious poisoning when a child is already intubated

Contraindications:

- stuporous or comatose
- absent gag reflex (unless endotracheal tube in situ)
- ingestion of corrosives: acids, alkali
- ingestion of hydrocarbons or petrochemicals

Method:

- child on left side
- head of bed tilted down
- insert orogastric tube (lubricated)
 

<2 years	12–14 size FG
2–4	14–18 size FG
5–12	18–22 size FG
>12	22–30
- check in stomach by aspiration
- instil 50–100 mL lukewarm tap water or saline via large syringe or funnel
- brief pause, then drain into bucket
- repeat often until washings clear
- use about 2–3 L
- restrict the total volume to 40 mL/kg
- be careful of water intoxication

**Table 96.5** Drugs not absorbed by active charcoal

Acids  
Alcohols (e.g. ethanol)  
Alkalis (caustics)  
Boric acid  
Bromides  
Cyanide  
Iodines  
Iron  
Lithium  
Other heavy metals

**Table 96.6** Drugs well absorbed by and often successfully treated by repeated doses of activated charcoal<sup>10</sup>

Amphetamines  
Barbiturates  
Benzodiazepines  
Carbamazepine  
Chlorpropamide  
Cocaine  
Cyclosporin  
Dextropropoxyphene  
Digoxin  
Methotrexate  
Paracetamol  
Phenobarbital  
Phenytoin  
Salicylates/aspirin  
Theophylline  
Tricyclic antidepressants

- Treat any complications:
  - respiratory failure: hypoventilation, apnoea
  - pulmonary aspiration of gastric contents
  - arrhythmias
  - hypotension
  - seizures
  - delayed effects (e.g. paracetamol—  
hepatotoxicity; tricyclics—arrhythmia)

### Whole bowel irrigation

This is performed with a solution of polyethylene glycol and electrolytes (e.g. ColonLYTLEY) via a nasogastric tube. It is usually limited to iron and lead, and slow-release drug preparations that don't bind to charcoal.

### Investigations

- Drug levels (e.g. paracetamol, aspirin, iron)
- Blood gas analysis

**Table 96.7** Important antidotes for poisons<sup>10</sup>

Poison	Antidote
Amphetamines (cause hypertension)	Glyceryl trinitrate IV Sodium nitroprusside
Benzodiazepines	Flumazenil Sodium bicarbonate
Beta blockers	Glucagon Isoprenaline
Calcium blocker	Calcium chloride IV or Calcium gluconate IV
Carbon monoxide	Oxygen 100% Hyperbaric oxygen
Cyanide	Hydroxocobalamin Dicobalt edetate Sodium nitrite IV Sodium thiosulphate IV
Digoxin	Digoxin-specific antibodies Magnesium sulphate
Heavy metals (e.g. Pb, As, Hg, Fe)	Chelating agents, e.g. dimercaprol
Heparin	Protamine IV
Iron	Desferrioxamine
Isoniazid	Pyridoxine
Methanol, ethylene glycol	Ethanol (ethyl alcohol)
Narcotics/opioids	Naloxone (Narcan)
Organophosphates	Atropine Pralidoxime (2-PAM)
Paracetamol (acetaminophen)	Acetylcysteine (IV) (effective within 12 hours) consider up to 36 hours
Phenothiazines	Benztropine
Potassium	Calcium gluconate Sodium bicarbonate Salbutamol aerosol
Tricyclic antidepressants	Sodium bicarbonate IV
Warfarin	Fresh frozen plasma Vitamin K

- X-ray:
  - chest
  - abdomen (e.g. radio-opaque iron tablets)
  - skull
- ECG

### Psychosocial care

The reasons for the poisoning need to be carefully evaluated and proper support and advice given.

## § Swallowed foreign objects

### A golden rule

The natural passage of most objects entering the stomach can be expected. Once the pylorus is traversed the FB usually continues.

This includes:

- coins
- buttons
- sharp objects
- open safety pins
- glass (e.g. ends of thermometers)
- drawing pins

Special cases are:

- very large coins: watch carefully
- hair clips (usually cannot pass duodenum if under 7 years)

### Management

- Manage conservatively.
- X-ray all children (mouth to anus, especially chest and abdomen) on presentation (the oesophagus is a concern).
- Investigate unusual gagging, coughing and retching with X-rays of the head, neck, thorax and abdomen (check nasopharynx and respiratory tract).
- Watch for passage of the FB in stool (usually 3 days). Defecate into a container.
- If not passed, order X-ray in 1 week.
- If a blunt FB has been stationary for 1 month without symptoms, remove at laparotomy.

### Button and disc battery ingestion

If not in stomach these (especially lithium batteries) create an emergency if in the oesophagus because electrical current generated destroys mucous membranes and perforates within 6 hours (must be removed endoscopically ASAP). This also applies to the ear canal and nares.

## § Fever<sup>11</sup>

Fever, which is commonly defined as a temperature  $>38^{\circ}\text{C}$ , is a significant symptom in a child, especially in neonates (see CHAPTER 53). One recommendation is that all febrile neonates should have a full septic work-up and be admitted for parenteral antibiotics.

## § Febrile convulsions

Diagnosis based on presence of fever, short duration and no clinical evidence of CNS pathology.

### Clinical features

- The commonest cause is an URTI (e.g. the common cold or similar viral syndrome).
- About 5 per 100 incidence in children.
- Rare under 6 months and over 5 years.
- Commonest age range 9–20 months.
- Recurrent in up to 50% of children.
- Consider meningitis and lumbar puncture after first convulsion if under 2 years or cause of fever not obvious.
- Epilepsy develops in about 2–3% of such children.

### Management of the convulsion (if prolonged $>15$ minutes), also for status epilepticus

- Undress the child to singlet and underpants or light clothing but take care to prevent the child getting cold.
- Maintain the airway and prevent injury.
- Place patient chest down with head turned to one side.
- Oxygen 8 L/min by mask.
- Give midazolam or diazepam.
- Give midazolam by one of four routes:  
IV 0.15 mg/kg, IM 0.2 mg/kg, buccal 2–5 mg/dose or (preferable) intranasal 0.3 mg/kg undiluted (use 1 mL of drops from vial) Buccal and nasal routes slower response—IM may be most practical.
- Give diazepam by one of two routes:  
IV 0.2 mg/kg, undiluted or diluted (10 mg in 20 mL N saline)  
or  
rectally 0.5 mg/kg (dilute with saline or in pre-prepared syringe) up to 10 mg or with suppository or rectal gel.

*Note:* Although the IV route is preferred, the rectal route is ideal in a home or office situation; for example consider a 2-year-old child (weight 12 kg) with a persistent febrile convulsion. The dose of diazepam injectable is 0.5 mg/kg, so 6 mg (1.2 mL) of diazepam is diluted with isotonic saline (up to 10 mL of solution) and the nozzle of the syringe pressed gently but firmly into the anus and injected slowly. *Observe carefully for respiratory depression.*

rectal paracetamol 15 mg/kg statim

The anti-epileptics can be repeated in 5 minutes if fitting continues.

Check blood glucose: if  $<3.5$  give a bolus dose of IV dextrose.

If still fitting, admit to an appropriate unit and rapidly induce 'coma' with thiopentone followed by intubation.

Explain risk of later epilepsy is small: <3%.

## § Meningitis or encephalitis

Diagnosing meningitis and encephalitis requires a high level of clinical awareness and watchfulness for the infective problem that appears more serious than normal. Follow the appropriate guidelines: ABCDEFG (see earlier in this chapter). Refer also to **CHAPTER 30**.

## Bacterial meningitis<sup>12</sup>

Bacterial meningitis is basically also a childhood infection. Neonates and children aged 6–12 months are at the greatest risk. For clinical features see **CHAPTER 30**. Meningococcal disease can take the form of either meningitis or septicaemia (meningococcaemia) or both. Most cases begin as septicaemia, usually via the nasopharynx.

## Treatment for suspected meningitis (summary)<sup>9</sup>

First—oxygen and IV access (interosseous if difficult):

- take blood for culture (within 30 minutes of assessment)
- for child give bolus of 10–20 mL/kg of N saline
- admit to hospital for lumbar puncture when patient is resuscitated and stable and without signs of raised ICP
- dexamethasone 0.15 mg/kg up to 10 mg IV
- ceftriaxone 100 mg/kg up to 4 g, IV statim then daily for 3–5 days
- or
- cefotaxime 50 mg/kg up to 2 g, IV statim then 6 hourly for 3–5 days

Neonates to 3 months:

- ampicillin (or benzylpenicillin) + cefotaxime

## § Meningococcaemia<sup>12,13</sup>

*Note:* Treatment is urgent once sepsis suspected (e.g. petechial or purpuric rash on trunk and limbs). It should be given before reaching hospital according to the following plans (see **CHAPTER 30**).

- Antibiotics:  
benzylpenicillin 60 mg/kg IV (max. 1.8 g), 4 hourly for 3–5 days. Give IM if IV access not possible
- or
- ceftriaxone 100 mg/kg IV or IM (max. 4 g) statim then daily for 5 days

- Admit to hospital
- Continue antibiotics for 7–10 days

Treat contacts who:

- live in the household and <24 months
- have kissed patient in the previous 10 days
- have attended the same day care centre

For prophylaxis—rifampicin dose:

adult — 600 mg bd for 3 days

child <1 month—5 mg/kg

child >1 month—10 mg/kg

give bd for 2 days

or (if unsuitable)

ceftriaxone 1 g (child: 25 mg/kg up to 1 g) IM

daily for two days

ciprofloxacin 500 mg (o) as single dose

give meningococcus type C vaccine

## A simple plan for children (prehospital): benzylpenicillin<sup>13</sup>

- infants <1 year: 300 mg IV or IM
- 1–9 years: 600 mg
- ≥ 10 years: 1200 mg

## Practice point

In a very sick child with fever give IV antibiotics while awaiting culture.

## § Acute epiglottitis

Acute epiglottitis due to *H. influenzae* is a life-threatening emergency in a child. A toxic febrile illness, with sudden onset of expiratory stridor, should alert one to this potentially fatal condition. A high index of suspicion of epiglottitis is always warranted in such presentations. This is uncommon since Hib immunisation.

## Differential diagnosis

The main alternative diagnosis is viral laryngo-tracheobronchitis (croup). There are, however, significant clinical differences.

Epiglottitis is characterised by fever, a soft voice, lack of a harsh cough, a preference to sit quietly (rather than lie down) and especially by a soft stridor with a sonorous expiratory component.

Croup is distinguished by a harsh inspiratory stridor, a hoarse voice and brassy cough.

Other differential diagnoses include tonsillitis, infectious mononucleosis and bacterial tracheitis.

### Diagnostic tip

Children with epiglottitis usually sit still with their mouth open, drooling saliva, and their eyes follow you around the room because limited head movement protects the compromised airway.

**DO NOT EXAMINE THE THROAT IN THE OFFICE**

A swollen, cherry-red epiglottis recognised on examination of the nasopharynx confirms the diagnosis. However, the initial diagnosis should be made on the clinical history and appearance of the child.

### Management

Admit the child to hospital for the following:

- Intubation: in theatre suck away profuse secretions and perform nasotracheal intubation
- Antibiotics:<sup>13</sup>  
cefotaxime 25 mg/kg up to 1 g IV for 5 days 8 hourly  
or  
ceftriaxone 25 mg/kg to max. 1 g/day IV daily for 5 days

### § Croup<sup>14</sup>

Croup refers to a symptom complex with a harsh, brassy cough, usually with an inspiratory stridor and with or without respiratory difficulty.

Clinical features of viral laryngotracheitis:

- caused by parainfluenzal and other viruses e.g. RSV
- most common type of childhood croup
- usually 6 months to 6 years—peak incidence 1–2 years
- prodrome of URTI or coryza for 2 days
- fever variable—rarely above 39°C
- loud barking cough—increased if upset
- usually self-limiting

### Treatment<sup>14,15,16</sup>

The grading system for croup is outlined in TABLE 96.8.

#### Grade 1 croup

Mild croup (barking cough, no stridor or stridor at rest without chest retraction, hoarse voice):

- manage at home if no signs of Grade 2 or 3 croup, keep child relaxed
- consider oral steroids (e.g. dexamethasone 0.15–0.3 mg/kg/dose or prednisolone 1 mg/kg/dose) if stridor and chest wall retraction develop

**Table 96.8** Grading system for croup

Croup score	
Grade 1: mild	Stridor at rest without retractions and no distress
Grade 2: moderate	Stridor at rest with sternal and chest wall retractions
Grade 3: severe	Marked respiratory distress indicated by irritability, pallor, cyanosis, tachycardia and exhaustion (i.e. impending airway obstruction)

A randomised controlled trial showed no additional benefit from mist (supersaturated air) therapy when coupled with oral corticosteroids (level II evidence).<sup>16,17</sup>

#### Grade 2 croup

Moderate croup (inspiratory stridor when upset or at rest with chest wall retractions):

- admit to hospital (e.g. emergency department)
- cool humidified air
- oral steroids  
dexamethasone 0.6 mg/kg  
or  
prednisolone (tablets or oral solution) 1 mg/kg (2–3 doses)  
and/or (for children 2 or more years)  
budesonide 100 mcg × 20 puffs or 2 mg nebulised
- nebulised adrenaline—if poor response to steroids
- observe for at least 4 hours

#### Grade 3 croup

Severe croup (inspiratory stridor at rest, use of accessory muscles, patient restless and agitated). Adrenaline is first-line therapy:

- nurse in intensive care
- oxygen
- nebulised adrenaline 1:1000 solution  
0.5 mL/kg/dose (to max. 5 mL)  
(beware of possible rebound effect after 2–3 hours—must be observed)

*Note:* Can use 4 ampoules of 1:1000 solution in a nebuliser run with oxygen 8 L/min. Repeat the dose if no response at 10–15 minutes, do not dilute solution.

- dexamethasone 0.2 mg/kg IV  
or

0.6 mg/kg IM  
followed by oral steroids

- have facilities for artificial airway
- may need endotracheal intubation (if going into respiratory failure) for 48 hours. Use a tube 0.5–1 mm smaller than normal for age.

There is no place for cough medicines or antibiotics. Steaming methods are discouraged.

### § Bronchiolitis<sup>18</sup>

- An acute viral illness usually due to RSV
- The commonest acute LRTI in infants
- Usual age 2 weeks to 9 months (up to 12 months)
- Prodromal symptoms for 48 hours (e.g. coryza, irritating cough, then 3–5 days of more severe symptoms)
- Wheezy breathing—often distressed
- Signs of hypoxia (restlessness, agitation, drowsiness)
- Tachypnoea
- Hyperinflated chest: barrel-shaped, usually subcostal recession

#### Auscultation

- Widespread fine inspiratory crackles (not with asthma)
- Frequent expiratory wheezes

*X-ray.* Hyperinflation of lungs with depression of diaphragm—but chest X-ray should not be used for diagnosis or routinely performed.<sup>19</sup>

Virus identified by PCR on nasopharyngeal aspirate. Rapid RSV viral test available. Blood glucose should be assessed in all sick patients.

#### Management

Admission to hospital is usual, especially with increasing respiratory distress reflected by difficulty in feeding (particularly less than half normal over 24 hours). Dehydration is a serious problem, especially with exhausted infants.

- Minimal handling/good nursing care
- Careful observation: colour, pulse, respiration, oxygen saturation (pulse oximetry)
- Oxygen (preferably warmed and humidified) for signs of hypoxia: by nasal prongs or even simple facemask to maintain  $P_aO_2$  above 90% (preferably  $\geq 95\%$ ),  $O_2$  not required if  $P_aO_2 > 95\%$  in room air
- Fluids IV preferably or by nasogastric tube if unable to feed orally

- Antibiotics not indicated unless secondary bacterial infection. There is no evidence to support the routine use of nebulised adrenaline, bronchodilators or corticosteroids.<sup>14</sup>

*Note:* Increased tendency to asthma later.

### § Very severe asthma<sup>20</sup>

See CHAPTER 82.

Observe closely according to the ABCD rule. Very severe asthma in children should be referred to an intensive care unit; stepwise action includes:

- inhaled salbutamol (4–8 puffs) from spacer, or
- continuous nebulised 0.5% salbutamol via mask<sup>4</sup>
- oxygen flow 6 L/min through the nebuliser (best option)
- IV infusion of  
salbutamol 5 mcg/kg/min  
hydrocortisone 4 mg/kg IV statim then 6 hourly

#### Common mistakes

- Using assisted mechanical ventilation inappropriately (main indications are physical exhaustion and cardiopulmonary arrest—it can be dangerous in asthma)
- Not giving high flow oxygen
- Giving excessive fluid
- Giving submaximal bronchodilator therapy

### § Acute heart failure

#### Clinical features (infants)

- Increasing fatigue, dyspnoea, poor feeding
- Failure to thrive
- Tachycardia, cardiomegaly, gallop rhythm
- Fine basal crackles
- Hepatomegaly
- Usually no peripheral oedema or wheezing

Causes include:

- congenital (e.g. VSD)
- cardiomyopathy
- tachyarrhythmias
- postprocedural myocardial dysfunction

#### Management

- Admit to hospital
- Pulse oximetry, ECG, CXR and echocardiography
- Diuretic (frusemide and spironolactone)
- ACE inhibitors—consider digoxin
- Oxygen to maintain  $P_aO_2$  at 85–95%
- CPAP

## § Breath-holding attacks

This is a dramatic emergency. There are two types: one is related to a tantrum (description follows) and the other is a simple faint.

### Clinical features

- Age group—usually 6 months to 6 years (peak 2–3 years)
- Precipitating event (minor emotional or physical)
- Children emit a long loud cry, then hold their breath
- They become pale and then blue
- If severe, may result in unconsciousness or even a brief tonic-clonic fit
- Lasts 10–60 seconds

### Management

- Reassure the parents that attacks are self-limiting, not harmful and not associated with epilepsy or intellectual disability.
- Advise parents to maintain discipline and to resist spoiling the child.
- Try to avoid incidents known to frustrate the child or to precipitate a tantrum.

*Note:* Important childhood emergency drugs with dosages are presented in [TABLE 96.9](#).

## § Aspirated foreign body

Parents or guardians may not be able to give a history of inhalation. One in eight episodes is not witnessed.

### Symptoms

- Choking or coughing episodes while eating nuts or similar food or while sucking a small object (e.g. plastic toy)
- Persistent coughing and wheezing ('all that wheezes is not asthma')
- Sudden onset of first wheezing episode in a toddler with no past history of allergy, especially after a choking bout

### Signs

- Reduced or absent breath sounds over whole or part of a lung
- Wheeze

### Investigations

Chest X-ray (full inspiration and full expiration) to exclude an area of collapse or obstructive hyperinflation.

*Note:* Normal X-rays do not absolutely exclude an FB.

## Management

First aid:

- most cough out the FB, so encourage coughing
- a finger sweep helps, as do back slaps, lateral chest compression and the Heimlich manoeuvre if >8 years (take care with viscera). A good rule is the rule of 5s—5 breaths, 5 back blows, 5 chest thrusts, 5 abdominal thrusts (older child).

If complete obstruction—attempt removal of the FB with forceps. If unsuccessful, perform a tracheostomy or cricothyroidotomy.

*Note:* Once an FB has passed through the larynx it is very rare for there to be an immediate threat to life, so referral is usually quite safe.

*Note:* Do not instrument the airways if the child is coping.

## Bronchoscopy

Bronchoscopy is necessary in almost every child where there is a strong suggestion of an inhaled FB. It is difficult and requires an expert with appropriate facilities.

## Prevention

- No child <15 months should have popcorn, hard lollies, raw carrots and apples
- Children <4 years—no peanuts
- Children <3 years—no toys with small parts

## § Anaphylaxis<sup>5</sup>

The management of airway obstruction and hypotension can be summarised as:

- oxygen 6–8 L/min by mask
- adrenaline 0.01 mL/kg of 1:1000 IM; 0.05–0.1 mL if <1 year (repeat adrenaline every 5 minutes as necessary) if no improvement set up a continuous infusion (1 mg adrenaline in 1000 mL N saline) avoid SC use
- nebulised salbutamol for bronchospasm
- admit to hospital (observe at least 4 hours)
- colloid or crystalloid solution IV: give repeated boluses 10–20 mL/kg
- only if necessary: corticosteroid 4 mg/kg IV

If persistent upper airways obstruction—try nebulised 1% adrenaline (max. 4 mL); intubation may be necessary. Admit to hospital and observe for at least 12 hours.

**Table 96.9** Important childhood emergency drugs<sup>21</sup>

Drug	Route	Dose	Notes
Adrenaline 1:10 000	IV	0.1 mL/kg/dose	Anaphylaxis, asystole (repeat every 5 minutes until response)
Adrenaline 1:1000	IM	0.01 mL/kg/dose	
Adrenaline 1:1000	Nebuliser	0.5 mL/kg/dose (max. 5 mL)	LTB* (patient must be admitted)
Aminophylline	IV slowly	5 mg/kg loading	Moderate to severe asthma
Atropine	IV	0.02 mg/kg	Bradycardia producing shock
Calcium gluconate 10%	IV	0.5 mL/kg (max. 20 mL)	Hyperkalaemia, hypocalcaemia
Dextrose 50%	IV	1 mL/kg	Hypoglycaemia
Diazepam	IV PR	0.2 mg/kg	Seizures
Fentanyl citrate	IV	1.2 mcg/kg (intranasal effective)	Pain control
Glucagon	IV or IM	0.1 mg/kg (max. 1 mg)	Hypoglycaemia
Hydrocortisone	IV	4 mg/kg	Anaphylaxis, asthma
Midazolam	IV or IM, intranasal	0.15–0.2 mg/kg/dose	Seizures
Morphine	IV or IM	0.1–0.2 mg/kg	Sedation, pain relief
Naloxone	IV or IM	0.01 mg/kg (max. 2 mg)	Opioid overdose
Paracetamol	O	15–20 mg/kg loading	Fever
Paraldehyde	PR	0.3 mL/kg (dilute 1:2 in peanut oil)	Seizures
Salbutamol	Nebuliser	0.3 mL/kg	Asthma
	Spacer	<6 yrs 6 puffs >6 yrs 12 puffs	
	IV	5 mcg/kg	
Sodium bicarbonate 8.4%	IV	2 mL/kg	Titrate against blood gases
Soluble insulin	IV infusion	0.1 U/kg/h	Only if glucose > 14 mmol/L

\*LTB = laryngotracheal bronchitis (croup)

Note: Volume resuscitation: IV fluid bolus 20 mL/kg statim of crystalloid (e.g. N saline)

Source: After Pitt<sup>21</sup>

## § Status epilepticus/prolonged seizure<sup>22</sup>

Ensure adequate oxygenation: attend to airway (e.g. Guedel tube): give oxygen. Check blood glucose.

Antiepileptic options include:<sup>5</sup>

midazolam 0.1–0.2 mg/kg IV or 0.2 mg/kg IM or 0.3 mg/kg intranasal

diazepam 0.2 mg/kg IV or 0.5 mg/kg per rectum

clonazepam 0.25 mg (<1 year), 0.5 mg (1–5 years), 1 mg (>5 years)

phenytoin 15 mg/kg slowly over 20–30 minutes

thiopentone: titrate the dose (usually 2–5 mg/kg)

If refractory (up to 60 minutes) use full anaesthetic with intubation.

Consider hyponatraemia as the cause of convulsions with meningitis. Perform an ECG (look for prolonged QT interval). Consider IV ceftriaxone if meningitis suspected.

## § Drowning

The differences between salt-water and freshwater drowning are usually not clinically significant. If global hypoxic cerebral ischaemia and pulmonary aspiration, treat as follows:<sup>6</sup>

- adequate oxygenation and ventilation
- decompress stomach with nasogastric tube
- support circulation with IV infusion of colloid solution and dopamine 5–20 mcg/kg per minute
- mannitol 0.25–0.5 g/kg IV if cerebral oedema
- correct electrolyte disturbances (e.g. hypokalaemia)
- give prophylactic penicillin

## § Intraosseous infusion<sup>3</sup>

In an emergency situation where intravenous access in a collapsed person (especially children) is difficult, parenteral fluid can be infused into the bone marrow (an intravascular space). Intraosseous infusion is preferred to an intravenous cutdown in children under 5 years. It is useful to practise the technique on a chicken bone.

### Site of infusion

- Adults and children over 5: distal end of tibia
- Children under 5: proximal end of tibia
- The distal femur: 2–3 cm above condyles in midline is an alternative

Avoid growth plates, midshaft and the sternum.

### Method for proximal tibia

*Note:* Strict asepsis is essential (skin preparation and sterile gloves).

- Inject local anaesthetic (if necessary).
- Choose 16 gauge intraosseous needle (Dieckmann modification, e.g. Cook critical needle 15.5 gauge) or a 16–18 gauge lumbar puncture needle (less expensive).
- Hold it at right angles to the anteromedial surface of the proximal tibia about 2 cm below the tibial tuberosity (see FIG. 96.1). Point the needle slightly downwards, away from the joint space (<90° to long axis).
- Carefully twist the needle to penetrate the bone cortex; it enters bone marrow with a sensation of giving way.
- Remove the trocar, aspirate a small amount of marrow to ensure its position.
- Hold the needle in place with a small plaster of Paris splint.
- Fluid, including blood, can be infused with a normal IV infusion—rapidly or slowly.
- The infusion rate can be markedly increased by using a pressure bag at 300 mmHg pressure.

## SERIOUS GASTROENTEROLOGICAL CONDITIONS

GIT conditions that cause vomiting require careful evaluation because of potentially fatal outcomes.

### Gastroenteritis<sup>23</sup>

This condition should not be treated lightly. Assessment of general signs such as arousal, presence of pallor, degree of weight loss, fluids in and fluids

FIGURE 96.1 Intraosseous infusion

out is important (see CHAPTER 44). If concerned or in doubt, arrange hospitalisation. The social situation needs to be taken into account.

## § Intussusception

It is important to recognise this condition as about 50% of infants with intussusception are not diagnosed on initial presentation.<sup>2</sup> Characteristic features include sudden-onset pallor which persists, episodic crying and vomiting. Rectal bleeding and an abdominal mass (see CHAPTER 34) are present in only 40% of cases.

## § Pyloric stenosis

Pyloric stenosis, which appears from 2 weeks to 3 months of age, should be suspected with projectile vomiting, acute weight loss and alkalosis. It must not be confused with projectile vomiting from overfeeding. If in doubt, expert ultrasound examination of the pylorus will assist diagnosis (refer CHAPTER 60).

### Red flag pointers for GIT conditions

- Bile-stained vomitus indicates urgent referral to consider possible intestinal malrotation and mid-gut volvulus
- Failure to pass meconium beyond 24 hours: may represent congenital intestinal atresia and stenosis, meconium ileus or Hirschsprung disease

## § Sudden infant death syndrome

- SIDS is the major cause of death between 1 and 12 months of age (peak incidence 4 months).

- The incidence is around 1 per 500 live births but improving.
- The causes are unknown but risk factors have been identified. Overwhelming infection is a possibility.
- No investigations have identified susceptible infants.
- Although SIDS can recur in a family, the risk is small.
- Association with low socioeconomic status.

### Risk factors

- Prone sleeping position
- Smothered airways (debatable)
- Artificial feeding (possible)
- Passive smoking (before or after birth)
- Hyperthermia or excess warmth
- Extreme prematurity <32 weeks
- Parental narcotic/cocaine abuse
- Intercurrent viral infections

### Preventive advice

After baby is born.

- Place baby to sleep on its back (preferable) with no pillow (unless special reason for placing it on its stomach, e.g. gastro-oesophageal reflux).
- Ensure the head is uncovered.
- Breastfeeding.
- Ensure the baby is not exposed to cigarette smoking (before and after birth).
- Ensure the baby does not get overheated (sweating around the head and neck indicates the baby is too hot).
- Bed coverings no more than adults require.
- Nothing else in cot (e.g. soft toys).

### Reactions of bereaved parents

- May be hostility to GP, especially if recent examination
- May 'hear' the baby cry
- Distressing dreams
- Guilt/self-blame, especially mother
- Psychiatric morbidity
- Other stages of bereavement: denial, anger, bargaining, depression, acceptance

### Management of SIDS

- Allow parents to see or hold baby.
- Give explanations, including reasons for coroner's involvement.
- Provide bereavement counselling.
- Early contact with counsellors and continuing support.

- Contact the SIDS support group.
- Revisit the home.
- Provide hypnotics (limited).
- Offer advice on lactation suppression (see CHAPTER 111).
- Remember: siblings can also experience grief reactions.
- The police and coroner must be notified—the law requires an autopsy.

### § Apparent life-threatening episode

ALTE, or 'near-miss SIDS', is defined as a 'frightening' encounter of apnoea, colour change or choking. At least 10% will have another episode. Management includes admission to hospital for investigation and monitoring.

### Guidelines for home apnoea monitoring

- ALTE
- Subsequent siblings of SIDS victims
- Twin of SIDS victim
- Extremely premature infants

Doubtful value—mainly for parental support.

### Obstructive sleep apnoea syndrome

A childhood disorder of breathing during sleep characterised by noisy, disturbed breathing and periods of apnoea. Leads to daytime sleepiness, disturbed behaviour and cognitive dysfunction. Requires referral.

*The feeling of apartness from others comes to most with puberty, but it is not always developed to such a degree as to make the difference between the individual and his fellows noticeable to the individual.*

W Somerset Maugham (1874–1965), *Of Human Bondage*

Adolescence is the transitional period of development between relatively dependent childhood and relatively independent adulthood. The time of onset and duration varies from one person to another but it is generally considered to occur between the ages of 10 and 19 years.<sup>1</sup> It is a critical period of transition in the human lifespan, marked by rapid growth and physical and mental changes second only to infancy.

While biological changes drive this transition, the duration and characteristics of adolescence can vary depending on cultural and socioeconomic settings. Adolescence has also altered over the past century, occurring earlier and being influenced by societal changes such as later marriage, increased urbanisation, global communication, information technology, social networking and changing sexual attitudes and behaviours.<sup>1,2</sup>

Adolescent patients require special understanding and caring from their family doctor. They can present very challenging and sometimes confronting issues. A profound increase in mental health issues (particularly mood disorders)<sup>3</sup> in adolescents has exacerbated the frequency of challenging adolescent consultations in general practice. Another common difficulty is establishing rapport and trust with adolescents, who may be trying to break away from the adult world to establish their own sense of adult self, so it can be vitally important to address confidentiality issues. Actively raising and clarifying confidentiality parameters and doing so at the beginning of the consultation can greatly assist the interaction with an adolescent patient.

In recent times, reference is made to the young person in the context of health policies. Young people are defined as those between the ages of 12 and 24 years and youths as those between 15 and 24 years.<sup>2</sup> Some 18% of the population are young people, and they tend to have a low rate of GP visits; if they do visit, it is usually for physical reasons, despite the fact that the largest health burden for adolescents is actually mental health issues.

## Adolescent development periods<sup>4</sup>

### Early adolescence (10–14 years): 'Am I normal?'

This stage is dominated by adjustment to physical and psychosexual changes and by the beginnings of psychological independence from parents. Girls generally advance through this stage more rapidly than boys.

### Middle adolescence (14–17 years): 'Who am I?'

Middle adolescence is a time when boys have caught up physically and psychologically with girls, so that peer group sexual attractions and relationships are common preoccupations at this stage. It is a phase of peer group alliances, clothes, music, jargon and food and drink. The average age for first sexual intercourse for both sexes is 16 years. It is a stage where intellectual knowledge and cognitive processes become quite sophisticated. Experimentation and risk-taking behaviour is a feature, and confidentiality issues are often important.

### Late adolescence (17–19 years): 'Where am I going?'

This is the stage of reaching maturity and leads to more self-confidence with relationships and successful rapport with parents. Thought is more abstract and reality-based. Relationships may become more intimate, moral value systems are more established, and vocational and educational goals become more central.

## Major areas of health problems

- Psychological health problems with high rates of first onset in adolescence include depression, self-harm, anxiety disorders, behavioural disorders (e.g. ADHD, conduct disorders) and

eating disorders. More than 80% of mental illness starts under the age of 25

- Other areas of concern: substance abuse, schizophrenia and drug-related psychosis
- Eating disorders, including obesity, fast food, bulimia nervosa and anorexia nervosa (refer to CHAPTERS 78 and 79)
- Injuries, including sporting injuries, motor vehicle accidents and interpersonal violence
- Risk-taking behaviour, including drug abuse
- Sexual adjustment, including unsafe sexual practices and teenage pregnancy
- Chronic illness and disability, including survivors of inherited disorders
- Asthma, which is a leading cause of hospital admissions for both sexes in the 10–14 years age group
- Overexposure to sunlight
- Acne, which can be very distressing for adolescents. Severe acne can increase the risk of suicide<sup>5</sup>

## Myths about the adolescent patient

The following are myths that some practitioners feel apply to the adolescent:

- different from adults in needs
- 'superficial' thinkers
- represent a 'quick' consultation
- shun personal questions
- resent invasion of space

It is important to treat adolescents as normal human beings.

## Age and informed consent

As a rule, parents and physicians should not exclude children and adolescents from decision making without persuasive reasons. Across Australia, common law states that 18 years of age is the age of consent. It also states that consent *may* be given under 18 years, but that the nature of the medical intervention and the ability of the young person to fully understand need to be taken into consideration. A concept that can be applied to this is the Gillick test, which prescribes that the parental right to determine their child's treatment terminates once an adolescent under the age of 16 is capable of fully understanding the medical treatment proposed. Two questions that GPs may be confronted with are:

- When can a young person under 18 years of age consent to medical treatment?

- When can parents or guardians consent to medical treatment for young people under 18 years of age?

When considering these questions, a competency assessment of the adolescent should be undertaken that includes considering:

- age
- level of independence
- level of schooling
- maturity
- ability to express own wishes

In NSW and South Australia, additional laws allow for those aged 14 years (NSW) and 16 years (SA) and over to consent to their own treatment. GPs in these states should familiarise themselves with these laws in situations where consent is problematic.

## What do adolescents value and what are they concerned about?

A large ongoing survey by Mission Australia<sup>6</sup> on 15–19-year-olds shows that these adolescents most value:

- friendships
- family relationships
- school and study satisfaction
- physical and mental health

The top issues of personal concern include:

- coping with stress (increasing from 19% to 38% from 2009 to 2013)
- school or study problems (37%)
- body image (31%)

Some 20% were also extremely or very concerned about family conflict.

The internet is the number one source of information for young people, 20% of whom spend >20 hours a week on social network sites.

## Access to general practice

There can be many barriers to adolescents accessing general practice. This is especially so for those marginalised by factors such as homelessness or risk of homelessness, involvement in the juvenile justice system, disability, same-sex attraction, or being from an Indigenous, non-English-speaking or refugee background. Barriers include:<sup>7</sup>

- knowledge of services
- concerns about confidentiality
- availability of services, particularly in regional, rural and remote areas

- cost
- poor previous experiences
- location of services
- complicated systems and referral processes

Because of these significant barriers, improving adolescents' access to health services in general, and specifically to general practice, is essential. While youth-specific services such as the national headspace initiative <[www.headspace.org.au](http://www.headspace.org.au)> have gained momentum in recent years, general practice remains the cornerstone of primary health care for young people.<sup>6</sup> The characteristics of a youth-friendly practice have been defined<sup>7</sup> as having:

- accessibility to young people (e.g. visual appearance, online services, registering for Medicare)
- youth participation in the practice (e.g. involving adolescents in policy development, employing adolescent/young person staff)
- collaboration and partnerships (e.g. with housing or mental health services)
- professional development in youth service provision
- evaluation by the practice of services provided to young people
- evidence-based approaches to the health of adolescents
- sustainability of these approaches

A video for GPs and young people about being and implementing a youth-friendly practice is available through NSW Kids and Families <[www.kidsfamilies.health.nsw.gov.au/current-work/youth-health-and-wellbeing/](http://www.kidsfamilies.health.nsw.gov.au/current-work/youth-health-and-wellbeing/)>. It includes issues such as adolescents accessing Medicare and the all-important issue of confidentiality.

## The clinical approach

### Confidentiality

Confidentiality is a major issue when seeing adolescent patients, especially those who are new to the practice or who have had negative experiences with authority previously (e.g. involvement in community services or the juvenile justice system) or in cases where other members of a family (particularly the parents) are also your patients. The whole concept of adolescents struggling to establish an identity separate from their carers is tied up in the burgeoning relationship with the GP, and the rules of medical confidentiality, well known to most adults, are often a mystery to young people.

Some tips on reassuring adolescents on confidentiality issues<sup>7,8</sup> include:

- having a practice confidentiality policy visible for all patients to see (e.g. online, in waiting room, in practice information leaflets/orientation pack)
- talking about or defining what medical confidentiality means (and the boundaries or exceptions to this—see TABLE 97.1) up front, i.e. before the first consult starts, especially if you suspect the patient may be worried about such issues
- reinforcing these principles when sensitive issues arise through the evolving GP–patient relationship (e.g. contraceptive or other sexual health issues, mental health issues)

**Table 97.1** Three main exceptions to confidentiality<sup>4</sup>

- 1 If the young person discloses suicidal intent or is threatening significant self-harming behaviour
- 2 If someone else is threatening or harming them (e.g. physical, sexual or emotional abuse)
- 3 If the young person is at risk of physically harming someone else (e.g. assault, abuse)

*Note:* Other exceptions exist (e.g. notification of infectious diseases) but these can be explained if and when necessary. The above are recommended exceptions to explain up front.

### Cost

One of the major barriers to adolescents accessing primary care is cost. They are often unaware of how Medicare operates and how to access a card. Adolescents can acquire their own Medicare card from the age of 15. Having application forms available in the surgery (you need photo identification) can help. Young people should be made aware that they do not need to have the card on them to see the doctor. Medicare doesn't reveal to anyone (including parents) who has used the card, provided they are over the age of 14.

### Who is in the room and who talks?

An adolescent may present alone or accompanied by others, including, often, a parent. The parent may take a dominating role, doing the talking for the adolescent. Teasing out the two roles (that of the adolescent and that of the parent) as two separate entities can be

a challenge, and needs to be done sensitively. The objective of the GP should be to establish rapport and a patient–doctor relationship with the adolescent him or herself, while not threatening the role of the parent.

Most parents will be aware of and sensitive to this, and may even encourage the adolescent to talk for themselves or offer to leave the consulting room. An offer like this should be taken up, with a view to bringing the parent back into the room after a private conversation with the adolescent. It should be made clear exactly what the adolescent will and will not allow to be revealed to the parent (once he or she returns) during the private conversation.

Asking a parent to leave (if no offer is made) may surprise an anxious or overbearing parent, and should be negotiated carefully. Normalising this early in the consultation, as your usual approach, can help.<sup>4</sup> ‘Normally when seeing a young patient like your son/daughter, I like to see them by themselves at some stage in the consultation and then get the parent back in afterwards. Is that okay by you?’

If a parent does not want to leave the room, or continues to talk for or over the top of the adolescent, a more forthright approach may be warranted, though this is unusual. It will be difficult to foster a patient–doctor relationship with the adolescent in such circumstances.

### Communication and rapport with adolescents

The single most crucial role of a GP caring for an adolescent, regardless of their presenting complaint, is to foster and develop a relationship of trust.<sup>9</sup>

Tips for fostering engagement with adolescents<sup>3</sup> include:

- Treat the young person as responsible and capable of contributing to decision making.
- Take a curious, non-intrusive and respectful stance.
- Be open and honest as much as possible.
- Clarify what the young person wants from you.
- Establish agreed goals or explain clearly why you cannot help.
- Be honestly interested in what the young person has to say.
- Be yourself, don’t fake it.
- Use metaphor and humour (where appropriate) to build rapport.
- Use language that is clear and easily understood and avoid jargon; overuse of slang is probably worse than not using it at all.

- Warn the young person if you are going to ask questions about topics that may be difficult (e.g. sexual matters).
- Avoid getting into a controlling, authoritarian position.
- Remember that engagement may wax and wane.

### HEEADSSS<sup>4</sup>

HEEADSSS is a guide (not a script or tick list) that can be useful for a GP when conducting a psychosocial assessment of an adolescent. It is a framework designed to progress from the (usually) less sensitive to more sensitive areas of potential concern in an adolescent. It does not have to be covered all in one consultation, and the areas that are covered may be tailored to the individual patient and his or her circumstances. A shortcut on clinical software may prompt the GP to use HEEADSSS. It has recently been expanded to reflect the major causes of adolescent morbidity and mortality.

**H** = Home

**E** = Education and Employment

**E** = Eating and Exercise

**A** = Activities and peer relationships

**D** = Drug use, cigarettes and alcohol

**S** = Sexuality

**S** = Suicide and depression (including mood and possible psychiatric symptoms)

**S** = safety

### Physical examination

Adolescents are often very sensitive about their bodies and physical appearance, especially when going through puberty. When physically examining adolescents:

- carefully explain what you are going to do before you do it
- obtain consent for examining adolescents
- consider offering a chaperone for examining breasts or genitals, especially a male doctor and female adolescent patient
- Gender and cultural differences and norms should be considered prior to physical examination

*Note:* A Pap test is not required until age 18 years or 2 years after the first sexual encounter, whichever is later.

### Risk behaviours

Risk behaviours are common in adolescents and should be actively but sensitively screened for.

The HEEADSSS model can be employed to do this screening. If there are risk behaviours:

- Assess how high the risk is (e.g. multiple risk behaviours? is it escalating? aware of the risk and potential consequences?).
- What are possible protective factors (e.g. support from family, school, positive peer relationships or culture)?
- Focus on strengths and abilities the adolescent may have.
- Build motivation and reinforce capacity to change.
- Actively promote behaviour change by using guided decision making.
- Provide appropriate information and education on the risk behaviour and potential consequences.
- If high-risk behaviours are identified, referral to appropriate services (e.g. drug and alcohol, psychologists) while the GP maintains a case management role.

### Developing a management plan<sup>4</sup>

Informing an adolescent of your assessment and actively involving him or her in the development of your management plan will help improve trust and compliance. It is also useful to:

- identify risk behaviours—provide relevant information and education
- set realistic treatment goals appropriate to your adolescent patient
- where appropriate, discuss how much he or she wants parents to be informed and involved
- guide parents in how to best support their adolescent child and best respond to risk-taking behaviours

### MENTAL HEALTH IN ADOLESCENTS<sup>4</sup>

- Up to 25% of adolescents suffer from a mental health and/or substance abuse problem.
- Mental health in adolescents is worsening.
- Many chronic mental health issues have their onset in adolescence.
- Anxiety and depression are the leading mental health problems in adolescents (17% of the male disease burden and 32% of the female).
- Behavioural disorders are also common (8% of 12–17-year-olds have ADHD, and 3% have conduct disorders) as are eating disorders.
- There is a marked increase in risk factors and risk-taking behaviours for mental health in adolescence (e.g. substance abuse, peer conflicts).

- Mental health issues in adolescents can present differently from in adults, with mood swings, poor school performance or attendance, irritability, anger, substance abuse, somatic complaints, risk-taking behaviours or conflict with peers or family being more common.
- Adolescents are generally ill informed about mental health (<25% seek help).

### Depression in adolescents<sup>3,4</sup>

(See CHAPTER 19 for a discussion on depression.)

- Up to 24% of adolescents will have suffered an episode of major depression by the age of 18.
- Depression can be more masked by the patient and harder to detect in adolescents, so requires more active screening.
- Psychosocial development may be compromised by depression in adolescence.
- Effective engagement and developing a trusting therapeutic alliance is critical in managing depressed adolescents.
- Using the HEEADSSS tool can help in assessment.
- Comorbidity with other mental health issues (anxiety disorders, behavioural disorders, eating disorders, substance abuse) is common.
- Encourage protective factors such as positive peer relationships, support from schools or families, regular sleep patterns and pleasurable activity scheduling.
- Counselling and psychological treatments are first line in the treatment of adolescents with depression.
- Using mental health Medicare item numbers may help improve access to services.

### Use of antidepressants in adolescents

In major depression in adolescents, treatment with fluoxetine can be considered. There appears to be an age-related mechanism linking SSRI treatment with an increased risk of suicidal thinking, with adolescents being at greatest increased risk. Because of this, if pharmacological therapy is warranted, it should be prescribed by a practitioner who is very familiar with the range of adverse effects and able to monitor the young person appropriately. Close monitoring for suicidality is especially important in the first 4 weeks. If there are concerns regarding severe symptoms or risk of suicide, referral to a psychiatrist who treats adolescents is recommended.

## Suicidality in adolescents<sup>4</sup>

- Hospital rates for suicide attempts are 3 times higher in females, but suicide deaths are 3 times higher in males (males use more lethal means).
- More than half of all adolescents who try to kill themselves will have visited a GP within the previous month (i.e. GPs can play a very important preventive role, see [TABLE 97.2](#)).

### Risk factors

- Previous suicide attempt/self-harm
- History of previous attempts in family/friends
- Concrete suicide plan
- Underlying mental disorders—e.g. depression, anxiety, substance abuse
- Comorbid conditions—e.g. eating disorder, conduct disorder
- Recent stressful life events (e.g. relationship breakdown, humiliation, school problem, conflict with peers)
- Ongoing family problems
- Victim of bullying
- Lesbian, gay, bisexual, transexual (LGBT) orientation
- Cultural conflicts or concerns

### Management

- Fully explore the adolescent's thoughts, plans and actions. Assess his or her level of risk.
- Do not agree to secrecy.
- Confidentiality is over-riden if there is serious or imminent danger of suicide. Gently explain this to the adolescent while trying to maintain and protect a therapeutic alliance.
- Contact and mobilise family and social supports.
- Get help from peers or other health providers where possible. Mental health services such as crisis teams may need to be involved.

**Table 97.2** Warning signs of potential suicide in adolescents<sup>10</sup>

Change in behaviour (e.g. risk taking, isolation, giving away possessions, losing interest in activities)

Change in mood (e.g. hopelessness)

Change in thinking (e.g. guilt, bizarre thoughts)

Preoccupation with death

Talk of suicide

Perceived intolerable loss or stress

Apparent resolution (e.g. sudden calmness/happiness after other warning signs)

- If possible, remove or limit access to means of self-harm (e.g. medications).
- Consider (in conjunction with other therapeutic approaches) a 'no-suicide contract'. Usually verbal, this is an agreement for the adolescent to commit to you that he or she will not act on any suicidal thoughts until you next see them. This should be done for only a short (<1 week) period.

## Anxiety disorders in adolescents

In a similar fashion to depression, anxiety disorders in adolescents are common, hard to detect and heavily reliant on the GP having a trusting relationship with the adolescent; they also have psychological therapies as the first-line treatment. See [CHAPTER 81](#) for further discussion on anxiety disorders.

## Eating disorders

Anorexia nervosa and bulimia nervosa arise usually in the early to mid-teens (see [CHAPTER 79](#)). There are many sub-syndromal variations that threaten to develop into a serious state but these can settle, especially with early identification and counselling.

### Practice tips in handling adolescents

- Confidentiality is of great importance to adolescents.
- Barriers to adolescents accessing general practice should be removed wherever possible.
- Seeing adolescents by themselves at some stage in the consultation is desirable.
- Developing a relationship of trust is critical when dealing with adolescents in general practice.
- HEEADSSS is a useful tool for conducting a psychosocial assessment.
- Mental health problems in adolescents are common, often hard to detect, and are heavily reliant on the GP having a trusting relationship with the adolescent.

# Part 6

## Women's health

---

*'What we've done is found a way of preventing one particular cancer. It's not absolute, in the sense that you'd have to get there not only before the cancer, but before the infection that causes the cancer.'*

Professor Ian Frazer, *Enough Rope*, 2006

## § Cervical cancer

Cervical cancer is the fourth most common cause of cancer death in women worldwide, especially in developing countries.<sup>1</sup> It is the most common cancer in women in Eastern and Middle Africa, and the 12th most common in Australian women.<sup>1,2</sup> Australia has the second lowest incidence of cervical cancer in the world as a result of the success of the National Cervical Screening Program introduced in 1991, which has halved its incidence.<sup>2</sup>

The most common cervical cancer is squamous cell carcinoma (SCC), accounting for 80% of cases. Adenocarcinoma is less common and more difficult to diagnose because it starts higher in the cervix. Cervical cancer almost exclusively occurs in women who have been sexually active, due to exposure to human papillomavirus (HPV). Other risk factors include smoking, multiparity, immunosuppression and exposure to diethylstilboestrol in utero.<sup>3</sup>

## Cervical cancer and human papillomavirus<sup>4</sup>

It is now well established that the primary cause of cervical cancer is human papillomavirus. There are approximately 200 different types of HPV, 40–50 of which specifically infect the anogenital area. These types are spread through genital skin-to-skin contact. Of the genital HPV types, 15 are classified as 'high risk', as they are associated with anogenital cancer (including squamous and adenocarcinoma of the cervix). HPV 16 and 18 are responsible for around 70% of invasive cervical cancers and 50% of high-grade lesions. Infection with HPV is common and mostly transient, with 80% of women being infected with at least one genital type of HPV in their lifetime. Cervical cancer is a rare outcome of HPV infection. Most cervical HPV infections are cleared or suppressed by cell-mediated immunity within 1–2 years of exposure. Persistent infection of the cervix with a high-risk

HPV is known to cause high-grade cervical changes that, if left untreated, can progress to cervical cancer. More than 99.7% of cervical cancers test positive for HPV DNA.<sup>5</sup>

## Basic pathology

The focus of attention is the transformation zone (see FIG. 98.1), where columnar cells lining the endocervical canal undergo metaplasia to squamous cells in the region of the squamocolumnar junction. It is important clinically to realise that this transformation zone can extend with progressive metaplasia of columnar epithelium and so the squamocolumnar junction may recede into the endocervical canal. This is a feature in postmenopausal women (see FIG. 98.2). As squamous cell carcinoma almost always arises in the transformation zone, it is vital that cells are taken from it when performing a Pap test.

FIGURE 98.1 The transformation zone: it is vital that cells are taken from this zone with Pap tests

**FIGURE 98.2** Changing position of the transformation zone with age, and a selection of sampling instruments according to its position

## HPV and the natural history of cervical neoplasia<sup>6</sup>

Low-grade squamous intraepithelial lesions (LSILs) represent an acute HPV infection of the transformation zone. LSILs are seen with both low- and high-risk HPV types. Most women will clear the virus over about 10 months with no lasting effect. Persistent infection with an oncogenic HPV type causes precancerous changes (high-grade squamous–intraepithelial lesion or HSIL).

HSILs may return to normal, persist or eventually progress to invasive cervical cancer. The average duration between HSILs and cancer is between 10 and 15 years. However, women with histologically confirmed moderate to severe dysplasia require a colposcopic assessment. **FIGURE 98.3** and **TABLE 98.1** illustrate the disease spectrum of cervical neoplasia.

## Clinical presentation

Many patients with cervical cancer are asymptomatic and when early symptoms do arise they are often dismissed as of little consequence.

Symptoms, if present, may be:

- vaginal bleeding, especially postcoital bleeding
- vaginal discharge
- symptoms of advanced disease (e.g. vaginal urine or flatus, weakness)

## Screening recommendations

### Routine Pap tests

Current cervical screening uses cytology from the Papanicolaou smear, or Pap test, as the screening tool.<sup>5</sup> A Pap test involves sampling cells from the cervix, which can then be assessed for premalignant cytological changes associated with HPV. Pap tests have been the cornerstone of the cervical screening program for many years. The role of the Pap test is likely to change as new guidelines emerge regarding HPV screening.

### Who should be screened and how often?<sup>2,3</sup>

- Women who have had sex, regardless of their sexual orientation.

FIGURE 98.3 Illustration of the various grades of squamous intraepithelial lesions and CIN (comparison of nomenclature)

**Table 98.1** Squamous cell abnormalities and the different nomenclatures<sup>5</sup>

	Description	CIN grade	Australian modified Bethesda system
1	Normal	Normal	Within normal limits
2	Atypia: reactive or neoplastic	Atypia	ASCUS
3	HPV	HPV	LSIL
4	Mild dysplasia	CIN 1	LSIL
5	Moderate dysplasia	CIN 2	HSIL
6	Severe dysplasia	CIN 3	HSIL
7	Carcinoma in situ	CIS	HSIL
8	Invasive carcinoma	Invasive carcinoma	Invasive carcinoma

**ASCUS** = Atypical squamous cells of undetermined significance

**CIN** = Cervical intraepithelial neoplasia

**CIS** = Carcinoma in situ

**HSIL** = High-grade squamous intraepithelial lesion

**LSIL** = Low-grade squamous intraepithelial lesion

- Commence cervical screening at 18–20 years or 2 years after first sexual intercourse, whichever is later.
- Perform every 2 years and cease at 70 years in those who have had two normal Pap tests within the last 5 years.
- Screen women over 70 years if they request it or if they have never had a Pap test.
- Screening applies only to asymptomatic women. Women with postcoital or persistent intermenstrual bleeding require a diagnostic Pap test and referral for colposcopy irrespective of the result.

Screening in particular groups<sup>5</sup>

**Hysterectomy.** Cervical screening is still required if the cervix was not completely removed. However, vaginal vault Pap tests are indicated if there is a history of gynaecological dysplasia or malignancy, or exposure to diethylstilboestrol in utero, as well as in immunosuppressed women.

**Pregnancy.** If due, cervical screening is still recommended and can be safely performed until 24 weeks gestation. Pap tests have not been associated with an increased rate of miscarriage in the first and second trimesters.

**Postmenopausal women.** If not taking hormone replacement therapy, postmenopausal women may

benefit from a short course of topical vaginal oestrogen before their Pap test. This may improve the quality of the test and comfort of the examination. Treatment should be stopped two days before the test to ensure tablets do not interfere with test interpretation.

### Underscreened populations<sup>5</sup>

Special attention should be focused on screening the following women:

- Aboriginal and Torres Strait Islander women (mortality of cervical cancer five times that of other women in Australia)
- Women from non-English-speaking backgrounds
- Women in rural and remote areas
- Lesbian and bisexual women
- Women with disabilities

### Taking a Pap test

The optimal Pap test contains:

- sufficient mature and metaplastic squamous cells to indicate adequate sampling from the whole of the transformation zone
- sufficient endocervical cells to indicate that the upper limit of the transformation zone was sampled; and to provide a sample for screening of adenocarcinoma and its precursors

### Optimal timing of specimens

- Avoid performing a Pap test during menstruation.
- Avoid in the presence of obvious vaginal infection.
- Avoid within 48 hours of use of vaginal creams or pessaries or douching.

### Communicating with the pathologist

Good communication with the pathologist is essential. It is important to provide basic details about the reason for the Pap test and the clinical history on the pathology form sent to the laboratory. Include patient age, LMP, hormone intake, previous treatment and clinical findings.

### The method

#### 1 *Explanation and history*

Take time to explain the reason for taking the Pap test, especially if it is the first. Emphasise that it is a preventive measure to detect early cell changes that could develop into cancer. Anatomical models, sample instructions or charts are useful in describing the procedure. Explain that it usually does not hurt or take long, that it may be

uncomfortable, but slow, deep breathing will help relaxation and make it easier.

Take a brief history, enquire about previous cervical screening results (if any), as well as direct questions about any intermenstrual or postcoital bleeding. Verbal consent should be obtained.<sup>5</sup>

Encourage the woman to empty her bladder if she desires and ensure privacy before asking her to undress below the waist. A gown or cover sheet should be provided.

It is advisable for a male doctor to have a chaperone present.

#### 2 *Equipment<sup>7</sup>*

Prepare the following equipment:

- adequate light source
- appropriate-sized speculum (preferably bivalve)
- glass slide labelled in pencil with the woman's name and date of birth
- spray fixative
- plastic gloves for both hands
- smear-taking instruments; choose from:
  - Ayer's spatula, wooden or plastic
  - Cervex sampler broom
  - Cervex-Brush Combi
  - endocervical brush

Refer to **FIGURE 98.2** for recommended choice.

Special notes:

- pregnancy—avoid use of the endocervical brush and the Cervex-Brush Combi
- eversion—take care to sample the squamocolumnar junction

#### 3 *Positioning*

The supine position is usually best (see **FIG. 98.4**). The left lateral position can be used if smears are difficult to obtain (e.g. older women with lax anterior vaginal walls, older women with poor hip mobility). The Sims exaggerated left lateral position (see **FIG. 98.5**) provides better exposure of the vulva but requires more manipulation of the patient. Better visualisation of the cervix is obtained if the patient elevates her buttocks with her fists, a small pillow or towel.

#### 4 *Inserting the speculum*

A metal speculum should be warmed with lukewarm water. A small amount of water-based lubricant is appropriate for a plastic speculum. Gently spread the labia with a gloved hand and introduce the speculum with the blades vertical or at 45° from the vertical. Gently advance the blades with slow firm pressure towards the rectum as far as possible. Rotate the blades during the process until they are horizontal and

**FIGURE 98.4** The supine or dorsal position is the best position for the speculum examination and subsequent bimanual palpation (patient should be appropriately clothed and/or draped)

**FIGURE 98.5** The Sims exaggerated left lateral position

exerting gentle pressure against the posterior wall of the vagina. Remember that the cervix is situated in the upper sixth of the anterior vaginal wall (not in the apex of the vagina).

5 *Visualising the cervix*

Good lighting and exposure of the cervix is essential. Note any significant features or abnormalities of the cervix. A cervical ectropion is normal in most premenopausal women and was formerly incorrectly called an erosion.

6 *Taking the smear*

Choose the sampling instrument that best suits the shape of the cervix and os. Place Ayer's spatula firmly on the os and rotate it through 360°, ensuring that the whole transformation zone is sampled (see FIG. 98.6a).

If the squamocolumnar junction is not visible (lying within the endocervical canal), use both spatula (first) and the endocervical brush (see FIG. 98.6c). The endocervical brush (tends to cause bleeding) should be advanced until only the lower bristles are still visible, then rotated for a quarter of a rotation. The endocervical brush should be avoided in pregnant women.

After removing the speculum, perform a bimanual pelvic examination if appropriate. A bimanual examination may assist in locating the cervix if it could not be visualised at the initial speculum examination.<sup>5</sup>

7 *Preparing the slide*

Transfer the cervical cell sample on to a glass slide with an even spreading motion (see FIG. 98.6b, d). Fix immediately (within 5 seconds from a distance of 20 cm to prevent air drying, which distorts cellular features) with an aerosol or pump-action alcohol spray (see FIG. 98.6e).

8 *The HPV and chlamydia sample*

If appropriate after the smear, place the brush and spatula in the tube with the transport medium (do not use a wooden spatula for a liquid-based sample). Swirl it around vigorously to release material. The specimen tube can be forwarded with the slide to the laboratory with a request to test for HPV and chlamydia.

*Note:* Yearly chlamydia screening is recommended for all sexually active people under 30 years.

*Follow-up*

Discuss mutually suitable arrangements to ensure that the woman obtains the result of the test, whether it is positive or negative. Inform her when her next test is likely to be due (special cards are available) and have a system in place to send a reminder note.

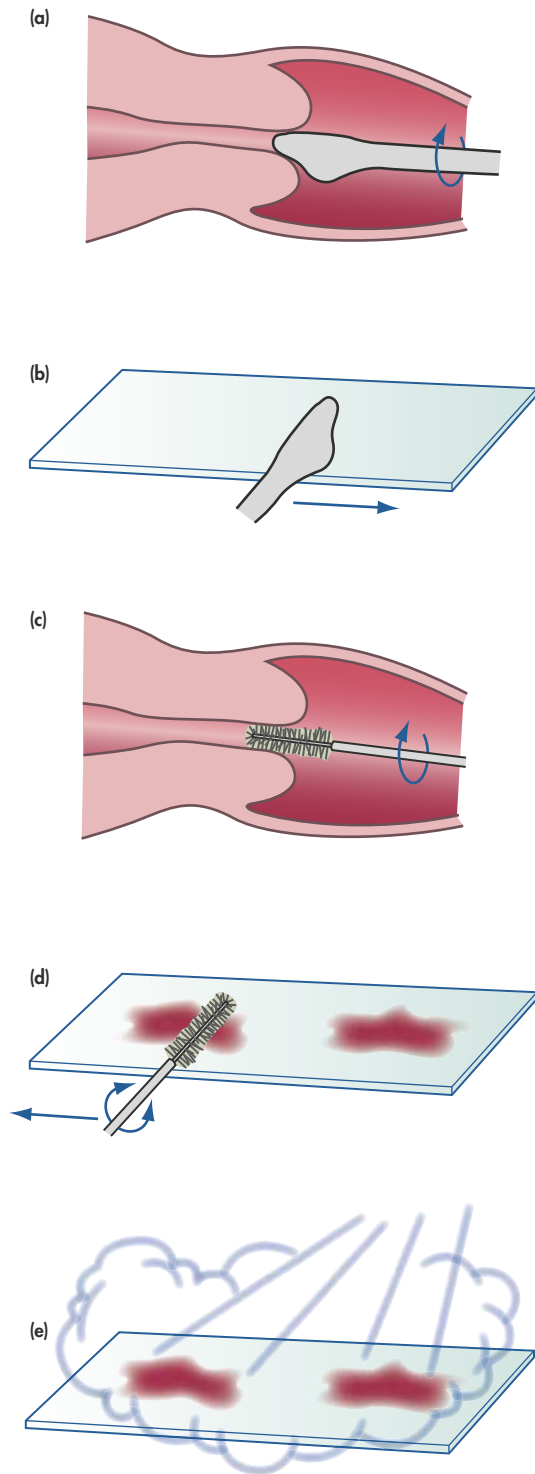

FIGURE 98.6 Method of smear taking and preparing the slide

The explanation of the results and follow-up required, especially if there is an abnormality present, should be crystal clear to the patient. Common medicolegal claims made against GPs include poor communication regarding abnormal Pap tests and failure to arrange adequate specialist referral for women with abnormal cytological results or a clinically suspicious cervical lesion.

### Role of liquid-based cytology<sup>6</sup>

Currently in Australia, liquid-based cytology can be used as an additional test to the conventional smear but not as a substitute. A statement released in 2011 by the Medical Services Advisory Committee concluded that both manual and automated liquid-based cytology are safe and at least as effective as conventional Pap tests. Liquid-based cytology may be useful if there is blood or inflammatory cells on the conventional slide, possibly obscuring the view. However, at present, these new technologies are not considered sufficiently cost-effective to be supported by public funding.

### Abnormal Pap tests

Follow the guidelines in TABLE 98.2 and FIGURE 98.7 for the abnormal test result.

### Post-treatment assessment of HSIL<sup>4</sup>

A woman treated for HSIL should have a colposcopy and cervical cytology at 4–6 months after treatment. Cervical cytology and HPV DNA testing should be done at 12 months and then annually until the woman has tested negative on both tests on two consecutive occasions. Return to usual 2-yearly screening when all four tests are negative.

### HPV vaccination<sup>6,8</sup>

In 2007, Australia led the world with its national publicly funded HPV vaccination program, using a three-dose schedule of the quadrivalent HPV vaccine that protects against HPV types 16 and 18 (high risk for cervical cancer) and types 6 and 11 (which cause genital warts). Vaccination ideally occurs before first sexual activity. Currently, the HPV vaccine (Gardasil®) is administered through the National Immunisation Program to males and females aged 12–13 years. Women who have been immunised still require cervical screening because the vaccine does not prevent all HPV types that cause cervical cancer. Over time, it is anticipated the vaccination program will result in a decline of cervical abnormalities detected

Table 98.2 Guidelines for abnormal Pap tests<sup>5</sup>

Pap test report	Investigation and management
Negative smear—no endocervical cells	Repeat in 2 years.
Negative smear—inflammatory cells	Repeat test in 2 years.
Unsatisfactory smear	Repeat smear in 6–12 weeks (allows regeneration of cells).
Low-grade epithelial lesion	
Possible LSIL and definite LSIL	Repeat Pap test at 12 months. If the woman is 30+ years, and has no negative cytology in previous 2–3 years, refer for colposcopy or repeat the test in 6 months.
High-grade epithelial lesion	
Possible HSIL and definite HSIL	Refer for colposcopy.
Glandular abnormalities including adenocarcinoma in situ	Refer to a gynaecologist.
Invasive squamous cell carcinoma or adenocarcinoma	Refer to appropriate specialist gynaecologist or unit.
Inconclusive—raising possibility of high-grade disease	Refer for colposcopy and possible biopsy.

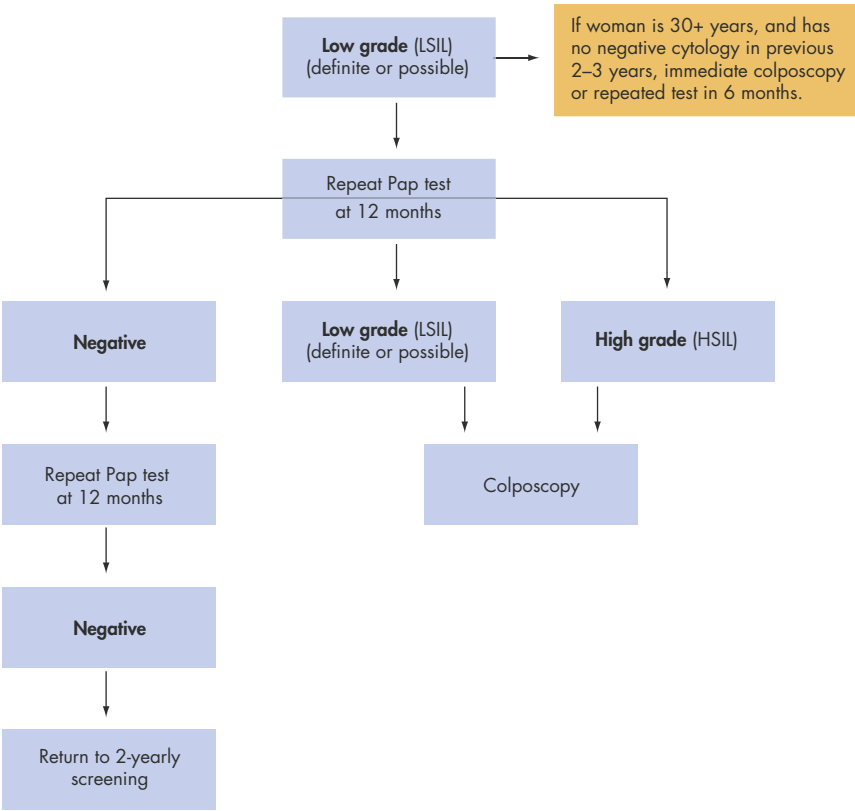

FIGURE 98.7 Algorithm for management of low-grade squamous cell abnormalities (based on NHMRC guidelines)

on Pap tests. As there is an eventual decline of the positive predictive value of the Pap test, it is likely to be replaced by HPV DNA testing as the primary screening tool.

### Cervical screening program renewal

Pending policy approval, in 2017 it is anticipated that the cervical cancer screening test will transition from the 2-yearly Pap test to 5-yearly HPV DNA testing.<sup>9</sup> HPV DNA tests have a higher sensitivity than cervical cytology for detection of HSILs and cervical cancer. However, prior to HPV vaccination, the role of HPV DNA testing was limited as a screening tool because as many as 25% of women aged <30 were likely to test positive for oncogenic viruses. It is known that women with a negative HPV test have a low risk of developing cervical cancer in the 5 years following testing. This would allow for an extension of the screening interval from 2 years to 5 years.<sup>6</sup>

The most significant change is from conventional cervical cytology (Pap test) every 2 years to a primary HPV test with partial genotyping every 5 years, using liquid-based cytology for triage, in a new target age range of 25–69 years, with exit from the program between 70 and 74 years.<sup>9</sup> Self-collection may also be an option, and has the potential to play a significant role in underscreened populations.

*The Membranous Envelope (condom) is prepared from the bladder of a fish caught in the Rhine. Its extreme thinness does not in the least interfere with the pleasure of the act . . . [its use] is of the greatest utility because, while it is a sure preventive of conception, it also prevents either party from contracting disease.*

Edward Bliss Foote, *Medical Common Sense*, 1864

The classic family planning consultation is the presentation of a young woman for contraceptive advice. It is a very critical visit and provides an excellent opportunity to develop a good rapport with the patient and provide education and counselling about important health concerns, such as health promotion, menses regulation, sexual activity, planned parenthood, fertility and infertility, pregnancy prevention, STI prevention, immunisation and cervical screening.

In counselling and treating patients, especially teenagers, confidentiality is of paramount importance. Keep in mind the Gillick test of competency for females aged under 16 (see CHAPTER 97). The issues and contraceptive methods can be confusing so careful education using charts and other aids is recommended to enhance the therapeutic relationship and facilitate better compliance. It is worth discussing the patient's attitude to pregnancy, including the fear of pregnancy and the possible reaction to contraceptive failure.

## Fertility control

The choice of contraceptive methodology will be determined not only by individual needs, personal preference and resources but also by its effectiveness, safety and incidence of side effects.

In developed countries of the Western world, the most widely used methods in order of preference are the male condom, combined oral contraceptive pill, intra-uterine device (IUD), female sterilisation and withdrawal.<sup>1</sup>

The past decade has seen a wider availability of long-acting reversible contraception (LARC). LARC methods are defined as non-permanent contraception administered less frequently than once a month. They include implants, IUDs and injectables. LARC methods are the most effective reversible contraceptives, with failure rates for typical use virtually the same as for perfect use. For this reason, LARC plays an important public health role

in reducing unintended pregnancies.<sup>2</sup> Approximately half the pregnancies in the US are unintended and occur because of non-use of contraception, failure of a specific method or discontinuation of contraception.<sup>3</sup> While many women are satisfied with oral contraceptives or barrier methods, it is important to check their awareness of LARC proactively.<sup>4</sup>

A comparison of the failure rates of the various contraceptive methods is presented in TABLE 99.1.

It should be noted that condoms are the only contraception that protect against STIs. For women at risk of acquiring STIs, dual protection should be recommended. This involves use of condoms in addition to an effective form of contraception, offering both STI and pregnancy protection.<sup>5</sup>

## Practice tip

Long-acting reversible contraception (LARC) methods include implants, IUDs and injectables. LARC methods are the most effective reversible contraceptives and have the potential to reduce unintended pregnancy rates.

## Safe prescribing<sup>4</sup>

Most women of reproductive age can safely use all contraceptive methods. However, there are some conditions, risk factors and concurrent medications that make a particular method unsuitable. Medical Eligibility Criteria (MEC) tables for contraceptive use are an internationally recognised system to guide clinicians in the safe provision of contraceptive methods. Conditions affecting eligibility are classified under one of four categories: MEC 1—no restrictions; MEC 2—the benefits generally outweigh the risks; MEC 3—the risks generally outweigh the benefits; MEC 4—an absolute contraindication. A full listing of the UK MEC is available at <[www.fsrh.org/pdfs/UKMEC2009.pdf](http://www.fsrh.org/pdfs/UKMEC2009.pdf)>; see also the WHO MEC

**Table 99.1** Effectiveness of contraceptive methods

Contraceptive method	Failure rate (%) during first year of use	
	Typical use	Perfect use (consistent and correct)
No method	85	85
Fertility awareness-based methods	24	0.4–5
Withdrawal	22	4
Barrier		
• Female:		
— diaphragm with spermicide	12	6
— condom	21	5
• Male:		
— condom	18	2
Intrauterine contraceptive device		
• copper	0.8	0.6
• levonorgestrel	0.2	0.2
Vaginal ring	9	0.3
Combined oral contraceptive pill	9	0.3
Injection (medroxyprogesterone acetate)	6	0.2
Implant (etonogestrel)	0.05	0.05
Sterilisation		
• female	0.5	0.5
• male	0.15	0.1

Note: Failure rate is the percentage of women who have an unintended pregnancy during the first year of use of the contraceptive method. United States data

at <[http://whqlibdoc.who.int/publications/2010/9789241563888\\_eng.pdf](http://whqlibdoc.who.int/publications/2010/9789241563888_eng.pdf)>.

## Hormonal contraception

Methods of hormonal contraception include:<sup>6,7</sup>

- Combined hormonal contraceptives:
  - combined oral contraceptive pill (COC or 'the pill')
  - vaginal ring (NuvaRing)
- Progestogen-only contraceptives:
  - etonogestrel implant (Implanon NXT)
  - levonorgestrel-releasing IUD (Mirena)
  - depot medroxyprogesterone acetate (DMPA)
  - progestogen-only pill (POP or 'mini-pill')
- Post-coital contraception:
  - levonorgestrel emergency contraceptive pill (ECP)

## Combined hormonal contraception (CHC)<sup>6</sup>

Combined hormonal contraceptives contain an oestrogen and progestogen, and their main mode of action is inhibition of hypothalamic and pituitary function leading to anovulation. They are available as a combined oral contraceptive pill (COC) and the vaginal ring. COCs and vaginal rings work in the same way and are treated similarly in terms of contraindications, complications, side effects and drug interactions.

## Combined oral contraception (COC)

COCs in Australia contain ethinylloestradiol (EE), oestradiol valerate (EV) or oestradiol (E2) and one of a range of progestogens. Efficacy is 99.7% with perfect use, 91% with typical use.

## Which oestrogen to use<sup>6</sup>

### Type

EE is the most commonly used oestrogen. The active oestrogen in the newer E2 and EV pills is structurally identical to the E2 produced by the ovaries. They have a theoretical but unproven benefit in terms of venous thromboembolism (VTE) risk. It will be some years before there is any evidence of VTE rates in women using these pill preparations.

### Dose

There is some association between increasing EE dose and risk of venous thromboembolism (VTE). Use of formulations containing 50 mcg EE is no longer recommended because there is no known additional benefit from their use and they are associated with an increased risk of VTE. However, it is not known whether the lowest dose pill formulations with 20 mcg EE are safer than those with 30 or 35 mcg EE. Women starting on a 20 mcg EE pill have a higher chance of discontinuation due to breakthrough bleeding.

## Which progestogen to use<sup>6</sup>

The early progestogens include levonorgestrel and norethisterone. Newer progestogens have been developed over recent decades to reduce androgenic side effects and to minimise the effect EE has on lipids. Norgestrel acetate, gestodene, desogestrel and etonogestrel are less androgenic, while cyproterone acetate, drospirenone and dienogest are anti-androgenic. Drospirenone is an analogue of spironolactone and has a mild diuretic effect. There is insufficient data to initially prescribe newer progestogens in preference to older versions.

Various COC preparations available in Australia are listed in [TABLE 99.2](#).

## Starting the pill: which COC to use<sup>6</sup>

The past menstrual and medical history of the woman should be documented and contraindications excluded.

A suitable first choice is a monophasic pill containing 30 mcg or 35 mcg ethinylloestradiol (EE) with levonorgestrel or norethisterone (e.g. Nordette, Microgynon 30, Monofeme, Levlen ED, Brevinor).

Education and counselling are very important for the woman starting the pill. Suitable patient education should be given. Pill swatches produced by manufacturers are a useful aid. Cover starts immediately if a hormone (active) pill is commenced on day 1–5 of the menstrual cycle.

*Note:* A 'quick-start' technique, described by Westhoff, can be used to start the COC on the day of the consultation. If commenced at any time other than day 1–5 of the menstrual cycle, abstinence/condoms are required for the first 7 days after the start.<sup>9</sup>

## Specific patient groups<sup>4,7</sup>

*Adolescents.* There is no lower age limit if the young woman has started menstruating.

*Acne and hirsutism.* The oestrogen in any CHC may improve acne and hirsutism via increased sex hormone binding globulin (SHBG) levels and reduction of free testosterone. COCs containing an anti-androgenic progestogen have a theoretical advantage for women who request management of androgenic symptoms. Any beneficial effect may take up to 6 months.

*Women over 35 years.* CHC use is safe for healthy non-smoking women until 50 years (MEC 2 for women over 40). CHC is not recommended if a woman is over 35 years and has multiple cardiovascular risk factors, including obesity, smoking, diabetes and hypertension (MEC 3/4).

*Women taking liver enzyme-inducing drugs.* Alternative contraception is strongly advised. The only hormonal contraceptives not affected by liver enzyme-inducing drugs are DMPA and IUDs. Current evidence suggests that most antibiotics do not interact with combined hormonal contraceptives. The only exceptions are liver enzyme-inducing rifabutin and rifampicin. Other liver enzyme-inducing drugs include many of the older anti-epileptics (e.g. phenytoin, carbamazepine), St John's wort and protease inhibitors. For women who still request the use of COC, an extended or tricycling regime of a higher dose pill (e.g. containing at least 50 mcg EE) may be effective. Further guidance on drug interactions is provided by the UK Faculty of Sexual Health & Reproductive Healthcare at [www.fsrh.org/pdfs/CEUguidancedruginteractions-hormonal.pdf](http://www.fsrh.org/pdfs/CEUguidancedruginteractions-hormonal.pdf).

Contraindications to CHC usage are shown in [TABLE 99.3](#).

## Non-contraceptive advantages of CHCs<sup>6</sup>

A number of significant beneficial effects arising from the use of COCs have now been documented:

- Reduction in most menstrual cycle disorders, including dysmenorrhoea, symptoms of endometriosis and heavy menstrual bleeding
- Reduction in the incidence of functional ovarian cysts and benign ovarian tumours

**Table 99.2** Combined oral contraceptive pill formulations available in Australia<sup>7,8</sup>

Oestrogen	Dose (mcg)	Progestogen	Dose (mcg)	Trade name
<b>Monophasic</b>				
Ethinylloestradiol	20	Drospirenone	3000	YAZ, YAZ Flex
Ethinylloestradiol	20	Levonorgestrel	100	Microgynon 20, Loette, Microlevlen, Femme-Tab ED 20/100
Ethinylloestradiol	30	Levonorgestrel	150	Nordette, Levlen ED, Microgynon 30, Monofeme, Femme-Tab ED 30/150
Ethinylloestradiol	30	Dienogest	2000	Valette
Ethinylloestradiol	30	Gestodene	75	Femoden ED, Minulet
Ethinylloestradiol	30	Desogestrel	150	Marvelon
Ethinylloestradiol	35	Cyproterone acetate	2000	Brenda-35, Diane-35, Estelle-35, Juliet-35, Laila 35
Ethinylloestradiol	35	Norethisterone	500	Brevinor, Norimin
Ethinylloestradiol	35	Norethisterone	1000	Brevinor-1, Norimin-1
Ethinylloestradiol	30	Drospirenone	3000	Yasmin, Isabelle
Ethinylloestradiol	50	Levonorgestrel	125	Microgynon 50
Mestranol	50	Norethisterone	1000	Norinyl-1
Oestradiol	1500	Nomegestrol acetate	2500	Zoely
<b>Triphasic</b>				
Ethinylloestradiol	30, 40	Levonorgestrel	50, 75, 125	Triphasil, Triquilar, Trifeme, Logynon
Ethinylloestradiol	35	Norethisterone	500, 1000	Improvil
<b>Quadraphasic</b>				
oestradiol valerate	1000–3000	Dienogest	2000, 3000	Qlaira

- Reduced incidence of ovarian and endometrial cancer
- Can reduce acne
- Can be useful in managing symptoms of polycystic ovarian syndrome
- Can assist with perimenopausal symptoms
- Can be used to manage premenstrual syndrome (PMS) and its more severe form (PMDD) in some women
- Can reduce the risk of bowel cancer

### Serious side effects of CHCs

The most serious side effects to be considered are the effects of COCs on the circulatory system and the incidence of cancer.

The following circulatory disorders have been linked with pill usage.

- Venous deep vein thrombosis, pulmonary embolism, *rarely*: mesenteric, hepatic and kidney thrombosis
- Arterial myocardial infarction, thrombotic stroke, haemorrhagic stroke, *rarely*: retinal and mesenteric thrombosis

The risk of circulatory disease has not been related to duration of use and there is no increased risk in perpetual users.

The oestrogen content of the pill is considered to be the aetiological factor and the problem is increased in women taking high oestrogen-content COCs, but now that the oestrogen content of each pill has been reduced to 35 mcg EE or less, these risks of morbidity and mortality have been reduced.

The progestogen effect on lipid metabolism is not considered significant in the aetiology of circulatory disease. Circulatory diseases have now been recognised as occurring predominantly in certain high-risk groups—the ‘at-risk female’, particularly the smoker over 35 years of age.

**Table 99.3** Contraindications for the use of COC<sup>6,7</sup>**Absolute (MEC 4)**

First 2 weeks postpartum  
 History of thromboembolic disease, including known thrombophilia  
 Cerebrovascular disease  
 Coronary artery disease  
 Uncontrolled hypertension  
 Complicated valvular heart disease  
 Migraine with aura  
 Malignancy of the breast or genital tract  
 Severely impaired liver function  
 Major surgery with prolonged immobilisation

**Relative (MEC 3)**

≥35 years and smoking or other risk factors of CAD  
 BMI >35 kg/m<sup>2</sup>  
 First-degree relative who had a VTE <45 years  
 Undiagnosed abnormal vaginal bleeding  
 Known gene mutation associated with breast cancer  
 Breastfeeding (fully or almost) <6 months postpartum  
 Gall bladder disease  
 Controlled hypertension  
 Long-term immobilisation

*Note:* Adapted from UK Medical Eligibility Criteria (UKMEC) 2009 for CHCs. Full listing available at <www.fsrh.org/pdfs/UKMEC2009.pdf>

Other at-risk groups include those with thrombophilia, hyperlipidaemia, diabetes, hypertension and a family history of cardiovascular disease or immobilisation.

## Venous thromboembolism<sup>7</sup>

Venous thromboembolism (VTE) risk is increased 2–3 times in users of CHCs compared to non-users. The risk is highest in the first 4 months of use and gradually decreases with duration of use. Pills containing *leq* 35 mcg EE and either levonorgestrel or norethisterone are associated with the lowest risk. Studies have shown that COCs containing cyproterone, desogestrel, drospirenone or gestodene have a higher risk of VTE than COCs containing levonorgestrel or other progestogens. However, the absolute risk of VTE in users of any CHC is very low and much lower than the risk associated with pregnancy and the postpartum period. Women who are eligible for an oestrogen-containing method of contraception can safely use any pill on the market with 35 mcg EE or less.

## CHC and cancer<sup>6</sup>

Women who have used CHC have an overall lower risk of cancer compared to women who have not.

- Possible very small increased risk:
  - cervix (benefits of use outweigh the risk with a low- or high-grade squamous intra-epithelial lesion)
  - breast
- Protective effect:
  - endometrial
  - epithelial ovarian
  - bowel

## Common side effects

The relatively minor side effects listed in **TABLE 99.4** may discourage women from persisting with oral contraception in the absence of appropriate explanation and reassurance. Management of these side effects is listed in the same table. It is useful in practice to have this list available as a ready reference for manipulating the COC if necessary. A common nuisance side effect is breakthrough bleeding in the first 2 months.

## Important advice for the patient

- No break from the pill is necessary.
- Diarrhoea and vomiting may reduce the effectiveness of the pill. If a woman vomits within 2 hours of taking an active pill, she should take an additional active pill.
- Withdrawal bleeds can be skipped for a woman's convenience, by going straight from the last active pill in the cycle to the first active pill in the next cycle. Running packs of multiphasic pills together can result in unpredictable bleeding as a result of the fluctuating dose of hormones.<sup>10</sup> A Cochrane Review did not demonstrate any additional safety concerns for women taking CHCs continuously without placebo breaks for up to 12 months.<sup>11</sup>

## Missed pills

A missed pill is defined as one that is taken more than 24 hours late (>48 hours since last pill was taken). The advice is to take the missed pill as soon as possible, even if it means taking two pills in one day. Any previously missed pills should be discarded and the usual pill-taking schedule resumed. Condoms or abstinence should be used for 7 days (the 'Seven-day rule'). This advice does not apply to the quadruphasic

**Table 99.4** Management of common side effects of COC<sup>4,7</sup>

Symptom change	Change
Acne	Change to a pill containing an anti-androgenic (drospirenone, dienogest or cyproterone acetate) or less androgenic (gestodene, desogestrel or etonogestrel) progestogen
Breakthrough bleeding	Exclude underlying causes (e.g. chlamydia, pregnancy, missed pills, malabsorption, diarrhoea or vomiting, concurrent medications) Increase oestrogen if taking a pill with 20 mcg EE to a maximum of 35 mcg EE Change progestogen if already taking a pill with 30 or 35 mcg EE Consider vaginal ring
Breast tenderness	Decrease oestrogen and/or progestogen dose Consider change of formulation Consider using pill containing drospirenone
Chloasma	Change to non-oestrogen-containing contraception Avoid direct sun (use blackout)
Amenorrhoea	Exclude pregnancy Absence of withdrawal bleed is not harmful and occurs in 6% of cycles with EE and 20–30% of EV or E2 pills Switch to a pill with a more predictable bleeding pattern
Lowered libido, mood changes	No evidence of a difference between COCs Trial a change of formulation
Headache	Any new headache or marked changes in headache should be evaluated Reduce oestrogen dose If occurs in pill-free week, consider a pill with a reduced number of placebo pills, running packs together or giving an oestrogen supplement in the pill-free weeks (100 mcg oestrogen patch or 2 mg or 4 mg oestradiol)
Nausea/vomiting	Reduce oestrogen Take the pills at night
Weight gain	Evidence does not support an increase in weight related to CHCs Drospirenone pills are associated with a small, unsustained average weight loss of 0.5 kg in the first year and may be useful for some women

pill Qlaira and the product information should be consulted. Refer to [FIGURE 99.1](#).

If the pill is missed with <7 pills left before the next placebo break, skip placebos and continue active pills.

If <7 active pills were taken before the missed pill, consider emergency contraception if unprotected sex took place in the past 5 days.

## Pill failure<sup>6</sup>

Causes of oral contraceptive failure include errors in administration, decreased absorption, missed pills and use of liver enzyme-inducing drugs. If the woman prefers to use a CHC, tricycling the COC or vaginal ring packs and having a shorter placebo break should be considered.

## Vaginal ring<sup>6</sup>

The first available contraceptive vaginal ring is NuvaRing®, a flexible polymer ring with 15 mcg EE and 120 mcg etonogestrel being released per 24 hours. Metabolic effects and side effects are virtually the same as for the COC. It is immediately protective when inserted on days 1–5 of the menstrual cycle. It is then removed after 21 days with a break of 7 days or can be used 'back-to-back'. The cycle control is good, with a reduced incidence of irregular bleeding. This method may be useful for women who prefer the COC but are prone to missing pills, or women with inflammatory bowel disease or other malabsorption syndromes. It is recommended that the vaginal ring is not removed for intercourse.

Note: These instructions do not apply to the quadriphasic pill Qlaira. See product information for advice

### Practice tip

Delaying a period:

- prescribe norethisterone 5 mg bd or tds for 3 days prior to expected period
- period resumes 2–3 days after stopping tablets

## Progestogen-only contraception<sup>6,7</sup>

Progestogen-only methods include the progestogen-only pill, implant, IUD and injection. These methods are safe in women who are breastfeeding or have a contraindication to taking oestrogen. Progestogen-only contraception is contraindicated in women with active breast cancer within the past 5 years (MEC 4), but has relatively few other contraindications. The harms outweigh the benefits in the following conditions (MEC 3): antiphospholipid antibodies with systemic lupus erythematosus, unexplained vaginal bleeding, ischaemic heart disease or stroke, severe cirrhosis or hepatocellular carcinoma.

Use of progestogen-only contraception is not associated with an increased risk of VTE. Women taking liver enzyme-inducing drugs are not advised to use the POP or etonogestral implant due to reduced effectiveness. DMPA and the levonorgestrel IUD are appropriate for use with liver enzyme-inducing drugs. If postcoital contraception is required, a double dose of the levonorgestrel-ECP is recommended.

## Etonogestrel implant (Implanon NXT)<sup>6</sup>

This is a subdermal contraceptive implant; it is a 3-year system consisting of a single rod containing the progestogen etonogestrel. It inhibits ovulation and has an anti-cervical mucus effect. Irregular bleeding is the most common side effect, with one in 5 women experiencing frequent or prolonged bleeding episodes. Twenty-two per cent of women are amenorrhoeic within 12 months. Several treatments (e.g. cyclical use of a COCP; mefenamic acid; tranexamic acid) are safe to use to reduce troublesome bleeding in the short term. Approximately 20–25% of women request the implant to be removed within 12 months and it is important to provide information about expected bleeding patterns prior to insertion. It requires a minor surgical procedure to insert it and also to remove it. The pregnancy rate is the lowest of all contraceptives at <1:1000 over 3 years of use.

## Intra-uterine contraceptive devices<sup>6</sup>

IUDs are highly effective LARCs that are increasingly used worldwide by women of all reproductive ages, including young and nulliparous women. They are made of an inert material to which may be added a bioactive substance such as copper (e.g. Multiload Cu375) or a progestogen (e.g. Mirena). All IUDs prevent pregnancy by inhibiting sperm migration and ovum transport and preventing implantation. The levonorgestrel IUD also causes endometrial suppression and cervical mucus thickening and may prevent or delay ovulation.

Efficacy:

- copper IUDs: 99.4% perfect use; 99.2% typical use
- levonorgestrel IUDs: 99.8% perfect and typical use

Absolute contraindications include active PID, undiagnosed abnormal genital tract bleeding and current or past history of breast cancer for those considering levonorgestrel IUD (MEC 4).

Recommended use time: copper IUD 5–10 years depending on brand, Mirena 5 years.

### Side effects and complications of IUD use

The biggest difference between copper and hormonal IUDs is the effect on bleeding patterns and pain. Women with a copper IUD will have their usual menstrual periods, usually with an increase in menstrual loss and dysmenorrhoea. Spotting, heavier and prolonged bleeding are common in the first 3–6 months but usually decrease with time.

The levonorgestrel IUD results in a reduction of blood loss. Sixty-five per cent of women are amenorrhoeic or have light bleeding only after the first year of use. For this reason, the hormonal IUD is particularly suitable for women with heavy menstrual bleeding. Persistent light vaginal bleeding and/or spotting are common initially for the first 3–5 months.

Menstrual bleeding and pain are the most common reason for IUD discontinuation. Discontinuation rates for both IUDs are similar.

### Pregnancy/ectopic pregnancy

If pregnancy occurs there is an increased risk of abortion and intra-uterine sepsis during the second trimester. Early removal of the IUD is essential. Since the IUD prevents intra-uterine rather than tubal pregnancies, the proportion of ectopic pregnancy is higher in the case of IUD failure, although the absolute risk is low compared to the risk for women using no contraception.

### Pelvic inflammatory disease

There is a small increased risk of PID in the first 20 days post-insertion. Subsequent risk of PID reverts to baseline and is related to the risk of STIs.

### Extrusion, perforation of uterus and translocation

Spontaneous extrusion occurs in about 5% with the highest risk within the first year. Perforation of the uterus occurs in up to 2.3 in 1000 insertions.<sup>6</sup> Factors

that increase risk of perforation include breastfeeding, first 6 months postpartum and previous caesarean section. If translocation of the IUD outside the uterus is proved by X-ray and pelvic ultrasound, referral for removal is mandatory. The woman should attend for a follow-up visit between 3–6 weeks after insertion specifically to exclude infection, perforation or expulsion.

## Injectable contraceptives

### Depot medroxyprogesterone acetate

Depot medroxyprogesterone acetate (DMPA) is the only injectable intramuscular contraceptive available in Australia. It is very effective for up to 14 weeks. Although DMPA is technically a LARC, it is not immediately reversible and is less effective than implants and IUDs due to the need for repeated injections.

- Dose: 150 mg by deep IM injection in first 5 days of the menstrual cycle. The same dose is given every 12 weeks  $\pm$  2 weeks to maintain contraception.
- Effectiveness: perfect use 99.8%; typical use 94%.

Side effects include a disrupted menstrual cycle (amenorrhoea rate 50–70% by 12 months), weight gain (average 2–6%), breast tenderness, mood changes and a delay in return of fertility (mean time 8 months).<sup>6</sup> Long-term use is associated with accelerated bone loss, but this is not clinically significant and does not translate into fracture risk. However, for this reason it is not recommended as a first-line contraceptive for women less than 18 and more than 45 years.

## Progestogen-only contraceptive pill

The POP (mini-pill) is most commonly prescribed for breastfeeding women for whom an oestrogen contraceptive would potentially suppress milk supply. It is safe from 6 weeks postpartum.

The two common formulations are:

- levonorgestrel 30 mcg/day
- norethisterone 35 mcg/day

The primary mechanism of action is cervical mucus thickening, preventing sperm penetration. In addition, POPs prevent ovulation in up to 60% of cycles.<sup>7</sup>

Efficacy is 99.7% in perfect use and 91% in typical use.<sup>6</sup> The failure rate is lower in women >40 years compared to younger women. The POP is considered to have a more vulnerable efficacy, and it is important

that the woman strictly adheres to taking the pill within a daily 3-hour timeframe for maximum efficacy. The POP is effective after 3 tablets have been taken.<sup>4</sup>

Compliance can be a problem because of cycle irregularity. Twenty per cent of women will be amenorrhoeic on the POP, 40% will have regular bleeding and 40% will have irregular bleeding.<sup>6</sup>

### Postcoital contraception<sup>6</sup>

- Levonorgestrel 1.5 mg as a single dose
- 25 levonorgestrel POPs (25 × 30 mcg) as an initial dose, repeating the same dose 12 hours later
- Yuzpe method: a large initial dose of COC, which is repeated 12 hours later, with each dose containing at least 100 mcg of EE and 500 mcg of levonorgestrel (example: 4 tablets of either Microgynon 30 or 5 tablets of Microgynon 20)
- Copper IUD inserted within 5 days

The levonorgestrel emergency contraceptive pill (LNG-ECP) is a high dose of progestogen that acts to prevent or delay ovulation by interfering with follicular development. It prevents up to 85% of pregnancies. The ECP is licensed for use up to 72 hours after unprotected intercourse, but may be effective for up to 120 hours (5 days). Effectiveness is improved the earlier it is taken. The Yuzpe method has an efficacy of 57–74% and is reserved only for when levonorgestrel is unavailable. The copper IUD is highly effective at 99% and can provide very reliable ongoing contraception. It may be appropriate to advise the woman seeking postcoital contraception to return for pregnancy testing in 3–4 weeks, depending on her risk. STI screening and the need for ongoing contraception need to be considered.

### Barrier methods<sup>6</sup>

Barrier methods include male and female condoms and vaginal diaphragms. If used correctly, male condoms are very effective contraceptives with an efficacy of 98% with perfect use and 82% with typical use.

Condoms are also very effective in preventing the spread of STIs, including HIV infection. The main disadvantage is that they are mainly reliant on the cooperation of the user.

*Diaphragms* are inserted at any convenient time before intercourse and removed after 6 hours have elapsed since the last act of intercourse. Their

presence on the Australian market in the future remains uncertain.

### Fertility awareness-based contraception

These methods require high motivation and regular menstrual cycles.

#### Basal body temperature method

Coitus should occur only after there has been a rise in basal body temperature of 0.2°C for 3 days (72 hours) above the basal body temperature measurement during the preceding 6 days, until the onset of the next menstrual period.

#### Calendar or rhythm method

The woman reviews and records six cycle lengths and then selects the shortest and longest cycles. She then subtracts 21 from the shortest cycle and 10 from the longest cycle to work out fertile and safe days (i.e. for a 26 to 30-day cycle: fertile days 5–20; for regular 28-day cycle: fertile days 7–18).

#### Billings or mucus method<sup>6,12</sup>

This method is based on careful observation of the nature of the mucus so that ovulation can be recognised and intercourse confined to when the vagina is dry. Fertile mucus is wet, clear, stringy, increased in amount and feels lubricative. The peak mucus day is the last day with this oestrogenised mucus before the abrupt change to thick tacky mucus associated with the secretion of progesterone. The infertile phase begins on the fourth day after the peak mucus day. Abstinence from intercourse is practised from the first awareness of increased, clearer wet mucus until 4 days after maximum mucus secretion.

#### Withdrawal method or coitus interruptus

Male withdrawal before ejaculation is still a widely used method of contraception and will continue to have a definite place in contraceptive practice.

#### Lactational amenorrhoea method (LAM)<sup>7</sup>

LAM is as reliable as hormonal methods of contraception if the baby is younger than 6 months, is exclusively breastfed with no long intervals between feeds (no more than 4 hours during the day or 6 hours at night) and the woman remains amenorrhoeic postpartum. Lactation is not a reliable contraceptive method once any of these criteria is not met—if the mother is still breastfeeding, a progestogen-only

method is advised. Since some women may ovulate prior to the onset of menses, an additional method of contraception should be advised to reduce the risk of another pregnancy.

### Ceasing contraception and menopause<sup>13</sup>

Women using non-hormonal contraception (i.e. barrier, copper IUD, rhythm) can be advised that contraception is no longer required once they have been amenorrhoeic for 12 months over the age of 50 years and after two years before the age of 50.

Oestrogen-containing contraception and DPMA injections are not recommended after 50 years. After this age, women should switch to an alternative progestogen-only or non-hormonal method.

Women over the age of 50 who are amenorrhoeic while using progestogen-only contraception are advised to continue the method for a further 12 months if they have two follicle stimulating hormone levels of 30 IU/L or above taken 6 weeks apart. Contraception is not required beyond the age of 55 years.

### Sterilisation

#### Vasectomy<sup>14</sup>

A vasectomy involves interruption or occlusion of the vas deferens, preventing the passage of sperm from the testes to the penis. The procedure is generally performed in an outpatient setting under local anaesthesia. It is important to confirm the absence of spermatozoa in the ejaculate 2–3 months after the operation, before ceasing other contraceptive methods. It takes about 12–15 ejaculations to clear the remaining sperm from the semen.

For the average man undergoing vasectomy reversal, pregnancy rates range between 50 and 70%. This rate decreases as the interval between vasectomy and its reversal increases.

#### Tubal ligation

Female sterilisation is usually performed by mini-laparotomy or laparoscopy, at which time clips are applied to each fallopian tube. This is a potentially reversible method of contraception with 50% of women achieving pregnancy after reversal. Efficacy is >99.5%.<sup>6</sup>

### Hysteroscopic transcervical occlusive sterilisation

This procedure—Essure—involves the placement of a flexible titanium micro-insert into each fallopian

tube. The insert expands and over time reactive tissue growth occludes the tubes.

This irreversible method requires alternative contraception until complete tubal occlusion is confirmed radiologically at 12 weeks.

### Unintended pregnancy

Up to 51% of Australian women have experienced an unplanned pregnancy.<sup>15</sup> It is estimated that 1 in 4 pregnancies in Australia end in termination. The main methods used are the traditional surgical methods such as suction curettage and medical abortion. Surgical abortions can be performed from 6–7 weeks. There is an increased risk of continuing pregnancy if performed before 6 weeks. Medical abortions are usually performed before 9 weeks using mifepristone, an anti-progesterone, and then the prostaglandin analogue misoprostol 24–48 hours later. Bleeding and cramping usually occur within 4–24 hours and a check-up visit is required in two weeks. Ideally, unintended pregnancies should be prevented, for which LARC methods are considered to play a vital role.

*Many women suffer breast pain so severe that it affects their lifestyles, marriages and sexual relationships, and even prevents them from hugging their children.*

Dr John Dawson 1990

Breast pain, or mastalgia, is a common problem, accounting for at least 50% of breast problems presenting in general practice and 14% of referrals to an Australian breast clinic.<sup>1</sup> As stated in the beginning, many women suffer breast pain so severe that it affects their lifestyles, marriages and sexual relationships, and even prevents them from hugging their children. If no obvious physical cause is found, the problem is all too often dismissed, without appropriate empathy and reassurance, as a normal physiological effect. However, its aetiology is not clear.

A careful, sympathetic clinical approach, however, followed by reassurance after examination, will be sufficient treatment for most patients.

## Symptoms

Mastalgia usually presents as a heaviness or discomfort in the breast or as a pricking or stabbing sensation. The pain may radiate down the inner arm when the patient is carrying heavy objects or when the arm is in constant use, as in scrubbing floors.

## Key facts and checkpoints

- The typical age span for mastalgia is 30–50 years.
- The peak incidence is 35–45 years.
- There are four common clinical presentations:
  - 1 diffuse, bilateral cyclical mastalgia
  - 2 diffuse, bilateral non-cyclical mastalgia
  - 3 unilateral diffuse non-cyclical mastalgia
  - 4 localised breast pain
- The specific type of mastalgia should be identified.
- The commonest type is cyclical mastalgia.
- Premenstrual mastalgia (part of type 1) is common.
- An underlying malignancy should be excluded.
- Less than 10% of breast cancers present with localised pain.
- Only about 1 in 200 women with mastalgia are found to have breast cancer.
- The problems, especially types 2 and 3, are difficult to alleviate.

## A diagnostic approach

A summary of the diagnostic strategy model for mastalgia is presented in TABLE 100.1.

## Probability diagnosis

In the non-pregnant patient, generalised pain, which may be cyclical or non-cyclical, is commonest. Typical patterns are illustrated in FIGURE 100.1.

FIGURE 100.1 Pain patterns for cyclical and non-cyclical mastalgia

Cyclical mastalgia is the commonest diffuse breast pain. It occurs in the latter half of the menstrual cycle, especially in the premenstrual days, and subsides with the onset of menstruation. It obviously has a hormonal basis, which may be an abnormality in prolactin secretion. The main underlying disorder is benign mammary dysplasia, also referred to as fibroadenosis, chronic mastitis, cystic hyperplasia or fibrocystic breast disease.

Non-cyclical mastalgia, which is pain that does not vary within the menstrual cycle, is also quite common and the cause is poorly understood. It may be associated with mammary duct ectasia (see CHAPTER 101).

## Serious disorders not to be missed

The three important serious disorders not to be missed with any painful chest condition—neoplasia, infection and myocardial ischaemia—are applicable for breast pain.

## Neoplasia

We must avoid the trap of considering that breast pain is not compatible with malignancy. Mastalgia can be a presenting symptom (although uncommon) of breast cancer. 'Mastitis carcinomatosa', which is a rare florid form of breast cancer found in young women, often during lactation, is red and hot but not invariably painful or tender.<sup>2</sup> Pain may also

**Table 100.1** Mastalgia: diagnostic strategy model

Q. Probability diagnosis
A. Pregnancy
Cracked or inflamed nipple
Cyclical mastalgia:
• benign mammary dysplasia
Q. Serious disorders not to be missed
A. Vascular:
• acute coronary insufficiency
• thrombophlebitis (Mondor disease)
Infection:
• mastitis
• breast abscess
Cancer:
• breast (uncommon presentation)
• mastitis carcinomatosa
Q. Pitfalls (often missed)
A. Pregnancy
Chest wall pain (e.g. costochondritis)
Pectoralis muscle spasm
Referred pain, esp. thoracic spine
Bornholm disease (epidemic pleurodynia)
Herpes zoster
Mechanical:
• bra problems
• weight change
• trauma
Rarities:
• hyperprolactinaemia
• nerve entrapment
• mammary duct ectasia
• sclerosing adenosis
• ankylosing spondylitis
Q. Masquerades checklist
A. Depression
Drugs (e.g. OCP, HRT, marijuana)
Spinal dysfunction
Q. Is the patient trying to tell me something?
A. Yes. Fear of malignancy. Consider psychogenic causes.

be a symptom in juvenile fibroadenoma, a soft rapidly growing tumour in adolescents, and in the fibroadenoma of adult women.

## Infection

Mastitis is common among nursing mothers. It should be regarded as a serious and urgent problem because a breast abscess can develop quickly. Apart from bacterial infection, infection with *Candida albicans* may occur following the use of antibiotics. *Candida* infection usually causes severe breast pain, producing a feeling like 'hot cords', especially during and after feeding.

## Myocardial ischaemia

A constricting pain under the left breast should be regarded as myocardial ischaemia until proved otherwise.

## Pitfalls

These include various causes of apparent mastalgia, such as several musculoskeletal chest wall conditions and referred pain from organs such as the heart, oesophagus, lungs and gall bladder and, in particular, from the upper thoracic spine.

Musculoskeletal conditions include costochondritis, pectoralis muscle strains or spasm, and entrapment of the lateral cutaneous branch of the third intercostal nerve. Ankylosing spondylitis can affect the chest wall under the breasts. Mastalgia may be the first symptom of pregnancy. Pregnancy should be excluded before commencing drug treatment.

## Seven masquerades checklist

Of these, depression, drugs and spinal dysfunction are probable causes. Drugs that can cause breast discomfort include oral contraceptives, HRT and methylxanthine derivatives such as theophylline. Drugs that cause tender gynaecomastia (more applicable to men) include digoxin, cimetidine, spironolactone and marijuana.

Dysfunction of the upper thoracic spine and even the lower cervical spine can refer pain under a breast. If suspected, these areas of the spine should be examined.

## Psychogenic considerations

The symptoms may be exaggerated as a result of an underlying psychogenic disorder, but with a symptom such as breast pain most women fear malignancy and need reassurance.

## The clinical approach

### History

It is important to relate the pain to the menstrual cycle and determine whether the patient is pregnant or not.

### Key questions

- Could you be pregnant?
- Is your period on time or overdue?
- Is the pain in both breasts or only one?
- Do you have pain before your periods (cyclical mastalgia) or all the time during your menstrual cycle?
- Do you have pain in your back or where your ribs join your chest bone?

### Examination

The breasts should be systematically palpated to check for soreness or lumps. The underlying chest wall and thoracic spine should also be examined.

### Investigations

The following specialised tests could be considered.

*Mammography* should be considered in older women. It is unreliable in young women. With few exceptions it should not be used under 40 years.

*Ultrasound* can be complementary to mammography for it is useful to assess a localised mass or tender area. It is inappropriate to evaluate a diffuse area. It is not so useful for the postmenopausal breast, which is fatty and looks similar to cancer on ultrasound.

*FNA excision biopsy* can be useful for an area of localised pain, especially in the presence of a possible mass.

Consider a chest X-ray and ECG.

### Mastalgia in children

Breast pain is uncommon in children, including puberty, but it may be a presenting problem in the late teens. Pubertal boys may complain of breast lumps under the nipple (adolescent gynaecomastia) but these are rarely tender and do not require specific treatment.

### Mastalgia in the elderly

Breast pain is rare after the menopause but is increasing with increased use of HRT, where it tends to present as the diffuse bilateral type. If the problem is related to the introduction of HRT, the oestrogen dose should be reduced or an alternative preparation used.

### § Cyclical mastalgia

The features of cyclical mastalgia are:

- the typical age is 30–40 years (mean 35)
- discomfort and sometimes pain are present
- usually bilateral but one breast can dominate (usually upper outer quadrant)
- mainly premenstrual
- usually resolves on commencement of menstruation
- breasts may be diffusely nodular or lumpy
- variable relationship to the pill

Cyclical mastalgia is rare after the menopause.

### § Non-cyclical mastalgia

The features of non-cyclical mastalgia are:

- the typical age is the early 40s (median age 41 years)
- bilateral and diffuse
- continuous or intermittent
- pain present throughout the cycle
- no obvious physical or pathological basis

### Management for mastalgia (both types)

After excluding a diagnosis of cancer and aspirating palpable cysts, various treatments are possible and can be given according to severity.<sup>3</sup>

Acknowledge the condition and its discomfort.

### Approach to treatment<sup>4</sup>

- Reassurance—explain high remission rate
- Regular review and breast self-examination
- Proper brassiere support—expert fitting
- Cease smoking (if applicable)
- Aim at ideal weight
- Adjust oral contraception or HRT (if applicable)
- Analgesia (e.g. paracetamol 0.5–1 g (o) 4–6 hourly prn)

Many products have been promoted and tried but there is no convincing evidence to support the use of vitamins B1, B6, B12 and E, diuretics, NSAIDs, narcotics, caffeine reduction and even evening primrose oil, which is a favoured product and has been helpful for many women.<sup>5,6,7</sup>

Evening primrose oil contains an essential fatty acid claimed to be lacking in the diet, and replacement allows for the production of prostaglandin E, which counters the effect of oestrogen and prolactin on the breast. However, according to the multi-centred

European RCT, it is no more effective than placebo,<sup>1</sup> but the placebo effect in these trials was strong.<sup>6,7</sup>

A dose of 1000 mg three times daily for 3–4 months is recommended if a trial of treatment is planned.<sup>6</sup> There is some evidence to support the use of a topical NSAID medication (e.g. diclofenac gel).<sup>5</sup>

Recent systemic reviews from RTCs assessed the effectiveness of danazol,<sup>8</sup> bromocriptine and tamoxifen and showed that all provided significant relief, but that all have the potential for severe adverse effects.

For very severe mastalgia it is recommended to refer to a breast specialist to consider prescribing tamoxifen or danazol.<sup>6</sup>

Non-cyclical mastalgia is very difficult to treat, being more refractory than cyclical mastalgia.

## Local lesions

Surgical excision may be required for local lesions. If there is no discrete lesion but a tender trigger point (including costochondritis), the injection of local anaesthetic and corticosteroid may relieve the problem.

### § Costochondritis (Tietze syndrome)

This is a common cause of referral to a breast pain clinic. The cause is often obscure, but the costochondral junction may become strained in patients with a persistent cough. The pain can appear to be in the breast with intermittent radiation round the chest wall and is initiated or aggravated by deep breathing and coughing.

Features:

- the pain is acute, intermittent or chronic
- the breast is normal to palpation
- palpable swelling about 4 cm from sternal edge due to enlargement of costochondral cartilage
- X-rays are normal
- it is self-limiting, but may take several months to subside

**Treatment.** Infiltration with local anaesthetic and corticosteroid with care. Otherwise use NSAIDs or paracetamol.

### § Mastitis

Mastitis is basically cellulitis of the interlobular connective tissue of the breast. Mostly restricted to lactating women, it is associated with a cracked nipple or poor milk drainage. The infecting organism

is usually *Staphylococcus aureus*, or more rarely, *Escherichia coli* and *Candida albicans*. *C. albicans* is common in breastfeeding women. Mastitis is a serious problem and requires early treatment. Breastfeeding from the affected side can continue as the infection is confined to interstitial breast tissue and doesn't usually affect the milk supply.

### Clinical features

- A lump and then soreness (at first)
  - A red tender area
- Possibly
- Fever, tiredness, muscle aches and pains

**Note:** *Candida* infection usually causes severe breast pain—a feeling like a hot knife or hot shooting pains, especially during and after feeding. It may occur after a course of antibiotics.

### Prevention (in lactation)

- Maintain free breast drainage—keep feeding
- Attend to breast engorgement and cracked nipples

### Treatment

If systemic symptoms develop:

- antibiotics: resolution without progression to an abscess will usually be prevented by antibiotics<sup>7</sup> di/(flu)cloxacillin 500 mg (o) 6 hourly for 10 days or (if hypersensitive to penicillin)<sup>9,10</sup> cephalixin 500 mg (o) 6 hourly for 10 days  
If severe cellulitis di/(flu)cloxacillin 2 g (IV) 6 hourly
- therapeutic ultrasound (2 W/cm<sup>2</sup> for 6 minutes) daily for 2–3 days
- ibuprofen or paracetamol for pain
- for *Candida albicans* infection: fluconazole 200–400 mg (o) daily for 2–4 weeks  
second line—nystatin 500 000 U (o) tds

### § Breast abscess

If tenderness and redness persist beyond 48 hours and an area of tense induration develops, then a breast abscess has formed (see FIG. 100.2).

The preferred treatment is serial aspiration drainage with a large bore needle under ultrasound guidance. Often 3 or 4 aspirations are required. Adjunct treatment is antibiotics, rest and complete emptying of the breast. Breastfeeding can continue, with provision of lactation support. Surgical drainage may be required but should be avoided if possible because fistula formation is common.

FIGURE 100.2 Localised cellulitis and breast abscess in a breastfeeding mother

### Inflammatory breast cancer

Also referred to as ‘mastitis carcinomatosa’, this rare condition develops quickly with florid redness, swelling, dimpling and heaviness of the breast. It is not as painful as it appears and can be confused with mastitis but does not respond to antibiotics.

Refer immediately.

### When to refer

- Undiagnosed localised breast pain or lump

### Practice tips

- The basis of management for benign mastalgia is firm reassurance.
- Although breast cancer rarely causes mastalgia, it should be excluded.
- Think of *C. albicans* if mastitis is very severe with hot shooting pains, especially after antibiotic treatment.

- Look for underlying disorders of the chest wall if examination of the breasts is normal.
- Consider caffeine intake as a cause of benign diffuse mastalgia.
- Mastitis should be treated vigorously—it is a serious condition.
- Fibroadenomas and breast cysts are capable of causing localised pain and tenderness.

# 101 Lumps in the breast

*Neither the cause of breast cancer, one of the most feared and emotion-engendering diseases, nor the means of preventing it are absolutely known.*

Anonymous lecturer on breast cancer

Breast lumps are common and their discovery by a woman provokes considerable anxiety and emotion (which is often masked during presentation) because, to many, a breast lump means cancer. Many of the lumps are actually areas of thickening of normal breast tissue. Many other lumps are due to fibrocystic disease with either fibrosis or cyst formation or a combination of the two producing a dominant (discrete) lump. However, a good working rule is to consider any lump in the breast as cancer until proved otherwise. See **TABLE 101.1** for causes of breast lumps in a specific outpatient study.

The genetic predisposition to breast cancer continues to be delineated with the strong predisposition from mutations in the genes *BRCA1* and *BRCA2*. Refer to **CHAPTER 18**.

## Key facts and checkpoints

- The commonest lumps are those associated with mammary dysplasia (32%).<sup>1</sup> See **TABLE 101.1**.
- Fibrocystic disease is also a common cause of cysts, especially in the premenopause phase.
- Over 75% of isolated breast lumps prove to be benign but clinical identification of a malignant tumour can only definitely be made following aspiration biopsy or histological examination of the tumour.<sup>1</sup>
- The investigation of a new breast lump requires a very careful history and the triple test.

## The triple test

- 1 Clinical breast examination
- 2 Imaging—mammography and/or ultrasound  $\pm$  MRI
- 3 Fine-needle aspiration cytology  $\pm$  core biopsy

- Breast cancer is the most common cancer in females. The risk of developing breast cancer before age 85 in Australian women is 1 in 8.<sup>2</sup>

**Table 101.1** Causes of breast lumps in women: diagnostic strategy model

- Q. Probability diagnosis
- A. Mammary dysplasia (32%)  
Fibroadenoma (23%)  
Cancer (22%)  
Cysts (10%)  
Breast abscess/periareolar inflammation  
Lactation cyst (galactocoele)
- 
- Q. Serious disorders not to be missed
- A. Vascular:
- thrombophlebitis (Mondor disease)
- Infection:
- mastitis/breast abscess
  - tuberculosis
- Cancer:
- carcinoma
  - ductal carcinoma in situ
  - Paget disease of the nipple
  - sarcoma
  - lymphoma
  - mastitis carcinomatosa
- Other:
- phyllodes tumour
- 
- Q. Pitfalls (often missed)
- A. Duct papilloma  
Lipoma  
Mammary duct ectasia  
Fat necrosis/fibrosis

*Note:* Statistics for probability diagnosis courtesy MA Henderson, PBR Kitchen, PR Hayes, University of Melbourne Department of Surgery, Breast Clinic, St Vincent's Hospital, Melbourne

- Breast cancer is uncommon under the age of 30 but it then steadily increases to a maximum at the age of about 60 years, being the most common cancer in women over 50 years. The average age of diagnosis is 60.7 years.<sup>3</sup>

**FIGURE 101.1** Changing frequencies of different discrete breast lumps with age

Source: From Dixon & Mansel.<sup>4</sup> Courtesy of Anthea Carter

**FIGURE 101.1** highlights the changing frequencies of different discrete breast lumps with age.<sup>4</sup>

- About 25% of all new cancers in women are breast neoplasms.
- A 'dominant' breast lump in an older woman should be regarded as malignant.

## The clinical approach

This is based on following a careful history and examination.

## History

The history should include a family history of breast disease and the patient's past history, including trauma, previous breast pain, and details about pregnancies (complications of lactation such as mastitis, nipple problems and milk retention).

## Key questions<sup>1</sup>

- Have you had any previous problems with your breasts?
- Have you noticed any breast pain or discomfort?
- Do you have any problems such as increased swelling or tenderness before your periods?
- Is the lump constant or changing?
- Have you noticed lumpiness in your breasts before?
- Has the lumpy area been red or hot?
- Have you noticed any discharge from your nipple or nipples?

- Has there been any change in your nipples?
- Does/did your mother or sisters or any close relatives have any breast problems?

## Breast symptoms<sup>5</sup>

- Lump (76%)
- Tenderness or pain (10%)
- Nipple changes (8%)
- Nipple discharge (2%)
- Breast asymmetry or skin dimpling (4%)
- Periareolar inflammation

Important 'tell-tale' symptoms are illustrated in **FIGURE 101.2**.

## Nipple discharge<sup>6</sup>

The diagnostic strategy is outlined in **TABLE 101.2**.

**Table 101.2** Nipple discharge: diagnostic strategy model

Q. Probability diagnosis	
A. Physiological	
	Pregnancy
	Intraduct papilloma
	Lactation/lactation cysts
	Mammary dysplasia
Q. Serious disorders not to be missed	
A. Infection:	
	• acute mastitis/discharging breast abscess
	• areolar abscess (infected gland of Montgomery)
	• tuberculosis abscess
	Cancer:
	• intraduct carcinoma
	• invasive carcinoma
	• Paget disease of nipple
	Other:
	• hyperprolactinaemia
	• hypothyroidism
Q. Pitfalls (often missed)	
A. Mammary duct ectasia	
	Drugs (e.g. chlorpromazine, metoclopramide, OCP, cimetidine, opiates, amphetamines, CCBs, SSRIs, tricyclic antidepressants, phenothiazine)
	Rarities:
	• mammary duct fistula
	• mechanical stimulation

FIGURE 101.2 Important 'tell-tale' symptoms of breast cancer

The discharge may be intermittent, from one or both nipples. It can be induced by quadrant compression. A common reason is physiological, which is usually part of a normal hormonal process.

### Types of discharge

- Bloodstained:
  - intraduct papilloma (commonest)
  - intraduct carcinoma
  - fibrocystic disease
- Green-grey:
  - fibrocystic disease
  - mammary duct ectasia
- Yellow:
  - fibrocystic disease
  - intraduct carcinoma (serous)
  - breast abscess (pus)
- Milky white (galactorrhoea):
  - lactation cysts
  - lactation
  - hyperprolactinaemia
  - drugs (e.g. antipsychotic, cocaine)

FIGURE 101.3 Woman with advanced breast cancer showing peau d'orange sign, brawny oedema and breast retraction

### Periareolar inflammation

This presents as pain around the areola with reddening of the skin, tenderness and swelling. Causes may be inverted nipple or mammary duct ectasia.

## Paget disease of the nipple

This rare but interesting sign and condition usually occurs in middle-aged and elderly women (see FIG. 101.4). It starts as an eczematous-looking, dry scabbing red rash of the nipple and then proceeds to ulceration of the nipple and areola (see TABLE 101.3). It is always due to an underlying malignancy.

**FIGURE 101.4** Paget disease of the breast: note the erythematous, eczematous, scaly appearance of the nipple

**Table 101.3** Differences between Paget disease and eczema of the nipple<sup>6</sup>

Paget disease	Eczema
Unilateral	Bilateral
Older patients	Younger: reproductive years
Ulceration	Ulceration rare
Possible nipple discharge	No discharge
Not pruritic	Pruritic
No pustules or vesicles	Pustules and vesicles
Deformity of nipple	Normal nipple
Possible palpable lump	No lump
Mammographic changes	Normal mammogram

## Examination of the breasts

### Objectives

- Identify a dominant lump (one that differs from the remainder of the breast tissue).
- Identify a lump that may be malignant.
- Screen the breasts for early development of cancer.

Time of examination: ideally, 4 days after the end of the period.

### Red flag pointers for breast lumps

- Hard and irregular lump
- Skin dimpling and puckering
- Skin oedema ('peau d'orange') (FIG. 101.3)
- Nipple discharge
- Nipple distortion
- Nipple eczema
- Postmenopausal women

### Method<sup>1</sup>

- 1 Inspection: sitting—patient seated upright on side of couch in good light, arms by sides, facing the doctor, undressed to waist.
  - A *Note:*
    - asymmetry of breasts or a visible lump
    - localised discolouration of the skin
    - nipples:
      - for retraction or ulceration
      - for variations in the level (e.g. elevation on one side)
      - or discharge (e.g. blood-stained, clear, yellow)
    - skin attachment or tethering → dimpling of skin (accentuate this sign by asking patient to raise her arms above her head)
    - appearance of small nodules of growth
    - visible veins (if unilateral they suggest a cancer)<sup>7</sup>
    - peau d'orange due to dermal oedema
  - B Raise arms above the head (renders variations in nipple level and skin tethering more obvious). Hands are pressed on the hips to contract pectoralis major to note if there is a deep attachment of the lump.
- 2 Examination of lymph glands in sitting position: patient with hands on hips. Examine axillary and supraclavicular glands from behind and front.
 

*Note:* The draining lymphatic nodes are in the axillae, supraclavicular fossae and internal mammary chain.
- 3 Palpation:
  - A Patient still seated: palpate breast with flat of hand and then palpate the bulk of the breast between both hands.
  - B In supine position:
    - patient lies supine on couch with arms above head
    - turn body (slight rotation) towards midline so breasts 'sit' as flat as possible on chest wall

*Method*

- Use the pulps of the fingers rather than the tips with the hand laid flat on the breast.
- Move the hand in slow circular movements.
- Examine up and down the breast in vertical strips beginning from the axillary tail (see FIG. 101.5).

FIGURE 101.5 Systematic examination of the breast

- Systematically cover the six areas of the breast (see FIG. 101.6):
  - the four quadrants
  - the axillary tail
  - the region deep to the nipple and areola

*Right breast*

FIGURE 101.6 The six areas of the breast

- 4 If a suspicious lump is present, inspect liver, lungs and spine.
- 5 Inspect the bra. Note possible pressure on breast tissue from underwiring of the bra, usually on the upper outer quadrant.

*Note:*

- Most cancers occur in the upper outer quadrant (see FIG. 101.7).<sup>6</sup>
- A useful diagram to record the findings is shown in FIGURE 101.8.
- Lumps that are usually benign and require no immediate action are: tiny (<4 mm) nodules in subcutaneous tissue (usually in the areolar margin); elongated ridges, usually bilateral and in the lower aspects of the breasts; and rounded soft nodules (usually <6 mm) around the areolar margin.<sup>8</sup>
- A hard mass is suspicious of malignancy but cancer can be soft because of fat entrapment.
- The inframammary ridge, which is usually found in the heavier breast, is often nodular and firm to hard.
- Lumpiness (if present) is usually most marked in the upper outer quadrant.

FIGURE 101.7 Relative frequencies of breast cancer at various anatomical segments

FIGURE 101.8 Diagrammatic scheme for recording the features of breast lumps and any lymphadenopathy (axilla and supraclavicular triangles)

### If a solitary lump is present, assess it for:

- position (breast quadrant and proximity to nipple)
- size and shape
- consistency (firm, hard, cystic, soft)
- tenderness
- mobility and fixation
- attachment to skin or underlying muscle

## Investigations

### X-ray mammography

Mammography can be used as a screening procedure and as a diagnostic procedure. It is currently the most effective screening tool for breast cancer.<sup>9</sup> Positive signs of malignancy include an irregular infiltrating mass with focal spotty microcalcification.

Screening:

- established benefit for women over 50 years
- possible benefit for women in their 40s
- follow-up in those with breast cancer, as 6% develop in the opposite breast
- localisation of the lesion for fine-needle aspiration

### Breast ultrasound

This is mainly used to elucidate an area of breast density and is the best method of defining benign breast disease, especially with cystic changes. It is generally most useful in women less than 35 years old (as compared with X-ray mammography).

Useful for:

- pregnant and lactating breast
- differentiating between fluid-filled cysts and solid mass
- palpable masses at periphery of breast tissue (not screened by mammography)
- for more accurate localisation of lump during fine-needle aspiration

*Note:* CT and MRI have limited use. An age-related schemata for likely diagnosis and appropriate investigations is presented in **TABLE 101.4**.

### Breast imaging for palpable lumps—summary

- <35 years: bilateral ultrasound; bilateral mammography if ultrasound suspicious
- 35–50 years: bilateral mammography + bilateral ultrasound
- >50 years: bilateral mammography ± bilateral ultrasound

**Table 101.4** Age-related schemata for likely diagnoses and appropriate investigations (after Hirst)<sup>8</sup>

#### 1 Very young women—12 to 25 years

Inflamed cysts or ducts, usually close to areola

Fibroadenomata, often giant

Hormonal thickening, not uncommon

Malignancy rare

*Investigations:*

- mammography contraindicated
- ultrasound helpful

#### 2 Young women—26 to 35 years

Classic fibroadenomata

Fibrocystic disease with or without discharge

Cysts uncommon

Malignancy uncommon

*Investigations:*

- mammography: breasts often very dense
- ultrasound often diagnostic

#### 3 Women—36 to 50 years (premenopausal)

Cysts

Fibrocystic disease, discharges, duct papillomas

Malignancy common

Fibroadenomata occur but cannot assume

Inflammatory processes not uncommon

*Investigations:*

- mammography useful
- targeted ultrasound useful

#### 4 Women—over 50 years (postmenopausal)

Any new discrete mass—malignant until proven otherwise

Any new thickening—regard with suspicion

Inflammatory lesions—probably duct ectasia (follow to resolution)

Cysts unlikely

*Investigations:*

- mammography usually diagnostic (first line)
- ultrasound may be useful

#### 5 Women—over 50 years, on hormones

Any new mass—regard with suspicion

Cysts may occur—usually asymptomatic

Hormonal change not uncommon

*Investigations:*

- mammography usually diagnostic but breast may become more dense
- ultrasound may be useful if above normal or unhelpful and lump suspicious

*Source:* After Hirst.<sup>8</sup> Reprinted with permission

## Needle aspiration and biopsy techniques

- Cyst aspiration
- Fine-needle aspiration biopsy: this is a very useful diagnostic test in solid lumps, and has an accuracy of 90–95% (better than mammography)<sup>6</sup>
- Large needle (core needle) biopsy
- Incision biopsy

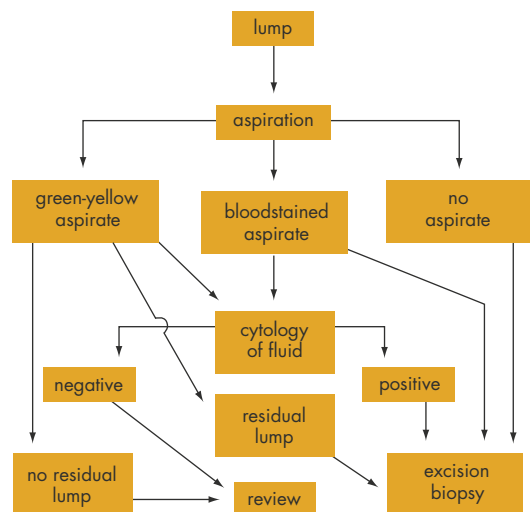

## Tumour markers

Oestrogen receptors are uncommon in normal breasts but are found in two-thirds of breast cancers, although the incidence varies with age. They are good prognostic indicators. Progesterone receptors can also be estimated.

## Fine-needle aspiration of breast lump

This simple technique is very useful, especially if the lump is a cyst, and will have no adverse effects if the lump is not malignant. If it is, the needle biopsy will help with the preoperative cytological diagnosis.

Follow-up: the plan for aspiration is outlined in **FIGURE 101.9**.

**FIGURE 101.9** Scheme for management of a breast lump by fine-needle aspiration

## Summary: investigation of a breast lump

If the patient presenting with a breast lump is younger than 35, perform an ultrasound;<sup>10</sup> if older than 35 perform a mammogram and an ultrasound. If the lump is cystic—aspicate; if solid—perform a fine-needle biopsy and then manage according to outcomes. If it is suspicious, an excisional biopsy is the preferred option.

## Indications for biopsy or excision of lump

- The cyst fluid is bloodstained.
- The lump does not disappear completely with aspiration.
- The swelling recurs within 1 month.

## § Breast cancer

Breast cancer is uncommon under the age of 30 but it then steadily increases to a maximum at the age of about 60 years.<sup>6</sup> About one-third of women who develop breast cancer are premenopausal and two-thirds postmenopausal. Ninety per cent of breast cancers are invasive ductal carcinomas, the remainder being lobular carcinoma, papillary carcinomas, medullary carcinomas and colloid or mucoid carcinomas.<sup>1</sup>

Risk factors include increasing age (>40 years), Caucasian race, pre-existing benign breast lumps, alcohol >1–2 SDs/day, HRT >5 years, personal history of breast cancer, family history in a first-degree relative (raises risk about threefold), nulliparity, late menopause (after 53), obesity, childless until after 30 years of age, early menarche,<sup>9</sup> ionising radiation exposure.

## Familial breast cancer

Up to 5% of cases are familial, with most being autosomal dominant. Refer to **CHAPTER 18**.

## Clinical features

- The majority of patients with breast cancer present with a lump (76%).<sup>6</sup>
- The lump is usually painless (16% associated with pain).
- Usually the lump is hard and irregular.
- Nipple changes, discharge, retraction or distortion.
- Rarely cancer can present with Paget disease of breast (nipple eczema) or inflammatory breast cancer (see **CHAPTER 100**).
- Rarely it can present with bony secondaries (e.g. back pain, dyspnoea, weight loss, headache).

*Note:* There are basically three presentations of the disease:

- the vast majority present with a local breast lump<sup>1</sup>
- ductal carcinoma in situ
- some present with metastatic disease

**FIGURE 101.10** Advanced adenocarcinoma of breast in patient showing denial for a problem of 2 years' duration. Photo courtesy Dr Victor Vanco

Of those who present with local disease, approximately 50% will develop metastatic disease.

### Management

Immediate referral to an expert surgeon on suspicion or proof of breast cancer is essential. The treatment has to be individualised according to the nature of the lump, age of the patient and staging. Accurate staging requires knowledge of whether the draining lymph nodes are involved with the tumour, as this is the single most powerful predictor of subsequent metastases and death. Staging for systemic disease also requires full blood examination and liver function tests (including alkaline phosphatase). A bone scan may be used as a valuable baseline. Size and histological grading of tumour plus nodal status and receptor status are the most important prognostic factors.

Optimal management of locally advanced breast cancer is a combined approach that uses chemotherapy, radiotherapy, surgery and/or endocrine therapy if applicable (level IV evidence).

Most relapses<sup>11</sup> after surgery occur in the first 3 years.

### § Ductal carcinoma in situ

DCIS is a non-invasive abnormal proliferation of milk duct epithelial cells within the ductal-lobular system and is a precursor lesion for invasive breast cancer. Since mammography screening it is readily detected

and now comprises about 20% of breast cancer. It may present clinically with a palpable mass or nipple discharge or Paget disease of the nipple with or without a mass.

### Management

Management decisions are challenging, with options being total mastectomy or breast-conserving therapy with or without radiotherapy. Patients usually have an excellent outcome with low local recurrence rates and a survival of at least 98%.<sup>12</sup>

### Adjuvant therapy for breast cancer

The consultant will choose the most appropriate surgical and adjuvant treatments for the individual patient.

The National Breast Cancer Consensus report emphasised that 'continuing care should be coordinated through the patient's GP as the impact of treatment may last longer than therapy and support must continue'. The report made the following recommendations:<sup>13</sup>

- Tumour excision followed by whole breast irradiation was the most preferred local therapy for most women with stage I or II cancer.
- Total mastectomy and breast-conservation surgery had an equivalent effect on survival.
- Total mastectomy is preferred for a large tumour, multifocal disease, previous irradiation and extensive tumour on mammography.
- Recommendations for radiotherapy after mastectomy are:<sup>14</sup>
  - tumours >4 cm in diameter
  - axillary node involvement of >3 nodes
  - the presence of positive or close tumour margins
- Intraoperative radiotherapy following tumour excision is one of several techniques for partial breast irradiation.<sup>15</sup>
- Cytotoxic chemotherapy has an important place in management, especially in young healthy women who are E receptor negative and have visceral spread.<sup>16</sup> Newer regimens containing anthracyclines (e.g. epirubicin) and a taxane (e.g. docetaxel) have largely replaced the traditional CMF (cyclophosphamide, methotrexate and fluorouracil) regimen.<sup>15</sup>
- Adjuvant hormonal therapy by the anti-oestrogen agent tamoxifen 20 mg (o) daily if E receptor +ve, which is a specific modulating agent, is widely used and is most suitable in postmenopausal women. The usual course is 5 years.

Adjunct agents available for treatment include:<sup>17,18</sup>

- anti-oestrogens (E receptor blockers or SERMS): tamoxifen, toremifene
- aromatase inhibitors (for hormone receptor +ve cancer in postmenopausal women): anastrozole, letrozole, exemestane
- monoclonal antibodies: trastuzumab (Herceptin)
- bisphosphonates: recommended for women with bony metastases since evidence indicates reversal of bone density loss and cancer recurrence<sup>16,17</sup>
- progesterones (e.g. medroxyprogesterone acetate)

Guidelines for adjuvant treatments can be accessed at <[guidelines.nbocc.org.au/guidelines/guideline\\_2.pdf](http://guidelines.nbocc.org.au/guidelines/guideline_2.pdf)>.

## § Fibrocystic disease

Synonyms: fibroadenosis, chronic mastitis, mammary dysplasia, cystic hyperplasia.

### Clinical features

- Most common in women between 30 and 50 years
- Hormone-related (between menarche and menopause)
- Pain and tenderness and swelling
- Premenstrual discomfort or pain and increased swelling
- Fluctuation in the size of the mass
- Usually settles after the period
- Unilateral or bilateral
- Nodularity ± a discrete mass
- Ache may extend down inner aspect of upper arm
- Nipple discharge may occur (various colours, mainly green–grey)
- Most cysts are premenopausal (final 5 years before menopause)

*Examination.* Look for lumpiness in one or both breasts, usually upper outer quadrant.

### Management

- Consider mammography if diffuse lumpiness is present in patient >40 years.
- Perform needle biopsy if a discrete lump is present and aspirate palpable cysts.
- Reassure patient that there is no cancer.
- Give advice to alleviate mastalgia (see treatment for cyclical mastalgia in CHAPTER 100).
- Use analgesics as necessary.
- Surgically remove undiagnosed mass lesions.

## § Breast cyst

- Common in women aged 40–50 years (perimenopausal)
- Rare under 30 years
- Associated with mammary dysplasia
- Tends to regress after the menopause
- Pain and tenderness variable, most asymptomatic
- Has a 1 in 1000 incidence of cancer
- Usually lined by duct epithelium

*Examination.* Look for a discrete mass, firm, relatively mobile, that is rarely fluctuant.

### Diagnosis

- Mammography
- Ultrasound (investigation of choice)
- Cytology of aspirate

### Management

- Drainage with a fine needle
- Surgery is rarely required.

## § Localised nodularity

Usually:

- in upper outer quadrant of breast
- a physiological change to breast
- managed with clinical surveillance
- investigate with imaging in older women if asymmetric or perceived change

## § Lactation cysts (galactoceles)

- These milk-containing cysts arise during pregnancy and present postpartum with similar signs to perimenopausal cysts.
- They vary from 1–5 cm in diameter.
- Treat by aspiration: fluid may be clear or milky.

## § Fibroadenoma

### Clinical features

- A discrete, asymptomatic lump
- Usually in 20s (range: second to sixth decade, commonly 15–35 years)
- Firm, smooth and mobile (the 'breast mouse')
- Usually rounded
- Usually in upper outer quadrant
- They double in size about every 12 months<sup>7</sup>

### Management

Ultrasound and fine-needle aspiration or core biopsy with cytology is recommended plus mammography

in older women. If needle aspiration or core biopsy is negative the patient can be reassured and left unless there is some concern by both patient and surgeon about size or subsequent change. Excision biopsy if large ( $>3\text{--}4\text{ cm}$ ), continues to enlarge, suspicious biopsy or woman  $>40$  years.

### § **Phyllodes tumour<sup>19</sup>**

These are giant fibroadenoma-like tumours that are usually benign but 25% are malignant and metastasise. They are completely excised with a rim of normal breast tissue.

### § **Fat necrosis**

Fat necrosis is usually the end result of a large bruise or trauma that may be subtle, such as protracted breastfeeding. The mass that results is often accompanied by skin or nipple retraction and thus closely resembles cancer. If untreated it usually disappears but the diagnosis can only be made on excision biopsy.

The full triple test is required.

### § **Duct papillomas**

These are benign hyperplastic lesions within large mammary ducts and are not premalignant (nor usually palpable). They present with nipple bleeding or a bloodstained discharge and must be differentiated from infiltrating carcinoma. Mammography and ductography are usually of limited value. The involved duct and affected breast segment should be excised.<sup>19</sup>

### § **Mammary duct ectasia**

Synonyms: plasma cell mastitis, periductal mastitis.

In this benign condition a whole breast quadrant may be indurated and tender. The larger breast ducts are dilated. The lump is usually located near the margin of the areola and is a firm or hard, tender, poorly defined swelling. There may be a toothpaste-like nipple discharge. It is a troublesome condition with a tendency to repeated episodes of periareolar inflammation with recurrent abscesses and fistula formation. Many cases settle but sometimes surgical intervention is necessary to make the diagnosis. The condition is most common in the decade around the menopause.

## **The problem of mammary prostheses<sup>8</sup>**

Clinical examination is still necessary and fortunately the residual mammary tissue is usually spread over the prosthesis in a thin, easily palpable

layer. The areas of clinical difficulty lie at the margin of the prosthesis, especially in the upper outer quadrant where most of the breast tissue is displaced. It should be noted that mammography may be of limited value in the presence of prostheses, especially if a fibrous capsule exists around the prosthesis. Ultrasound examination may be helpful.

### § **Lymphoedema of arm**

This is a long-term complication of surgery plus irradiation for breast cancer treatment when there is a failure of the lymphatic system to adequately drain extracellular fluid. The limb feels tight and heavy with decreased mobility. Exclude obstruction of the deep venous system by Doppler ultrasound.

Skin changes can occur from long-term lymphoedema without treatment, and cellulitis from abrasions and wounds is a concern.

### **Management**

- Encourage movement; elevation of the arm on a pillow at night; avoid slings
- Physiotherapy: a reduction phase with non-elasticised bandages then maintenance with graduated pressure support sleeves
- Elastic sleeves worn all day but not at night
- Lymphoedema massage at home
- Skin hygiene: regular use of non-perfumed emollients, prevention of infection and injury. Avoid sunburn and insect bites
- Avoid BP measurement, venesection and IV therapy in that arm
- Consider diuretics to relieve pressure

## **Breast lumps in children**

There are several benign conditions that can cause a breast lump in children, although the commonest presentation is a diffuse breast enlargement.

### **Neonatal enlargement<sup>20</sup>**

Newborn babies of either sex can present with breast hyperplasia and secretion of breast milk (see CHAPTER 91). This is due to transplacental passage of lactogenic hormones. The swelling usually lasts 7–10 days if left alone. Any attempts to manipulate the breasts to facilitate emptying will prolong the problem.

### **Premature hyperplasia<sup>20</sup>**

The usual presentation is the development of one breast in girls commonly 7–9 years of age but

sometimes younger. The feature is a firm discoid lump 1–2 cm in diameter, situated deep to the nipple. The same change may follow in the other breast within 3–12 months. Reassurance and explanation is the management and biopsy must be avoided at all costs.

### Counselling of patients

‘Treat the whole woman, not merely her breasts.’<sup>8</sup> Extreme anxiety is generated by the discovery of a breast lump and it is important that women are encouraged to visit their doctor early, especially as they can learn that there is a 90% chance of their lump being benign. It is possible that denial may be a factor or there is a hidden agenda to the consultation. The decision to perform a lumpectomy or a mastectomy should take the patient’s feelings into consideration—many do fear that a breast remnant may be a focus for cancer. Long-standing doctor–patient relationships are the ideal basis for coping with the difficulties.

### Screening

Screening mammography should be encouraged for women between 50 and 70 years, and performed at least every 2 years (see CHAPTER 9). Technically it is a better diagnostic tool in older women because of the less dense and glandular breast tissue. It has a specificity of around 90%. A management program for women at high risk of breast cancer is presented in TABLE 101.5.

Breast self-examination is a controversial issue and has no proven benefit in reducing morbidity and mortality. The false positive rate is high, especially in those under 40 years. However, regular BSE is recommended for all women 35 years and over.

### When to refer

- Patients with a solitary breast mass
- Following cyst aspiration:
  - blood in aspirate
  - palpable residual lump
  - recurrence of the cyst
- Patients given antineoplastic drugs, whether for adjuvant therapy or for advanced disease, require skilled supervision

Lumps that require investigation and referral are presented in TABLE 101.6.

Table 101.5 Management program for women at high risk of breast cancer<sup>9</sup>

- Monthly breast self-examination
- At least an annual consultation with GP—if aged 40 or older
- Aspiration of cysts
- Mammography, ultrasound and/or fine-needle biopsy to diagnose any localised mass
- Ultrasound alone for further assessment of young, dense breasts
- Regular screening mammography after 50 years of age—every 2 years

Source: After Barraclough<sup>9</sup>

Table 101.6 Lumps that require investigation and referral<sup>8</sup>

- A stony, hard lump or area, regardless of size, history or position
- A new palpable ‘anything’ in a postmenopausal woman
- A persisting painless asymmetrical thickening
- An enlarging mass—cyclic or not
- A ‘slow-to-resolve’ or recurrent inflammation
- A bloodstained or serous nipple discharge
- Skin dimpling, of even a minor degree, or retraction of the nipple
- A new thickening or mass in the vicinity of a scar

Source: After Hirst<sup>8</sup>

### Practice tips

- Any doubtful breast lump should be removed.
- Fibroadenomas commonly occur in women in their late teens and 20s, benign breast cysts between 35 years and the menopause, and cancer is the most common cause of a lump in women over 50 years.<sup>6</sup>
- Never assume a palpable mass is a fibroadenoma in any woman over 30 years of age.<sup>8</sup>
- Gentle palpation is required. Squeezing breast tissue between finger and thumb tends to produce ‘pseudolumps’.
- Any eczematous rash appearing on the nipple or areola indicates underlying breast cancer.

- Mammary duct ectasia and fat necrosis can be clinically indistinguishable from breast cancer.
- Nine out of 10 women who get breast cancer do not have a strong family history.
- The oral contraceptive pill has been generally shown *not* to alter the risk of breast cancer.
- Never assume that a lump is due to trauma unless you have seen the bruising and can observe the lump decrease in size.<sup>8</sup>
- Never assume a lesion is a cyst—prove it with ultrasound or successful aspiration.<sup>8</sup>
- Never ignore skin dimpling even if no underlying mass is palpable.<sup>8</sup>
- Never ignore a woman's insistence that an area of her breast is different or has changed.<sup>8</sup>
- Mammography can detect breast cancers which are too small to feel.
- Mammography is not a diagnostic tool.
- Recommended mammography screening for women 50–69 years and those aged 40–49 who request it.

SORAMUS OF EPHEBUS (2ND CENTURY), TEXT ON DISEASES OF WOMEN

Abnormal uterine bleeding is a common problem encountered in general practice. Heavy menstrual bleeding is the commonest cause of iron-deficiency anaemia in the Western world. A classification of abnormal uterine bleeding is presented in **TABLE 102.1**.

**Table 102.1** Classification of abnormal uterine bleeding

Abnormal rhythm
Irregularity of cycle
Intermenstrual bleeding (metrorrhagia)
Postcoital bleeding
Postmenopausal bleeding
Abnormal amount
Increased amount = menorrhagia
Decreased amount = hypomenorrhoea
Combination (rhythm and amount)
Irregular and heavy periods = metromenorrhagia
Irregular and light periods = oligomenorrhoea

### Key facts and checkpoints

- Up to 20% of women in the reproductive age group complain of increased menstrual loss.<sup>1</sup>
- At least 4% of consultations in general practice deal with abnormal uterine bleeding.
- Up to 50% of patients who present with perceived menorrhagia (or excessive blood loss) have a normal blood loss when investigated.<sup>1</sup> Their perception is unreliable.
- The possibility of pregnancy and its complications, such as ectopic pregnancy, abortion (threatened, complete or incomplete), hydatidiform mole or choriocarcinoma should be kept in mind.<sup>2</sup>
- A menstrual record is a useful way to calculate blood loss.

- The mean blood loss in a menstrual cycle is 30–40 mL.
- Blood loss is normally less than 80 mL.
- Heavy menstrual bleeding (menorrhagia)—HMB—is a menstrual loss of more than 80 mL per menstruation.
- HMB disposes women to iron-deficiency anaemia.
- Two common organic causes of HMB are fibroids and adenomyosis (presence of endometrium in the uterine myometrium).<sup>3</sup>
- Various drugs can alter menstrual bleeding (e.g. anticoagulants, cannabis, steroids).

### Defining what is normal and what is abnormal

This feature is based on a meticulous history, an understanding of the physiology and pathophysiology of the menstrual cycle and a clear understanding of what is normal. Most girls reach menarche by the age of 13 (range 10–16 years).<sup>1</sup> Dysfunctional bleeding is common in the first 2–3 years after menarche due to many anovulatory cycles resulting in irregular periods, heavy menses and probably dysmenorrhoea.

Once ovulation and regular menstruation are established the cycle usually follows a predictable pattern and any deviation can be considered as abnormal uterine bleeding (see **TABLE 102.2**). It is abnormal if the cycle is less than 21 days, the duration of loss is more than 7 days, or the volume of loss is

**Table 102.2** Normal menstruation in the reproductive age group

	Mean	Range
Length of cycle	26–28 days	21–35 days
Menstrual flow	3–4 days	2–7 days
Normal blood loss	30–40 mL	20–80 mL

Source: After Fung<sup>1</sup>

such that menstrual pads of adequate absorbency cannot cope with the flow or clots.<sup>4</sup>

A normal endometrial thickness, as measured by ultrasound, is between 6 and 12 mm. The menstrual cycle is confirmed as being ovulatory (biochemically) if the serum progesterone (produced by the corpus luteum) is  $>20$  nmol/L during the mid-luteal phase (5–10 days before menses).<sup>2</sup>

## Relationship of bleeding to age

Dysfunctional uterine bleeding (DUB) is more common at the extremes of the reproductive era (see FIG. 102.1).<sup>2,3</sup> The incidence of malignant disease as a cause of bleeding increases with age, being greatest after the age of 45, while endometrial cancer is predicted to be less than 1 in 100 000 in women under the age of 35.<sup>1</sup>

**FIGURE 102.1** The relationship between age and various causes of abnormal uterine bleeding. Dysfunctional uterine bleeding is more common in the extremes of the reproductive era, while the incidence of cancer as a cause of bleeding is greatest in the perimenopausal and postmenopausal phases.

Source: After Mackay et al<sup>2</sup>

## Heavy menstrual bleeding

### Heavy menstrual bleeding is:

- blood loss  $>80$  mL per menstrual cycle
- bleeding that persists  $>7$  days
- bleeding that is unacceptable to the woman

Menorrhagia<sup>4</sup> is essentially caused by excessive local production of prostaglandins in the endometrium and myometrium and/or excessive local fibrinolytic activity. Heavy bleeding, possibly with clots, is the

major symptom of menorrhagia. Dysmenorrhoea may accompany the bleeding and, if it does, endometriosis or PID should be suspected. With care a 60–80% accuracy can be achieved in clinical assessment.<sup>4</sup> A summary of the diagnostic strategy model is presented in TABLE 102.3.

By far the most common single ‘cause’ of menorrhagia is ovulatory dysfunctional uterine bleeding (DUB). Anovulatory DUB occurs at the extremes of the reproductive period—around menarche and perimenopausally. The most common organic causes are fibromyomas (fibroids),

**Table 102.3** HMB: diagnostic strategy model

Q. Probability diagnosis
A. Dysfunctional uterine bleeding—ovulatory
Fibroids
Complications of hormone therapy
Adenomyosis
Q. Serious disorders not to be missed (see TABLE 101.4)
A. Disorders of pregnancy:
• ectopic pregnancy
• abortion or miscarriage
Neoplasia:
• cervical cancer
• endometrial cancer
• oestrogen-producing ovarian tumour (cancer)
• leukaemia
• benign tumours (polyps, etc.)
Endometrial hyperplasia
Severe infections:
• PID
Q. Pitfalls (often missed)
A. Genital tract trauma
IUCD
Adenomyosis/endometriosis
Pelvic congestion syndrome
SLE
Rarities:
• endocrine disorders (e.g. thyroid disease)
• bleeding disorder (e.g. von Willebrand disease)
• liver disease
Q. Seven masquerades checklist
A. Depression (association)
Diabetes
Drugs
Anaemia (association)
Thyroid disorder (hypothyroidism)
Q. Is the patient trying to tell me something?
A. Consider exaggerated perception. Note association with anxiety and depression.

**Table 102.4** Important 'not to miss' causes of irregular bleeding<sup>5</sup>

15–20	20–30	30–45	45–55	55 + (years)
Chlamydia/PID			Endometrial/ovarian cancer	
Pregnancy and pregnancy complications				
		Endometrial polyps		
		Endometrial hyperplasia		
Cervical cancer <sup>5</sup> —————>				

endometriosis, adenomyosis ('endometriosis' of the myometrium), endometrial polyps and PID.<sup>2</sup>

Acute heavy bleeding or 'flooding' most often occurs in pubertal girls before regular ovulation is established.

## History

Bearing in mind that abnormal uterine bleeding is a subjective complaint, and a detailed history is the key initial step in management. The patient's perception of abnormal bleeding may be quite misleading and education about normality is all that is necessary in her management. A meticulous history should include details of the number of tampons or pads used and their degree of saturation. A menstrual calendar (over 3+ months) can be a very useful guide. A history of smoking and other psychosocial factors should be checked. For unknown reasons, cigarette smokers are five times more likely to have abnormal menstrual function.<sup>1</sup>

Questions need to be directed to rule out:<sup>1</sup>

- pregnancy or pregnancy complications (e.g. ectopic pregnancy)
- trauma of the genital tract
- medical disorders (e.g. bleeding disorder)
- endocrine disorders
- cancer of the genital tract
- complications of the pill

## Examination<sup>1</sup>

A general physical examination should aim at ruling out anaemia, evidence of a bleeding disorder and any other stigmata of relevant medical or endocrine disease.

Specific examinations include:

- speculum examination: ? ulcers (cervical cancer) or polyps

- Pap test (ensure up to date)
- bimanual pelvic examination: ? uterine or adnexal tenderness, size and regularity of uterus

It is prudent to avoid vaginal examination in selected patients, such as a young virgin girl, as the procedure is unhelpful and unnecessarily traumatic.

## Investigations

Investigations, especially vaginal ultrasound scans, should be selected very carefully and only when really indicated. Abnormal pelvic examination findings, persistent symptoms, older patients and other suspicions of disease indicate further investigation to confirm symptoms of menorrhagia and exclude pelvic or systemic pathology.

Consider foremost:

- full blood count (to exclude anaemia and thrombocytopenia)
- iron studies: serum ferritin

Special investigations (only if indicated):

- pregnancy testing (SBHG)
- laparoscopy where endometriosis, PID or other pelvic pathology is suspected
- serum biochemical screen
- coagulation profile screen
- thyroid function tests, especially TSH
- tests for SLE: antinuclear antibodies
- transvaginal ultrasound

**Ultrasound:** reserved for women who fail conservative treatment or who are at increased risk of endometrial cancer (see later in this chapter). US is an initial screening tool for identifying risk—high and low. It is best performed in the first half of the menstrual cycle when endometrial thickness should be requested. If it is >12 mm for premenopausal women or >5 mm for perimenopausal women, endometrial biopsy (with or without hysteroscopy) is indicated.

**Note:** Hysteroscopy and D&C remain the gold standard for abnormal uterine bleeding. In some women, a transvaginal ultrasound, Pipelle endometrial sampling or hysteroscopy and D&C will be indicated.<sup>6</sup>

## § Dysfunctional uterine bleeding

DUB, which is a diagnosis of exclusion, is defined as 'excessive bleeding, whether heavy, prolonged or frequent, of uterine origin, which is not associated with recognisable pelvic disease, complications of pregnancy or systemic disease'.<sup>2</sup>

### Clinical features

- It is a working clinical diagnosis based on the initial detailed history, normal physical examination and normal initial investigation.
- Very common: 10–20% incidence of women at some stage. It is more common in ovulatory (regular) rather than anovulatory (irregular) cycles.
- Peak incidence of ovulatory DUB in late 30s and 40s (35–45 years).
- Anovulatory DUB has two peaks: 12–16 years and 45–55 years. The bleeding is typically irregular with spotting and variable menorrhagia.
- The majority complain of menorrhagia.
- The serum progesterone and the pituitary hormones (LH and FSH) will confirm anovulation.
- Up to 40% with the initial diagnosis of DUB will have other pathology (e.g. fibroids, endometrial polyps) if detailed pelvic endoscopic investigations are undertaken.

### Symptoms

- Heavy bleeding: saturated pads, frequent changing, 'accidents', 'flooding', 'clots'
- Prolonged bleeding:
  - menstruation >7–8 days
  - or
  - heavy bleeding >4 days
- Frequent bleeding—periods occur more than once every 21 days
- Pelvic pain and tenderness are not usually prominent features

### Principles of management<sup>7</sup>

- Establish diagnosis by confirming symptoms and exclude other pathology.
- If no evidence of iron deficiency or anaemia, and significant pathology has been excluded, prospective assessment of the menstrual pattern is indicated using a menstrual calendar.
- Conservative management is usually employed if the uterus is of normal size and there is no evidence of anaemia.
- Drug therapy is indicated if symptoms are persistently troublesome and surgery is contraindicated or not desired by the patient and D&C doesn't alleviate.

- Provide reassurance about the absence of pathology, especially cancer, and give counselling to maximise compliance with treatment.
- Consider surgical management if fertility is no longer important and symptoms cannot be controlled by at least 3–4 months of hormone therapy.

### Medical and surgical management<sup>4,7</sup>

#### Medical

Treatment regimens are presented in TABLES 102.5 and 102.6. First-line treatment is with fibrinolytic

Table 102.5	Regimens used in management of HMB <sup>4</sup> (includes options)	
		Mean reduction <sup>12</sup> in blood loss 80 mL/cycle %
Therapy		
Levonorgestrel (IUD) Mirena 52 mg—replace every 5 years		94
Oral progestogen		87
Ovulatory cycle:		
• medroxyprogesterone 10 mg (o), 1–3 times daily on days 1–21 (of 28-day cycle)—up to 6 months		
or		
• norethisterone 5 mg (o) 2–3 times daily on days 1–21 of cycle—up to 6 months		
Anovulatory cycle:		
• medroxyprogesterone 10 mg, once daily for the same 12 days of each calendar month		
or		
• norethisterone 5 mg (o), once daily for the same 12 days of each calendar month		
Tranexamic acid 1 g (o) 6 hourly on days 1–4 of menstruation		47
Combined oral contraceptive pill		43
NSAIDs (oral):		29
• ibuprofen 400 mg 3–4 times daily		
• naproxen 500 mg statim then 250 mg every 6–8 hours		
• mefenamic acid 500 mg tds		

\*Effectiveness supported by EBM<sup>7</sup>

**Table 102.6** Typical treatment options for acute and chronic heavy bleeding<sup>4,10</sup>

#### Acute heavy bleeding

##### Curettage/hysteroscopy

- oral high-dose progestogens (e.g. norethisterone 5–10 mg 4 hourly until bleeding stops then 5 mg bd or tds for 14 days<sup>3</sup>)

#### Chronic bleeding

##### For anovulatory women:

- cyclical oral progestogens for 12 days
- tranexamic acid

##### For ovulatory women:

- cyclical prostaglandin inhibitor (e.g. mefenamic acid) or (one of)
- oral contraceptive
- antifibrinolytic agent (e.g. tranexamic acid 1 g (o) qid, days 1–4)
- progesterone-releasing IUDs (e.g. Mirena)

inhibitors or antiprostaglandin agents, given as soon as possible and throughout the menses. These agents are simple to use, generally very safe and can be used over long periods of time. About 60–80% of patients with ovulatory menorrhagia will respond if compliance is good.<sup>4</sup> Such agents include tranexamic acid, mefenamic acid, naproxen, ibuprofen and indomethacin. The agent of first choice is usually mefenamic acid, which reduces blood loss by 20–25% as well as helping dysmenorrhoea. Treatment needs to start just before or with the onset of menstrual bleeding and continue for up to 5 days. Evidence-based reviews confirm the benefit of NSAIDs and tranexamic acid for menorrhagia over the other agents.<sup>6</sup>

Hormonal agents include progestogens, combined oestrogen–progestogen oral contraceptives and danazol.<sup>8,9</sup> The COC constitutes important first-line therapy in both ovulatory and anovulatory patients, but at least 20% of patients do not respond.

Progestogens can be given via several routes. Oral use is usually of no benefit in ovulatory DUB. In the adolescent with anovulatory DUB, cyclical oral progestogens may be required for 6 months until spontaneous regular ovulation eventuates.<sup>8</sup> Intramuscular medroxyprogesterone acetate (Depo-Provera) will induce amenorrhoea in 50% of users in 1 year.

The most effective agent for both ovulatory and anovulatory DUB is tranexamic acid, which inhibits endometrial plasminogen activation. The dose is 1 g (up to 1.5 g if necessary) orally qid for the first 4 days

of the menstrual cycle commencing at the onset of visible bleeding.<sup>4,10</sup>

The intra-uterine progesterone implant system (Mirena) releasing 20 mcg of levonorgestrel/day has shown considerable effectiveness.<sup>11</sup> It is regarded as the most efficacious of the hormone treatments with a mean blood loss of 94% of women with menorrhagia.<sup>7</sup>

## Surgical treatment

This is indicated if menorrhagia interferes with lifestyle despite medical (drug) treatment. The surgical options are:

- endometrial ablation or electrodiathermy excision—to produce amenorrhoea
- hysterectomy; this requires a very carefully planned approach. It is preferred to drug therapy for women with endometrial hyperplasia with atypia—endometrial ablation is not appropriate

## Practice tip

### Emergency menorrhagia (acute flooding)<sup>4</sup>

#### First line:

- tranexamic acid 10 mg/kg IV, every 8 hours until bleeding stops
- or
- tranexamic acid 1–1.5 g (o) 6 to 8 hourly until bleeding stops

If above unavailable or not tolerated, other options are:

- norethisterone 5–10 mg 4 hourly (o) till bleeding stops, then 5 mg bd or tds (or 10 mg daily) for 14 days
- or
- medroxyprogesterone acetate 10 mg (o) 4 hourly until bleeding stops for 7 days then 20 mg daily for 21 days
- or
- COCP e.g. until bleeding stops then re-evaluate after 48 hours

## General guidelines for surgical intervention

### Women who:<sup>4</sup>

- no longer wish to be able to conceive
- are perimenopausal
- have poorly controlled symptoms
- have adverse effects from the drugs
- have significant uterine pathology

## Cycle irregularity<sup>13</sup>

For practical purposes patients with irregular menstrual cycles can be divided into those under 35 and those over 35 years.

Patients under 35 years:

- the cause is usually hormonal, rarely organic, but keep malignancy in mind
- management options:<sup>1</sup>
  - explanation and reassurance (if slight irregularity)
  - COC pill for better cycle control—any pill can be used
  - progestogen-only pill (especially anovulatory cycles) norethisterone (Primolut N) 5–15 mg/day from day 5–25 of cycle

Patients over 35 years should be referred for investigation for organic pathology, usually by endometrial sampling and/or hysteroscopy. If normal, the above regimens can be instituted.

## Intermenstrual bleeding and postcoital bleeding

These bleeding problems are due to factors such as cervical ectropion (often termed cervical erosion), cervical polyps, the presence of an IUCD and the oral contraceptive pill. Cervical cancer and intra-uterine cancer must be ruled out, hence the importance of a Pap test in all age groups and endometrial sampling, especially in the over-35 age group. Mismanagement of these presentations is a legal minefield. A Pap smear should be taken, using the speculum carefully so as not to provoke bleeding, if one has not been taken within the previous 3 months, and sent to a laboratory that uses appropriate quality control procedures with notation of the bleeding on the smear request form. Remember that it is only a screening test. Refer women with these bleeding problems with an abnormal smear or even without any unusual features. Those with a friable ectropion that is causing persistent symptoms should also be referred.<sup>14</sup> Thus, intermenstrual bleeding (IMB) should always be investigated. Order a pregnancy test if appropriate.

Cervical ectropion, which is commonly found in women on the pill and postpartum, can be left untreated unless intolerable discharge or moderate postcoital bleeding (PCB)<sup>1</sup> is present. An IUCD should be removed if causing significant symptoms and the causative pill should be changed.

## § Uterine fibroids (leiomyoma)

Fibroids are benign tumours of smooth muscle of the myometrium. They are classified according to their location: subserosal, intramural, subendometrial or intra-uterine. They are oestrogen-dependent and shrink with onset of menopause.

### Clinical features

- Present in 30% of women >35
- Only 1 in 800 develop malignancy
- Usually asymptomatic

### Symptoms (especially if large)

- Menorrhagia
- Dysmenorrhoea
- Pelvic discomfort ± pain (pressure)
- Bladder dysfunction
- Pain with torsion of pedunculated fibroid
- Pain with 'red degeneration'—only in pregnancy (pain, fever, local tenderness)

### Other features

- Infertility (acts like IUCD if submucosal)
- Calcification

### Examination

- Bulky uterus

### Investigations

- Pelvic ultrasound (investigation of choice). Endometrial thickening >4 mm demands endometrial sampling. If >7 mm, endometrial cancer should be excluded. CT scan and plain X-ray of limited value but MRI is accurate
- FBE ? anaemia
- Uterine biopsy (malignancy suspected)

### Management

- Consider COCP (30 mcg oestrogen can reduce bleeding)
- GnRH analogues—especially if >42 years can shrink fibroids (maximum 6 months)—use only immediately pre-operative
- Surgical options:
  - myomectomy (remove fibroids only, esp. child-bearing years)
  - hysteroscopic resection/endometrial ablation
  - hysterectomy
- Other option: uterine embolisation

## § Cervical cancer

This should be the diagnosis until proved otherwise for postcoital, intermenstrual or postmenopausal bleeding.

### Clinical features

- Peak incidence in sixth decade
- 80% due to squamous cell carcinoma
- Risk factors (refer CHAPTER 98)

### Symptoms

- Postcoital bleeding
- Intermenstrual bleeding
- Vaginal discharge—may be offensive

Mainly diagnosed on routine screening.

### Examination

- Ulceration or mass on cervix
- Bleeds readily on contact—may be friable

### Management

- Urgent gynaecological referral

## § Endometrial cancer

This is the diagnosis until proved otherwise in any woman presenting with postmenopausal bleeding.

### Clinical features

- Peak incidence 50–70 years
- Risk factors:
  - age
  - obesity
  - nulliparity
  - late menopause
  - diabetes mellitus
  - history of chronic anovulatory bleeding
  - polycystic ovarian syndrome
  - drugs (e.g. unopposed oestrogen, tamoxifen)
  - family history—breast, ovarian, endometrial or colon cancer (Lynch syndrome)

### Symptoms

Ninety per cent present with abnormal bleeding, especially postmenopausal bleeding.<sup>3</sup>

*Note:* intermenstrual bleeding or prolonged bleeding in postmenopausal women should be treated with suspicion.

### Examination

- Uterus usually feels normal, but may be bulky.

### Investigations

- Smear (after pregnancy excluded)—detects some cases. Endometrial cancer is not excluded by a normal cervical smear
- Transvaginal ultrasound/endometrial biopsy

### Management

- Urgent gynaecological referral

## § Endometriosis

Refer to CHAPTER 103.

## Amenorrhoea and oligomenorrhoea

Amenorrhoea is classified as primary or secondary.

Primary amenorrhoea is the failure of the menses to start by 16 years of age.<sup>2</sup> Secondary amenorrhoea is the absence of menses for over 6 months in a woman who has had established menstruation.<sup>15</sup>

The main approach in the patient with primary amenorrhoea is to differentiate it from delayed puberty, in which there are no signs of sexual maturation by age 13. It is important to keep in mind the possibility of an imperforate hymen and also excessive exercise, which can suppress hypothalamic GnRH production. A good rule is to note the presence of secondary sex characteristics.<sup>2</sup> If absent it implies that the ovaries are non-functional. Causes of primary amenorrhoea include genital malformations, ovarian disease, pituitary tumours, hypothalamic disorder and Turner syndrome. Diagnostic tests include serum FSH, LH, prolactin, oestradiol and also chromosome analysis. Early referral is appropriate.

In secondary amenorrhoea, consider a physiological cause such as pregnancy or the menopause, failure of some part of the hypothalamic-pituitary-ovarian-uterine axis (e.g. PCOS) or a metabolic disturbance. Important causes to consider are emotional, psychiatric and constitutional causes such as anorexia nervosa, hyperprolactinaemia, strenuous exercise, weight loss below 75% of ideal, and drugs/hormone therapy (e.g. oral contraceptives).

Oligomenorrhoea is the term for infrequent and usually irregular periods, where the cycles are between 6 weeks and 6 months.

Gynaecological intervention is appropriate for women with prolonged amenorrhoea due to the increased risk of endometrial cancer.

## § Premature ovarian failure

Apart from iatrogenic causes this may be caused by idiopathic early menopause and autoimmune ovarian failure. It can be treated with mid- to high-dose oestrogens plus corresponding cyclical progestogen or cyclical combined preparations.<sup>4</sup>

## Postmenopausal bleeding

Postmenopausal bleeding is vaginal bleeding of any amount occurring 6 months or more after the menopause.<sup>2</sup> It suggests cervical or uterine body cancer (up to 25%).<sup>2</sup> Other causes include polyps, atrophic vaginitis, endometrial hyperplasia and urethral caruncle. Care has to be taken with women on HRT who have irregular bleeding—they require investigation.

Early referral is usually indicated with a view to a diagnostic procedure (hysteroscopy and D&C). If bleeding recurs despite curettage, hysterectomy should be performed since early cancer of the uterus may be missed.

## When to refer

- As indicated by investigation results
- Women with persistent IMB and/or PCB without any unusual features
- Women with IMB/PCB and an abnormal smear<sup>14</sup>
- Women with a friable ectropion
- To exclude intra-uterine pathology
- The patient does not respond to initial therapy
- There is evidence of underlying disease (e.g. endometriosis, SLE)
- Surgery is indicated (minor or major)

## Practice tips

- Remember that mental dysfunction can obscure the organic causes of menorrhagia.
- Non-menstrual bleeding suggests cancer until proved otherwise: it may be postcoital (cervical cancer); intermenstrual (common with progestogen-only pill); postmenopausal (endometrial cancer).
- Hysteroscopy is more effective than the traditional curettage. Studies have shown that usually less than 50% of the uterine cavity is sampled by curettage.<sup>15</sup>

ANONYMOUS

Pain in the lower abdomen and pelvis is one of the most frequent symptoms experienced by women. The diagnostic approach requires a wide variety of consultative skills, especially when the pain is chronic. The examination of acute abdominal pain has been simplified by the advent of sensitive serum pregnancy tests, ultrasound investigation and the increasing use of laparoscopy. However, an accurate history and examination for all types of pain will generally pinpoint the diagnosis. The ever-present problem of PID, the leading cause of infertility in women, demands an early diagnosis and appropriate management.

### Key facts and checkpoints

- A distinction has to be made between acute, chronic and recurrent pain.
- Ectopic pregnancy remains a potentially lethal condition and its diagnosis still requires a high index of suspicion.
- Sudden sharp pain in the pelvis that becomes more generalised indicates rupture of an ectopic pregnancy or an ovarian cyst.
- Recurrent sharp self-limiting pain indicates a ruptured Graafian follicle (mittelschmerz).
- Recurrent pain related to menstruation is typical of dysmenorrhoea or endometriosis.
- A UK study<sup>1</sup> of chronic lower abdominal pain in women showed the causes were adhesions (36%), no diagnosis (19%), endometriosis (14%), constipation (13%), ovarian cysts (11%) and PID (7%). An Australian study found that endometriosis accounted for 30% and adhesions 20%.<sup>2</sup>
- The principal afferent pathways of the pelvic viscera arise from T10–12, L1 and S2–4. Thus disorders of the bladder, rectum, lower uterus, cervix and upper vagina can refer pain to the low back, buttocks and posterior thigh.<sup>3</sup>

### A diagnostic approach

A summary of the diagnostic strategy model is presented in **TABLE 103.1**.

### Probability diagnosis

The commonest causes are primary dysmenorrhoea, the pain of a ruptured Graafian follicle (mittelschmerz),

endometriosis and adhesions. In many instances of pain no diagnosis is made as no pathological cause can be found.

### Serious disorders not to be missed

The potentially lethal problem of a ruptured ectopic pregnancy must not be missed, hence the axiom 'be ectopic minded'. PID can be overlooked, especially if chronic, and requires early diagnosis and aggressive treatment. Neoplasia must be considered, especially malignancy of pelvic structures, including the 'silent' ovarian cancer.

### Pitfalls

Several disorders are very difficult to diagnose and these include haemorrhage into the ovary or a cyst, torsion of the ovary or pedunculated fibroid. Endometriosis may be missed so it is important to be familiar with its symptoms. Chronic constipation may be a trap.

### Seven masquerades checklist

Two important conditions to consider are urinary tract infection and spinal dysfunction. Just as disorders of the pelvic organs, such as endometriosis and PID, can refer pain to the low back and buttocks, so can disorders of the lumbosacral spine cause referred pain to the lower abdomen and groin.

### Psychogenic considerations

These can be extremely relevant. Problems in the patient's social, marital or sexual relationships should be evaluated, especially in the assessment of chronic

pain. Many patients with undiagnosed chronic pain exhibit psychoneurotic traits and this renders management very complex. Some appear to have the 'pelvic congestion syndrome' and need to be handled with sensitivity and tact, especially if the help of a psychiatrist or psychologist is sought.

## The clinical approach

### History

The pain should be linked with the menstrual history, coitus and the possibility of an early pregnancy. For recurrent and chronic pain, it is advisable to instruct the patient to keep a diary over two menstrual cycles. The severity of the pain can be assessed as follows:<sup>2</sup>

- does not interfere with daily activity
- results in days off work
- results in confinement to bed

In this way the pain can be classified objectively as mild, moderate or severe.

Risk factors in the past history should be assessed, for example:

- IUCD (salpingitis, ectopic pregnancy)
- infertility (endometriosis, salpingitis)
- tubal surgery (ectopic)

The typical pain patterns in relation to menstruation are shown in **FIGURE 103.1**.

### Examination

One objective is to correlate any palpable tenderness with the patient's statement of the severity of the pain. Use the traditional abdominal and pelvic

**FIGURE 103.1** Typical pain patterns for menstrual cycle related gynaecological pain

examination to identify the site of tenderness and rebound tenderness, and any abdominal or pelvic masses. The pelvis should be examined by speculum (preferably bivalve type) and bimanual palpation.

Proper assessment can be difficult if the patient cannot relax or overreacts, if there is abdominal scarring or obesity, or if extreme tenderness is present. It is therefore important, especially in the younger and apprehensive patient, to conduct a gentle, caring vaginal examination with appropriate explanation and reassurance. Explanation of the procedure during vaginal examination, preferably using eye contact with the patient, can help her relax and be more confident in the procedure.

### Investigations

Investigations may be selected from:

- haemoglobin level
  - white blood cell count (limited value)
  - haematocrit
  - ESR/CRP
  - microbiology (limited value):
    - urine for microscopy and culture  $\pm$  *Chlamydia* PCR
    - endocervical, urethral, cervical and vaginal swabs
  - serum  $\beta$ -hCG assay
  - urinary hCG tests (can be negative in the presence of an ectopic pregnancy)
- Diagnostic imaging:
- vaginal ultrasound—to define a gestation sac
  - pelvic ultrasound—to differentiate a cystic from a solid pelvic mass Indicated for:
    - pelvic pain
    - a palpable pelvic mass
    - a palpable lower abdominal mass
    - ascites

Laparoscopy is indicated if the history and examination are suggestive of ectopic pregnancy and ultrasound fails to confirm an intra-uterine pregnancy.

### Acute pain

The causes of acute pain are summarised in **TABLE 103.2**. The patient is usually young (20–30 years old), sexually active and distressed by the pain, and should be considered foremost to have a bleeding ectopic pregnancy. Important differential diagnoses include acute PID, rupture or torsion of an ovarian cyst and acute appendicitis. Cases of acute ruptured ectopics are obviously easier to diagnose in the presence of circulatory collapse.

**Table 103.2** Causes of acute lower abdominal and pelvic pain in women<sup>3</sup>

Genital
Acute salpingitis
Pelvic peritonitis
Bleeding
Rupture or torsion of ovarian cyst
Threatened or incomplete abortion
Rupture or aborting tubal ectopic pregnancy
Rupture or bleeding endometrioma
Non-genital
Acute appendicitis
Bowel obstruction
Urinary tract infection (cystitis)
Ureteric colic (calculus)
Functional
Primary dysmenorrhoea
Retrograde menstruation

Source: After Soo Keat Khoo<sup>3</sup>

### Chronic pain

Chronic pelvic pain is constant or recurrent pain of at least 6 months' duration.

#### Features

- Incidence 15% in 18–50-year-olds
- Endometriosis causes 33%, adhesions 24%
- It is the reason for up to 40% of gynaecological laparoscopies
- Reason for 15% hysterectomies

The pain can be cyclical (e.g. endometriosis, mittelschmerz) or continuous.

The common causes of chronic pain are listed in **TABLE 103.3**. Chronic pain is more difficult to diagnose and it is often difficult to differentiate between problems such as endometriosis, PID, an ovarian neoplasm and the irritable bowel syndrome. A comparison of the clinical features of endometriosis and PID is presented in **TABLE 103.4**. Furthermore it is difficult to distinguish clinically between endometriosis of the uterus (adenomyosis) and pelvic congestion syndrome. Both conditions are associated with dysmenorrhoea and a tender normal-sized uterus.

**Table 103.3** Causes of chronic lower abdominal and pelvic pain in women<sup>3</sup>

Genital
Endometriosis/adenomyosis
Pelvic inflammatory disease (chronic; adhesions)
Ovarian neoplasm
Fibromyomata (rarely)
Non-genital
Diverticulitis
Bowel adhesions
Irritable bowel syndrome
Urinary disorders e.g. urethral syndrome
Functional
Secondary dysmenorrhoea—IUCD, polyp
Irritable bowel, chronic bowel spasm

## § Ectopic pregnancy

Ectopic pregnancy occurs approximately once in every 100 clinically recognised pregnancies. If ruptured it can be a rapid, fatal condition so we have to be 'ectopic minded'. It is the commonest cause of intraperitoneal haemorrhage. There is usually a history of a missed period but a normal menstrual history may be obtained in some instances.

### Clinical features of a ruptured ectopic pregnancy

- Average patient in mid-20s
- First pregnancy in one-third of patients
- Patient at risk
  - previous ectopic pregnancy
  - previous PID
  - previous abdominal or pelvic surgery, especially sterilisation reversal

**Table 103.4** Comparison of clinical features of PID and pelvic endometriosis

Feature	Chronic PID	Endometriosis
History	Acute pelvic infection (e.g. ruptured appendix) IUCD usage	Dysmenorrhoea Infertility Dyspareunia Pelvic pain
Pelvic pain	+ to ++ (mild to moderate) Premenstrual Lower abdominal location	++ to +++ (moderate to severe) Premenstrual and menstrual Acute pain if rupture of endometrioma
Backache	+ mild	++ moderate Low sacral pain with menstruation
Secondary dysmenorrhoea	Moderate to severe From onset of acute PID Decreases with menstruation	Moderate to severe Gradual onset increases in severity throughout menstruation
Menstruation	Irregular and heavy	Heavy
Dyspareunia	Moderate	Often severe
Infertility	+++	++
Urinary symptoms	—	Frequency, dysuria and haematuria if bladder wall involved
Bowel symptoms	—	Painful defecation if rectal wall involved
Vaginal symptoms	May be chronic purulent discharge or leucorrhoea	—

- IUCD use
- in-vitro fertilisation/GIFT

**DxT** amenorrhoea (65–80%) + lower abdominal pain (95 + %) + abnormal vaginal bleeding (65–85%) → ectopic pregnancy

- Pre-rupture symptoms (many cases):
  - abnormal pregnancy
  - cramping pains in one or other iliac fossa
  - vaginal bleeding
- Rupture:
  - excruciating pain (see FIG. 103.2)
  - circulatory collapse

*Note:* In 10–15% there is no abnormal bleeding.

- Pain may radiate to rectum (lavatory sign), vagina or leg
- Signs of pregnancy (e.g. enlarged breasts and uterus) usually not present

### Examination

- Deep tenderness in iliac fossa
- Vaginal examination:
  - tenderness on bimanual pelvic examination (pain on cervical provocation i.e. cervical motion tenderness)

- palpable adnexal mass
- soft cervix

- Bleeding (prune juice appearance)
- Temperature and pulse usually normal early

### Diagnosis<sup>4</sup>

It is possible to diagnose ectopic pregnancy at a very early stage of pregnancy.

- Urine pregnancy test (positive in <50%)
- Serum  $\beta$ -hCG assay >1500 IU/L (invariably positive if a significant amount of viable trophoblastic tissue present)—may need serial quantitative tests to distinguish an ectopic from a normal intra-uterine pregnancy (IUP). If it is <1000 IU/L an IUP should be visible on vaginal ultrasound. If not, ectopic is more likely. If <1000 IU/L, repeat every second day to see if it is increasing normally as expected in a normal IUP.
- Transvaginal ultrasound can diagnose at 5–6 weeks (empty uterus, tubal sac, fluid in cul-de-sac)
- Laparoscopy (the definitive diagnostic procedure)

103

FIGURE 103.2 Clinical features of ectopic pregnancy

### Ectopic pregnancy diagnosis

- Pregnancy test
- $\beta$ -hCG assay
- Transvaginal ultrasound
- Laparoscopy

### Management

Possible options are surgery, medical or watchful expectancy. Treatment may be conservative (based on ultrasound and  $\beta$ -hCG assays); medical, by injecting methotrexate into the ectopic sac; laparoscopic removal; or laparotomy for severe cases. Rupture with blood loss demands urgent surgery. Organise blood and contacts, resuscitate as necessary.

### Post management

- Successful pregnancy 60–65%
- Subsequent risk of ectopic pregnancy 10–15%

### § Ruptured ovarian (Graafian) follicle (mittelschmerz)

When the Graafian follicle ruptures a small amount of blood mixed with follicular fluid is usually released into the pouch of Douglas. This may cause

peritonism (mittelschmerz), which is different from the unilateral pain experienced just before ovulation due to distension of the ovarian capsule.

### Clinical features

- Onset of pain in mid-cycle
- Deep pain in one or other iliac fossa (RIF > LIF)
- Often described as a 'horse kick pain'
- Pain tends to move centrally (see FIG. 103.3)
- Heavy feeling in pelvis
- Relieved by sitting or supporting lower abdomen
- Pain lasts from a few minutes to hours (average 5 hours)
- Patient otherwise well

*Note:* Sometimes it can mimic acute appendicitis.

### Management

- Explanation and reassurance
- Simple analgesics: aspirin or paracetamol
- 'Hot water bottle' comfort if pain severe

### OVARIAN TUMOURS

Benign ovarian tumours, particularly ovarian cysts, may be asymptomatic but will cause pain if complicated. They are common in women under 50 years of age. Ovarian cysts are best defined by vaginal ultrasound, which can identify whether haemorrhage has occurred inside or outside the cyst.

FIGURE 103.3 Typical clinical features of a ruptured Graafian follicle (mittelschmerz)

## Symptoms

- Pain (usually torsion or haemorrhage)
- Pressure symptoms
- Menstrual irregularity

## § Ruptured ovarian cyst

The cysts tend to rupture just prior to ovulation or following coitus.

### Clinical features

- Patient usually 15–25 years
- Sudden onset of pain in one or other iliac fossa
- May be nausea and vomiting
- No systemic signs
- Pain usually settles within a few hours

### Signs

- Tenderness and guarding in iliac fossa
- PR: tenderness in rectovaginal pouch

### Investigation

- Ultrasound  $\pm$  colour Doppler (for enhancement)

### Management

- Appropriate explanation and reassurance

- Conservative:
  - simple cyst  $<4$  cm
  - internal haemorrhage
  - minimal pain
- Needle vaginal drainage by ultrasonography for a simple larger cyst
- Laparoscopic surgery:
  - complex cysts
  - large cysts
  - external bleeding

## § Acute torsion of ovarian cyst

Torsions are mainly from dermoid cysts and, when right-sided, may be difficult to distinguish from acute pelvic appendicitis.

### Clinical features

- Severe cramping lower abdominal pain (see FIG. 103.4)
- Diffuse pain
- Pain may radiate to the flank, back or thigh
- Repeated vomiting
- Exquisite pelvic tenderness
- Patient looks ill

FIGURE 103.4 Typical clinical features of acute torsion of an ovarian cyst

## Signs

- Smooth, rounded, mobile mass palpable in abdomen
- May be tenderness and guarding over the mass, especially if leakage

## Diagnosis

- Ultrasound  $\pm$  colour Doppler

## Treatment

- Laparotomy and surgical correction

## § Malignant ovarian tumours

Ovarian cancer has an incidence of 10 cases per 10 000 women per year and accounts for 5% of all cancers in women and 20% of all gynaecological cancers. It is responsible for more gynaecological cancer deaths because the tumour is often well advanced at the time of clinical presentation.<sup>5</sup> Earlier discovery may sometimes be made on routine examination or because of investigation of non-specific pelvic symptoms.

Ovarian cancer tends to remain asymptomatic for a long period. No age group is spared but it becomes progressively more common after 45 years (peak incidence 60–65 years) (see CHAPTER 26).

The familial causes and relationship to breast cancer are being delineated. Refer to CHAPTER 18.

## Risk factors

- Age
- Family history (first-degree relatives)
- Nulliparity

## Protective factors

- COC pill
- Pregnancy

## Clinical features

- Constitutional symptoms: fatigue, anorexia
- Ache or discomfort in lower abdomen or pelvis
- Abdominal bloating and 'fullness'
- Gastrointestinal dysfunction (e.g. epigastric discomfort, diarrhoea, constipation, wind)
- Sensation of pelvic heaviness
- Genitourinary symptoms (e.g. frequency, urgency, prolapse)
- $\pm$  Abnormal uterine bleeding
- Postmenopausal bleeding
- Dyspareunia and/or dysmenorrhoea (10–20%)
- A combined vaginal–rectal bimanual examination assists diagnosis. Look for mass, ascites, pleural effusion
- $\pm$  Weight loss

*Note:* Any ovary that is easily palpable is usually abnormal (normal ovary rarely  $>4$  cm).

## Diagnosis

- Ultrasound  $\pm$  colour Doppler
- Tumour markers such as CA-125,  $\beta$ -hCG (choriocarcinoma) and alpha-fetoprotein are becoming more important in diagnosis and management

Refer urgently to gynaecologist. Treatment is usually laparotomy  $\pm$  adjuvant chemotherapy.

## DYSMENORRHOEA

Dysmenorrhoea (painful periods) may commence with the onset of the menses (menarche) when it is called primary dysmenorrhoea, or later in life when the term secondary dysmenorrhoea is applied.

## § Primary (functional) dysmenorrhoea

This is menstrual pain associated with ovular cycles without any pathologic findings. The pain usually commences within 1–2 years after the menarche and becomes less severe with age. It affects about 50% of menstruating women and up to 95% of adolescents.

## Clinical features

- Low midline abdominal pain
- Pain radiates to back or thighs (see FIG. 103.5)
- Varies from a dull dragging to a severe cramping pain
- Maximum pain at beginning of the period
- May commence up to 12 hours before the menses appear
- Usually lasts 24 hours but may persist for 2–3 days
- May be associated with nausea and vomiting, headache, syncope or flushing
- No abnormal findings on examination

## Management

- Full explanation and appropriate reassurance
- Promote a healthy lifestyle:
  - regular exercise
  - avoid smoking and excessive alcohol
- Recommend relaxation techniques such as yoga
- Avoid exposure to extreme cold
- Place a hot water bottle over the painful area and curl the knees onto the chest

## Medication

Options include (trying in order):

- simple analgesics (e.g. aspirin or paracetamol)

FIGURE 103.5 Typical pain of dysmenorrhoea

- NSAIDs (e.g. naproxen, ibuprofen 200–400 mg (o) tds) at first suggestion of pain in the first 3 days of the period (if simple analgesics ineffective)
- Vitamin B1 (thiamine) 100 mg daily
- COC (low-oestrogen triphasic pills preferable)<sup>5</sup>
- progestogen-medicated IUCD

If not helped by these treatments, further investigation is required.

A Cochrane review found that the most beneficial medication was the NSAIDs, and vitamin B1 and magnesium also proved effective. There was no evidence so far that vitamin B6, vitamin E or herbal remedies were effective. Spinal manipulation was unlikely to be beneficial.<sup>6</sup>

### § Secondary dysmenorrhoea

Secondary dysmenorrhoea is menstrual pain for which an organic cause can be found. It usually begins after the menarche after years of pain-free menses; the patient is usually over 30 years of age. The pain begins as a dull pelvic ache 3–4 days before the menses and becomes more severe during menstruation.

Commonest causes:

- endometriosis (a major cause)
- PID (a major cause)
- IUCD
- submucous myoma
- intra-uterine polyp
- pelvic adhesions

### Investigations

Investigations include laparoscopy, ultrasound and (less commonly) assessment of the uterine cavity by dilation and curettage, hysteroscopy or hysterosalpingography.

Management involves treating the cause.

### Pelvic adhesions

Pelvic adhesions may be the cause of pelvic pain, infertility, dysmenorrhoea and intestinal pain. They can be diagnosed and removed laparoscopically when the adhesions are well visualised and there are no intestinal loops firmly stuck together.

### § Endometriosis

Endometriosis is the condition where ectopically located endometrial tissue (usually in dependent parts of the pelvis and in the ovaries) responds to female sex hormone stimulation by proliferation, haemorrhage, adhesions and ultimately dense scar tissue changes. The average time to diagnosis is 10 years. The diagnosis is masked by taking NSAIDs and the COC.

Patients experience varying degrees of symptoms and loss of gynaecological function according to the site and severity of the endometriosis deposits. Pregnancy is beneficial but recurrence can follow.

### Clinical features<sup>7</sup>

- 10% incidence
- Puberty to menopause, peak 25–35 years

- Secondary dysmenorrhoea
- Infertility
- Dyspareunia
- Non-specific pelvic pain
- Menorrhagia
- Acute pain with rupture of endometrioma
- Premenstrual spotting

**DxT** dysmenorrhoea + menorrhagia + dyspareunia = abdominal/pelvic pain → endometriosis

### Possible signs

- Fixed uterine retroversion
- Tenderness and nodularity in the pouch of Douglas/retrovaginal septum
- Uterine enlargement and tenderness

Adenomyosis: this is endometriosis of the myometrium affecting the endometrial glands and stroma. The symptoms are similar to endometriosis plus an enlarging tender uterus.

### Differential diagnosis

- PID—see TABLE 103.4
- Ovarian cysts or tumours
- Uterine myomas

### Diagnosis

- Usually by direct visual inspection at laparoscopy (the gold standard) or laparotomy
- Ultrasound scanning helpful
- Curettage, which shows small sensory C nerve fibres in the endometrium

### Treatment

- Careful explanation
- Basic analgesics
- Treatment can be surgical or medical

*Medical:*<sup>8</sup> To induce amenorrhoea (only two-thirds respond to drugs):

- levonorgestrel-releasing IUCD (Mirena) 5 yearly and indefinite
- danazol (Danocrine)—for 3–6 months
- COC: once daily continuously—long term
- progestogens (e.g. medroxyprogesterone acetate—Depo-Provera) or orally 10 mg bd for up to 6 months
- GnRH analogues (e.g. goserelin, 3.6 mg SC implant every 28 days for up to 6 months, nafarelin)

In young teenagers an initial trial of ovarian suppression may be tried.

*Surgical:* Surgical measures depend on the patient's age, symptoms and family planning. Laser surgery, diathermy ablation and microsurgery can be performed via either laparoscopy or laparotomy.

## § Pelvic inflammatory disease

There are great medical problems in the serious consequences of PID, namely tubal obstruction, infertility and ectopic pregnancy. PID may be either acute, which causes sudden severe symptoms, or chronic, which can gradually produce milder symptoms or follow an acute episode. Acute PID is a major public health problem and is the most important complication of STIs among young women. The majority are young (less than 25 years), sexually active women who are also nulliparous.

Some patients may experience no symptoms but others may have symptoms that vary from mild to very severe. The clinical diagnosis can be difficult as signs and symptoms can be nonspecific and correlate poorly with the extent of the inflammation.

### Clinical features

#### Acute PID

- Fever  $\geq 38^{\circ}\text{C}$
- Moderate to severe lower abdominal pain

#### Chronic PID

- Ache in the lower back
- Mild lower abdominal pain

#### Both acute and chronic

- Dyspareunia
- Menstrual problems (e.g. painful, heavy or irregular periods)
- Intermenstrual bleeding
- Abnormal, perhaps offensive, purulent vaginal discharge
- Painful or frequent urination

The diagnostic criteria for acute PID are presented in TABLE 103.5.

### Examination

- In acute PID there may be lower abdominal tenderness  $\pm$  rigidity.
- Pelvic examination: in acute PID there is unusual vaginal warmth, cervical motion tenderness and adnexal tenderness. Inspection usually reveals a red inflamed cervix and a purulent discharge.

**Table 103.5** Diagnostic criteria for acute PID<sup>3,9</sup>

All three of the following should be present

- 1 Lower abdominal tenderness (with or without rebound)
- 2 Cervical motion tenderness
- 3 Adnexal tenderness (may be unilateral) plus

One of the following should be present

- 1 Temperature  $\geq 38^{\circ}\text{C}$
- 2 White blood cell count  $\geq 10\,500/\text{mm}^2$
- 3 Purulent fluid obtained via culdocentesis
- 4 Inflammatory mass present on bimanual pelvic examination and/or sonography
- 5 ESR  $\geq 15\text{ mm/h}$  or CRP  $>1.0\text{ mg/dL}$
- 6 Isolation of *N. gonorrhoeae* and/or *C. trachomatis*
- 7 Histological evidence of infection (e.g. plasma cells)

### Causative agents

These can be subdivided into three broad groups:

- 1 *Exogenous organisms*: those which are community acquired and initiated by sexual activity. They include the classic STIs, *Chlamydia trachomatis* (the

most common causative organism) and *Neisseria gonorrhoeae*. This usually leads to salpingitis.

- 2 *Endogenous infections*: these are normal commensals of the lower genital tract, especially *Escherichia coli* and *Bacteroides fragilis*. They become pathogenic under conditions that interrupt the normal cervical barrier, such as recent genital tract manipulation or trauma (e.g. abortion, presence of an IUCD, recent pregnancy or a dilatation and curettage). The commonest portals of entry are cervical lacerations and the placental site. These organisms cause an ascending infection and can spread direct or via lymphatics to the broad ligament, causing pelvic cellulitis (see FIG. 103.6).
- 3 *Actinomyces*: due to prolonged IUCD use. Look for *Actinomyces israelii* on culture.

### Investigations

A definitive diagnosis is difficult since routine specimen collection has limitations in assessing the organisms. Definitive diagnosis is by laparoscopy but this is not practical in all cases of suspected PID.

- Cervical swab for Gram stain and culture, PCR (*N. gonorrhoeae*)
- Cervical swab and special techniques (e.g. PCR for *C. trachomatis*)

**FIGURE 103.6** The pathogenesis of PID

- Blood culture
- Pelvic ultrasound

### Treatment

*Note:* Any IUCD or retained products of contraception should be removed at or before the start of treatment. Sex partners of women with PID should be treated with agents effective against *C. trachomatis* and *N. gonorrhoeae*.

### Sexually acquired infection<sup>10</sup>

Mild to moderate infection (treated as an outpatient):

ceftriaxone 500 mg (in 2 ml 1% lignocaine) IM or 500 mg IV, as a single dose (for gonorrhoea)

*plus*

azithromycin 1 g (o), as 1 dose

*plus*

metronidazole 400 mg (o) 12 hourly for 14 days

Severe infection (treated in hospital):

ceftriaxone 1 g IV daily

*plus*

azithromycin 500 mg IV daily

*plus*

metronidazole 500 mg IV 12 hourly

until there is substantial clinical improvement, when the oral regimen above can be used for the remainder of the 14 days

### Infection non-sexually acquired (related to genital manipulation)

Mild to moderate infection:

amoxycillin + clavulanate (875 mg/125 mg) (o) 12 hourly for 14 days

*plus*

azithromycin 1 g (o) as single dose

Severe infection (including septicaemia):

amoxy/ampicillin 2 g IV 6 hourly

*plus*

gentamicin 4–6 mg/kg IV for 1 dose, then 1 or 2 further doses based on renal function

*plus*

metronidazole 500 mg IV 12 hourly

### Actinomycosis

amoxycillin 500 mg tds + metronidazole 400 mg bd for 14 days. Ensure IUCD is removed

### When to refer

- All cases of 'unexplained infertility'
- All teenagers with dysmenorrhoea sufficient to interfere with normal school, work or recreational activities, and not responding to prostaglandin inhibitors
- Patients with dysmenorrhoea reaching a crescendo mid-menses
- Patients with dysmenorrhoea and unexplained bowel or bladder symptoms
- Patients with positional dyspareunia
- Patients with cyclic pain or bleeding in unusual sites

*Note:* Pelvic disease that can be treated by advanced laparoscopy surgery includes ectopic pregnancy, ovarian cysts, endometriosis and endometriomas, fibromyomata, pelvic adhesions and hydrosalpinx.

### Practice tips

- Think of endometriosis and ovarian cysts in any woman with lower abdominal pain.
- In any woman whose normal activities are disturbed by dysmenorrhoea unrelieved by NSAIDs, endometriosis should be suspected.
- If an ectopic pregnancy is suspected and there are no facilities for resuscitation, digital vaginal examination should be deferred for it may provoke rupture.<sup>2</sup>
- Acute abdominal and pelvic pain in the presence of a negative  $\beta$ -hCG is most often due to an ovarian cyst.
- A positive  $\beta$ -hCG plus an empty uterus and an adnexal mass are the classic diagnostic features of ectopic pregnancy.

JEAN KERR 1961

Premenstrual syndrome (PMS) is defined as a group of physical, psychological and behavioural changes that begin 2–14 days before menstruation and are relieved immediately the menstrual flow begins.<sup>1</sup>

These symptoms occur in the luteal phase of the menstrual cycle yet the pathogenesis of PMS is still uncertain. Among the proposed causes are pyridoxine deficiency, excess prostaglandin production and increased aldosterone production in the luteal phase.<sup>1</sup> However, PMS is most probably related to enhanced sensitivity to progesterone with an underlying serotonin deficiency.<sup>2</sup>

## Key facts and checkpoints

- PMS increases in incidence after 30 years, with a peak incidence in the 30–40 years age group.
- PMS also occurs in the 45–50 years age group, when it may alternate with menopausal symptoms, causing clinical confusion.<sup>3</sup>
- The symptoms of PMS decrease in severity just before and during menstruation.
- The symptoms cannot be explained by the presence of various psychological or psychiatric disorders.
- The severe form of PMS is classified in the *Diagnostic and Statistical Manual of Mental Disorders* (4th and 5th edns) as premenstrual dysphoric disorder (PMDD).

## Incidence

Up to 90% of women may experience premenstrual symptoms, which can vary from moderately severe in 20–40% of women to disabling in 2%.<sup>4</sup> Interestingly, up to 15% of women can feel better premenstrually.<sup>5</sup> Statistics from countries such as Sweden, the US and the UK indicate that up to 40% of women are significantly affected.<sup>5</sup> About 5–10% of women experience such severe symptoms that PMS disrupts their quality of life.

## Aetiology

Various aetiological factors have been identified as contributing to PMS.<sup>1</sup>

Predisposing factors:

- mental illness
- alcoholism
- sexual abuse
- family history
- stress

Precipitating factors:

- hysterectomy
- tubal ligation
- cessation of the OCP

Sustaining factors:

- diet containing caffeine, alcohol, sugar
- smoking
- stress
- sedentary lifestyle

## Symptoms

Various symptoms from among the 150 reported are summarised in **FIGURE 104.1**.

The most common symptoms are depression 71%, irritability 56%, tiredness 35%, headache 33%, bloatedness 31%, breast tenderness 21%, tension 19% and aggression/violence 13%.<sup>6</sup> Other important symptoms include weight gain, lowered performance, decreased libido and feeling out of control.

## Classification of PMS

It is convenient to classify PMS in terms of severity of symptoms.<sup>3</sup>

- 1 **Mild:** symptoms signal onset of menstruation. No medical advice sought or needed.
- 2 **Moderate:** symptoms annoying but insufficient to interfere with function at home or work. Medical advice sought in about one-third.

**Psychological symptoms**

- insomnia
- moodiness
- irritability
- anxiety
- tension
- depression
- confusion
- food cravings

**Physical symptoms**

- nausea
- headache
- dizziness
- hot flushes
- acne
- breast swelling and tenderness
- bloated abdomen
- constipation
- swelling of ankles

FIGURE 104.1 Symptoms of premenstrual syndrome

- 3 *Severe*: symptoms are such that functions at work or home are disrupted. Medical advice is usually sought. This disruptive form is labelled PMDD (see TABLE 104.1).

### Differential diagnosis<sup>3</sup>

- Menopause syndrome
- Mastalgia
- Other causes of fluid retention—kidney or adrenal
- Thyroid disorder (hyper- or hypo-activity)
- Polycystic ovarian syndrome (PMS may be a feature of oestrogen excess)
- Psychiatric disorders: depression, mania

### Diagnosis

- Thorough history—including diet, exercise habits, psychosocial background, emotional influences and family history
- Menstrual calendar—for 3 months, showing timing of the three main symptoms<sup>3</sup>
- Physical examination to exclude gynaecological, endocrine or other systemic disease; and also include:
  - breast examination
  - vaginal examination and Pap test

Table 104.1 Summary of PMDD criteria\*<sup>7</sup>

- A Symptoms must occur during the week before menses and start to improve within a few days after onset of menses.
- B One (or more) of the following symptoms must be present and marked:
- 1 Affective lability
  - 2 Irritability or anger
  - 3 Depressed mood or dysphoria
  - 4 Anxiety, tension or feelings of being on edge
- C One or more of the following to reach a total of 5 symptoms when combined with those from criterion B above:
- 1 Decreased interest in usual activities
  - 2 Concentration difficulties
  - 3 Marked lack of energy; lethargy
  - 4 Marked change in appetite, overeating, or food cravings
  - 5 Hypersomnia or insomnia
  - 6 Feeling overwhelmed or out of control
  - 7 Other physical symptoms (e.g. breast tenderness, bloating)
- D Symptoms must interfere with work, school, productivity, usual activities or relationships
- E Symptoms must not merely be an exacerbation of another disorder such as major depression
- F Criteria for A must be confirmed by prospective daily ratings for at least two cycles
- G The symptoms are not attributable to the physiological effects of a substance or other medical condition

\*Adapted from DSM-5-TR

- Investigations (if considered appropriate, perform one or more serological tests):
  - thyroid function tests
  - serum progesterone and oestradiol in mid-luteal phase of three representative cycles
  - electrolytes and creatinine
  - prolactin—if galactorrhoea or oligomenorrhoea present

### Management<sup>2,4</sup>

The basic aim of management is to reassure and treat the woman in such a way that she makes changes in her lifestyle to cope with the hormonal dysfunction rather than rely on medication. The management strategies include the following, with the emphasis on lifestyle factors.

### Explanation, reassurance and insight<sup>4</sup>

Cognitive-based therapy, which has been shown to have a positive effect in several RCTs,<sup>4,8</sup> is very helpful for the patient to understand the nature of

her symptoms and to receive appropriate support and rapport. Advise her to be open about her problem and inform her family and close friends about her symptoms. This is the prime treatment strategy.

### Keeping a diary<sup>3</sup>

Advise the patient to keep a daily diary of all her symptoms and when they occur over a 2–3 month period. This information should help her to plan around her symptoms: for example, avoid too many social events and demanding business appointments at the time when PMS symptoms are worst.

### Dietary advice<sup>3</sup>

Advise the patient to eat regularly and sensibly; eat small rather than large meals and aim for ideal weight (if necessary).

Increase amount of complex carbohydrates (whole grains, vegetables and fruit), leafy green vegetables and legumes.

Decrease or avoid: refined sugar, salt, alcohol, caffeine (tea, coffee, chocolate), tobacco, red meat and excessive fluid intake during premenstrual phase. Decrease total protein to 1 g/kg/day; decrease fats.<sup>9</sup>

### Exercise

Recommend a program of regular exercise such as swimming, aerobics, jogging or tennis. Such exercise has been proven to decrease depression, anxiety and fluid retention premenstrually.<sup>9</sup>

### Relaxation

Advise patients to plan activities that they find relaxing and enjoyable at the appropriate time. Consider stress reduction therapy, including appropriate counselling.

### Appropriate dress

Advise sensible dressing to cope with breast tenderness and a bloated abdomen, such as a firm-fitting brassiere and loose-fitting clothes around the abdomen.

### Medication

Pharmaceutical agents that have been used with success in some patients and little or no relief in others include diuretics (e.g. spironolactone), vitamins and minerals (e.g. pyridoxine and evening primrose oil), antiprostaglandin preparations (e.g. mefenamic acid, indomethacin), bromocriptine,

danazol (suppresses ovulation), GnRH agonists and hormone preparations such as the OCP, progestogens and oestradiol implants. A combination of agents may have to be used.

The evidence base for symptom relief so far is as follows:<sup>2,10</sup>

- nil or negative—evening primrose oil,<sup>11</sup> ginkgo biloba, progesterone/progestogens, OCP, bromocriptine, massage, homeopathy, reflexology, multivitamins
- weak—magnesium, calcium, vitamin E, vitex angus castus (chaste tree)
- moderate—vitamin B6,<sup>12</sup> St John's wort, spironolactone
- strong (for PMDD)—SSRI agents and clomipramine, GnRH agonists, danazol

### Oral contraception<sup>4</sup>

If contraception is required it is appropriate to use a COC-containing ethinylestradiol and drospirenone since a meta-analysis of drospirenone, which is a progestogen derivative of spironolactone, concluded that it was effective in reducing the severe symptoms of PMDD.

ethinylestradiol 20 mg + drospirenone 3 mg  
(o) once daily on days 1 to 24 of a 28-day cycle

### Mild to moderate symptoms

A trial of pyridoxine (vitamin B6) 50–100 mg daily.

### Moderate to severe symptoms<sup>4,13</sup>

A trial of an SSRI is warranted in women with incapacitating PMDD who are unresponsive to CBT.

fluoxetine 20 mg mane for 14 days before the anticipated onset of menstruation<sup>4</sup>

or

sertraline 50 mg daily for 14 days before the anticipated onset of menstruation

### Individualised therapy<sup>14</sup>

- PMS + fluid retention—use spironolactone 100 mg daily 3 days before expected onset of symptoms to day 1 of menstruation
- PMS + severe mastalgia—consider danazol 200 mg (o) daily from onset of symptoms to onset of menses

No matter what medication is taken, up to 70% of women will report an improvement in the early months of treatment, suggesting that a strong placebo factor is involved in management.<sup>15</sup>

## Practice tip

Moderate to severe PMDD

- Fluoxetine 20 mg (o) or sertraline 50 mg (o) daily in morning for 14 days before anticipated onset of menstruation and through to the first full day of menses of each cycle.

## When to refer<sup>3</sup>

- If the recommended approach of support, education, reassurance and stress management is still not effective.
- Refer to a gynaecologist if underlying disease is suspected or proven (e.g. polycystic ovarian syndrome, endometriosis)
- Consider referral if prescribing of danazol is contemplated
- Refer to an endocrinologist if an endocrine disorder such as adrenal, pituitary or thyroid is suspected or proven
- Consider referral if depression or psychosis worsens or is not cyclical

## Practice tips

- Keeping a daily diary of symptoms is very helpful for both patient and clinician.
- Aim for lifestyle changes and commonsense non-pharmacological management.
- Allow at least three cycles of treatment to provide a reasonable time for a particular medication.
- Drugs such as danazol are second-line drugs with significant side effects and should be used with caution.
- High doses of pyridoxine, such as 500 mg a day, are associated with peripheral neuropathy so the dosage should be kept at or below 100 mg/day.
- Be careful of overdiagnosing PMS and overlooking disorders such as depression, which may be exacerbated in the premenstrual phase.

*Every woman should use what Mother Nature gave her before Father Time takes it away.*

LAURENCE J PETER 1977

## Definitions

The menopause is the permanent cessation of menstruation in a non-hysterectomised woman. In most Western women it occurs between the ages of 45 and 55 years, with an average age of 51.5 years.<sup>1</sup> Premature menopause is menopause occurring before age 40.

The WHO has defined the menopause as signifying the permanent cessation of menstruation, resulting from the loss of ovarian follicular activity.<sup>2</sup> However, the term is used in a broader sense to include the perimenopausal phase when ovarian function waxes and wanes and the periods become irregular. This may last 2–5 years and sometimes longer and involves the premenopausal and menopausal phases.

The postmenopause is the period following the menopause but cannot be defined until after 12 months of spontaneous amenorrhoea, except in women who have had an oophorectomy.

Surgical menopause is known as bilateral oophorectomy.

## Summary

The climacteric can be subdivided into four phases:

*Phase 1* Premenopausal: up to 5 years before the last menstrual period.

*Phase 2* Perimenopausal: the presence of early menopausal symptoms with vaginal bleeding (usually irregular).

*Phase 3* Menopausal: the last menstrual period.

*Phase 4* Postmenopausal: the phase beginning 12 months after the last menstrual cycle.

## Osteoporosis

Osteoporosis, which literally means porous bone, is reduced bone mass per unit volume. Osteoporosis is usually addressed in the context of the menopause because it is found mainly in postmenopausal middle-aged and elderly women and can be largely prevented by correcting oestrogen deficiency.

## Physiology of the menopause

FIGURE 105.1 provides an overview of how menopausal symptoms are related to ovarian follicular activity and hormonal activity.

The number of ovarian primary follicles declines rapidly as the menopause approaches, with few if any being identifiable following the cessation of menstruation. In the postmenopause phase, FSH rises to levels 10–15 times that of the follicular phase of the cycle while LH levels rise about threefold. The ovary secretes minimal oestrogen but continues to secrete significant amounts of androgens.

An uncomfortable effect of oestrogen withdrawal, often not appreciated by medical practitioners, involves urogenital problems where the epithelium of the vagina, vulva, urethra and the base of the bladder becomes thin and dry, leading possibly to dysuria and frequency, itching, dyspareunia and atrophic bleeding. Hormone replacement therapy (HRT) can ameliorate these urogenital symptoms.

## Clinical features

Because small amounts of oestrogen are still being produced in the adrenal glands, symptoms other than cessation of periods may be mild or absent. Up to 80% of women experience vasomotor symptoms for an average duration of 5 years.<sup>3</sup>

## Symptoms

Vasomotor:<sup>1</sup>

- hot flushes (80%)
- night sweats (70%)
- palpitations (30%)
- lightheadedness/dizziness
- migraine

Psychological:

- irritability
- depression
- anxiety/tension

- tearfulness
- loss of concentration
- poor short-term memory
- unloved feelings
- sleep disturbances
- mood changes
- loss of self-confidence

Urogenital (60%):

- atrophic vaginitis
- vaginal dryness (45%); itching; burning
- dyspareunia
- decline in libido
- bladder dysfunction (e.g. frequency dysuria)
- stress incontinence/prolapse

Musculoskeletal:

- non-specific muscular aches
- non-specific joint aches and pains

Skin and other tissue changes:

- dry skin

- formication (17%)
- new facial hair
- breast glandular tissue atrophy

Other:

- unusual tiredness
- headache

Clinical approach

A thorough evaluation of the patient is important, including a good history.

History

Enquire about any symptoms related to oestrogen deficiency and other related symptoms, with an emphasis on the menstrual history and hot flushes. Enquire about mental state symptoms, such as anger, irritability, depression, moodiness, loss of self-esteem and other such problems. Ask about sexual history, contraception, micturition and social history, including relationships.

FIGURE 105.1 Schematic representation of some clinical, biological and endocrinological features of the perimenopausal and postmenopausal phases

Source: After Burger<sup>3</sup>

Consider all women at the menopause to be at risk for cardiovascular disease, cancer (especially breast, ovary and cervix), diabetes and osteoporosis.<sup>2</sup>

Information on family history of osteoporosis, cancer and cardiovascular disease should be sought.

### Physical examination

The general examination should include measurement of blood pressure, weight and height, breast palpation, abdominal palpation, vaginal examination and Pap test. Note the texture of the vaginal epithelium.

### Investigations<sup>2</sup>

Apart from a Pap test, the following tests should be considered:

- urinalysis
- full blood count, lipids including HDL
- liver function tests
- thyroid stimulating hormone (TSH)
- mammography (all women, preferably before or after 3 months on HRT)
- diagnostic hysteroscopy and endometrial biopsy only if undiagnosed vaginal bleeding
- bone density study (if risk factors)

If diagnosis is in doubt (e.g. perimenopause, younger patient <45 years, hysterectomy):

- serum FSH
  - serum oestradiol
- } diagnostic

### Differential diagnosis of menopause syndrome

- Depression
- Anaemia
- Thyroid dysfunction
- Hyperparathyroidism
- Gynaecological disorders
  - dysfunctional uterine bleeding

## Management

### Education and lifestyle

Patients should receive adequate understanding, support and explanation with the emphasis being that the menopause is a natural fact of life. For many, menopausal symptoms will be relatively shortlived; often within 2 years. Emphasise the importance of leading a healthy lifestyle:

- correct diet
- avoid obesity
- adequate relaxation
- adequate exercise

- reduced smoking
- reduced caffeine intake
- reduced alcohol intake

### Sexual activity

Advise that it is normal to continue sexual relations, using a vaginal lubricant for a dry vagina. Contraception is advisable for 12 months after the last period for women over 50 years and two years for those under 50 years. The OCP can be used up to 50–51 years if there are no risk factors.

### Hormone replacement therapy

The modern treatment of HRT at the menopause not only reduces climacteric symptoms and enhances the quality of life in the short term but also reduces the risk of bowel cancer, osteoporosis and fractures. On the other hand, there is evidence of increased risk of endometrial hyperplasia, breast cancer and thromboembolism, especially with long-term use. The use, especially the prolonged use, of HRT has undergone considerable modification in recent years in the light of the findings of increased risk for breast cancer, albeit a small risk.

### The Women's Health Initiative study<sup>4</sup>

The arguably flawed Women's Health Initiative (WHI) trial conducted in the US investigated the use of long-term HRT in postmenopausal women with an intact uterus using long-term combined oral oestrogen and progesterone. The study raised concerns about the safety of HRT. The trial did not include people using other forms of HRT, such as patches, gels or implants. The findings were that there was a slightly increased risk of breast cancer (1.26-fold), coronary heart disease (1.29-fold), stroke (1.41-fold) and pulmonary embolism (2.13-fold) with prolonged use greater than 5 years.<sup>5</sup> The study also found a reduction in risk of bowel cancer and fracture in these women.

Points to emphasise:

- there is no firm evidence of an increased risk of breast cancer with use of HRT <5 years
- HRT cannot be recommended in asymptomatic menopausal women to prevent osteoporosis
- women choosing to cease HRT should reduce their dose gradually over 2–3 months

In 2013, an international meeting formulated a Global Consensus Statement on Menopause Hormone Therapy (MHT)<sup>6</sup> that has been endorsed by many menopause societies. A key recommendation is that 'MHT is the most effective treatment for

vasomotor symptoms associated with menopause at any age, but benefits are more likely to outweigh risks for symptomatic women before the age of 60 years or within 10 years after menopause.’

Indications for HRT

HRT is the most effective method for relieving distressing symptoms of hot flushes, urogenital symptoms, sleeplessness and joint symptoms (level I and II evidence) (NHMRC criteria).<sup>7</sup>

HRT has to be tailored to the individual patient and depends on several factors, including the presence of a uterus, individual preferences and tolerance.<sup>8</sup>

The hormones to consider are:

- oestrogen
- progestogen
- testosterone

If perimenopausal, the OCP cyclical HRT (non-contraceptive) or progestogen-only regimens such as LNG-IUD can be used. If menopausal—use HRT.

Oestrogen

Oestrogen comes in various preparations: oral, patches, implants, injections and topical vaginal preparations.<sup>9</sup> Injectables are not very effective so the common modes of administration are oral, implants or skin patches. Transdermal patches and gels are the most favoured mode worldwide. A goal of therapy is to prescribe the lowest possible dose to relieve symptoms.

Vaginal creams or tablets are usually restricted to women who have mild menopausal symptoms and a dry vagina, or who cannot tolerate parenteral medication. Most women find the use of vaginal pessaries and creams messy and the older preparations are heavily absorbed, but the oestradiol tablet, Vagifem, is a very effective topical therapy. The oral oestrogens in common use include Premarin, Estrofem and Progynova. Implants of 50–100 mg (usually 50 mg) of oestradiol are given 3–12 monthly; patches (usually 50 mcg) are applied weekly or every three and a half days. Continuous daily oestrogen use is recommended; there is no reason to stop therapy for 1 week.

Progestogen

Progestogen is given to women with a uterus and may be given continuously or cyclically. If it is not given, many women will develop hyperplasia of the uterus and there is a 5–10 times increased risk of endometrial cancer with unopposed oestrogen

therapy. If given cyclically (postmenopausal) it is given for the first to the fourteenth day of the calendar month, generally as Provera or Primolut N (see TABLE 105.1). A withdrawal bleed will occur, which many elderly women find unacceptable. Thus, continuous therapy may be more appropriate. Avoid continuous use in perimenopausal women because of heavy irregular bleeding.

Progestogen alone can be given for menopausal symptoms in a woman with an oestrogen-dependent tumour.

Progestogens should be given in the smallest possible dose, to prevent endometrial hyperplasia.

Table 105.1 Progestogens used in the menopause<sup>7,10</sup>

Generic name	Daily dose range	Usual daily protective dose
Dydrogesterone	10–20 mg	10 mg
Medroxyprogesterone acetate	2.5–20 mg	10 mg
Norethisterone	1.25–5 mg	2.5 mg

Golden rule

A progestogen must be used with oestrogen if the woman still has a uterus.

Testosterone

Testosterone is usually reserved for women whose libido does not improve with HRT and those with a premature menopause but this indication is controversial and it should be used with caution because of the lack of data about adverse effects. If available it is given as an implant of 50 mg and will last 3–12 months. An oestrogen implant of 50 mg should be given concurrently.

Tibolone

This is a selective tissue oestrogenic activity regulator with combined oestrogenic, progestogenic and androgenic properties that can be used as an excellent alternative to conventional HRT in postmenopausal women. Positive effects are on vasomotor and urogenital symptoms, sexual function, bone density and fracture risk. It is unsuitable in perimenopausal women because of an increased risk of breakthrough bleeding. It should be considered for women who are surgically postmenopausal or who have not had

a natural menstrual bleed for at least 12 months.<sup>2</sup> Adverse effects with breakthrough bleeding and virilisation are a concern.<sup>7</sup>

Dose: tibolone 2.5 mg (o) daily

## Contraindications to HRT<sup>2</sup>

Important contraindications to HRT are listed in **TABLE 105.2**. The main absolute contraindications are active oestrogen-dependent neoplasms, such as endometrial and breast cancer, deep venous thrombosis, acute thrombophlebitis and undiagnosed, abnormal vaginal bleeding. HRT is protective for bowel cancer but not ovarian cancer.

**Table 105.2** Contraindications (absolute or relative) to HRT

Oestrogen-dependent tumour:

- endometrial cancer
- breast cancer

Recurrent thromboembolism

Acute ischaemic heart disease (absolute)

History of coronary artery disease (relative)

Cerebrovascular disease

Uncontrolled hypertension

Undiagnosed vaginal bleeding

Active liver disease/liver dysfunction

Active SLE

Pregnancy

Otosclerosis

Acute intermittent porphyria

## HRT regimens

**TABLE 105.3** presents terminology defining some types of HRT, while **TABLE 105.4** presents current commonly used regimens, especially oral oestrogen and progestogen (oral or as an IUD releasing system) and the transdermal system. The transdermal system appears to be the most favoured, although some women find it unsuitable, mainly due to skin irritation. A useful regimen, especially for irregular bleeding in the perimenopausal phase, is the combined sequential pill, which can be continued for several years if necessary. Sufficient oestrogen should be given to control symptoms.

There is a proliferation of combination packs with permutations of various oestrogens and

**Table 105.3** Modified: terminology defining some types of HRT regimens

Regimen	Oestrogen	Progestogen
Cyclic	Day 1–28	Last 12–14 days of ET cycle
Cyclic combined	Day 1–28	Day 1–28
Continuous-sequential	Daily	12–14 days every month
Long cycle	Daily	14 days every 2–6 months
Continuous-combined	Daily	Daily

**Table 105.4** Hormone replacement therapy (options)

Uterus intact	Post-hysterectomy
Oral O + oral P	Oral O
Oral O + LNG-IUD	Transdermal O patch or gel
Transdermal O + P patch	Tibolone
Transdermal O patch or gel + oral P or LNG-IUD	
Tibolone	

O = oestrogen

P = progestogen

LNG-IUD = levonorgestrel IUD

Source: Adapted from Jane and Davis, Figure 3<sup>2</sup>

progestogens (pills and patches), usually sequential, some combined. These preparations are most suitable for perimenopausal women. The continuous combined preparation is best suited to women at least 1 year postmenopausal. The newer progestogen, cyproterone acetate, is regarded as useful in the presence of hirsutism.

## Informed consent

HRT should be prescribed only after the woman has been informed of the regimens available, their relative benefits and risks and side effects.<sup>5</sup> It must be emphasised that HRT, especially the combined sequential formulation, is not a contraceptive.

## Side effects of therapy<sup>12,13</sup>

In the first 2–3 months the woman may experience oestrogenic side effects, but these usually resolve

or stabilise. Starting with a lower dose may minimise these side effects. The main short-term risk of oral HRT in women aged 50–59 is venous thromboembolism.<sup>5</sup>

### Premenstrual syndrome (in 15%)

Action: decrease progestogen dose  
or change to alternative progestogen

### Nausea and breast disorders

Cause: initial sensitivity to oestrogen  
Action: reduce oestrogen to starting or low dose  
or use intravaginal oestrogen

### Bleeding problems

Heavy bleeding

Action: decrease oestrogen

Breakthrough bleeding

Action: increase progestogen

Irregular bleeding

Action: investigate + endometrial sampling

Intolerance of bleeding

Action: use continuous regimen

No bleeding

Action: reassure that this is not a problem

### Leg cramps

Action: decrease oestrogen

### Follow-up after commencing HRT<sup>10</sup>

- Three months (ideal time for mammography if not performed beforehand)
- then 6 monthly

Allow 6 months to stabilise therapy.

### Duration of treatment

The duration of treatment depends on several factors, including the severity of symptoms, the response to therapy and the long-term aims, such as osteoporosis prevention (at least 10 years). However, long-term therapy should be an informed decision made by the patient in consultation with the doctor. A useful working rule is to aim for treatment for a maximum of 2 years and then review with an aim of using HRT for 5 years if appropriate for that person. Current evidence is that combined oestrogen and progestogen therapy will not increase the risk of breast cancer for up to 5 years of use, and oestrogen-only therapy will not increase risk for at least 7.2 years.<sup>9</sup>

According to the respected authority, Burger, 'prolonged use of HRT (for more than 5–7 years), particularly combined continuous treatment at doses equivalent to 0.625 mg conjugated equine oestrogens, increases breast cancer risk moderately, an observation that must be balanced against improved quality of life, protection against osteoporotic fracture, and reduction in colorectal cancer risk'.<sup>3</sup>

### Vaginal dryness

The first-line therapy is a non-hormonal preparation such as Replens or K-Y Gel. If these are ineffective, low-dose vaginal oestrogen preparations can be useful, for example:

oestradiol 25 mgm or oestriol 500 mcg  
intravaginal pessary daily at bedtime for 2 weeks  
then twice weekly

### Non-hormonal therapy regimens

Several non-hormonal regimens have been employed to manage menopausal symptoms. These include medical therapies, such as gabapentin clonidine, tranquillisers and antidepressants, and also natural therapies, such as acupuncture, evening primrose oil, soy products and other phytoestrogens (plants containing oestrogen-like compounds). Although there is considerable anecdotal evidence about the efficacy of phytoestrogens, evidence from long-term double-blind trials is lacking.

The front-line treatments are the SSRIs and SNRIs, for example:<sup>10</sup>

paroxetine 10 mg (o) daily increasing up to 20 mg daily after one week if necessary

or

venlafaxine 37.5 mg (o) daily, increasing to 75 mg if necessary

### Evidence base for prevention of menopausal symptoms and osteoporosis

A systematic review from North America<sup>13</sup> concluded 'all middle aged women should be counselled about the benefits and risks of HRT. Smoking cessation, low-fat and high-fibre nutrition, 1500 mg calcium daily, 400–800 IU vitamin D daily and moderately strenuous weight-bearing exercises every day are recommended'.

Rymer and Morris<sup>14</sup> report that there is evidence that oestrogen relieves symptoms of urogenital atrophy and vasomotor symptoms and improves short-term quality of life but that long-term use is

associated with an increased risk of thromboembolic disease and endometrial and breast cancers. Further RCTs have found that tibolone relieves vasomotor symptoms and improves sexual symptoms and clonidine reduces hot flushes.<sup>14</sup>

The National Prescribing Service concluded that 'most complementary medicine has little evidence of efficacy and poor quality safety data. Anecdotal evidence is particularly unreliable as hot flushes improve by up to 60% with placebo, partly due to natural fluctuation in symptoms'.<sup>15,16</sup> However, an open mind is needed in the task of relieving the distressing symptoms of menopause and it would be helpful if a proven effective natural alternative to hormones could be identified.

## When to refer

- A problem arises in establishing the correct regimens for HRT
- Complications not corrected by routine measures develop with HRT

## Practice tips

- Careful pretreatment assessment is important.
- Encourage conservative self-help management with an emphasis on lifestyle if symptoms are mild.
- Explain benefits and risks and get informed consent.
- Individualise HRT therapy.
- Regular follow-up is essential.
- Allow about 6 months to stabilise with HRT.
- The prime treatment for an oestrogen-deficiency disorder is oestrogen.
- Use oestrogen-only therapy for women without a uterus.
- If a uterus is present give combined oestrogen–progestogen therapy (cyclical or continuous).
- Always start with a low dose of oestrogen.
- Women who have experienced side effects such as migraine with the COC may have the same problem with HRT.
- Problematic loss of libido can be treated with tibolone or testosterone in the short term (e.g. as a single parenteral dose or as a short course of oral tablets).
- Oestrogen deficiency results in a loss of elasticity and dryness of the vagina, which can be partially helped with HRT.

# 106 Vaginal discharge

*In all cases of abnormal vaginal discharge consider the possibility of the sexually transmitted infections, gonorrhoea and non-specific urethritis.*

DR STELLA HELEY, VICTORIAN CYTOLOGY SERVICE, 2001

Vaginal discharge is one of the commonest complaints seen by family physicians yet it is one of the most difficult to solve, especially if it is recurrent or persistent. It is present if the woman's underclothes are consistently stained or a pad is required. It is important to make a proper diagnosis, to differentiate between abnormal (physiological) and pathological discharge and to be aware of the considerable variation in secretion of vaginal fluid.

This variation extends to different age groups, from prepubertal girls where dermatoses and *Streptococcus* sp. infections occur to the elderly with postmenopausal dermatoses and atrophic vaginitis.

The differential diagnoses should include consideration of normal discharge, vaginitis, either infective or chemical, STIs, and urinary tract infection.

## Key facts and checkpoints

- A survey of a large family planning clinic found that 17% of women complained of vaginal discharge.<sup>1</sup>
- Vaginal discharge may present at any age but is very common in the reproductive years.
- Vaginal discharge is a common presentation of those STIs responsible for PID.
- The first step in diagnosis is to determine if the discharge is cervical or vaginal in origin.
- One of the simplest methods of making a proper diagnosis is a wet film examination.

## A diagnostic approach

A summary of the diagnostic strategy model is presented in TABLE 106.1.

## Probability diagnosis

The two most common causes of vaginal discharge are physiological discharge and infective vaginitis.

## Physiological discharge

Normal physiological discharge is usually milky-white or clear mucoid and originates from a combination of the following sources:

- cervical mucus (secretions from cervical glands)
- vaginal secretion (transudate through vaginal mucosa)
- vaginal squamous epithelial cells (desquamation)
- cervical columnar epithelial cells
- resident commensal bacteria

The predominant bacterial flora are lactobacilli, which produce lactic acid from glucose derived from the epithelial cells. The lactic acid keeps the vaginal pH acidic (<4.7). Other commensal bacteria include staphylococci, diphtheroids and streptococci.

With physiological discharge there is usually no odour or pruritus.

In addition, the egg-white discharge accompanying ovulation may be noted. The discharge may be aggravated by the use of the pill. The normal discharge usually shows on underclothing by the end of the day. Clear or white, it oxidises to a yellow or brown on contact with air. It is increased by sexual stimulation.

Management is largely based on reassurance and explanation.

## Infective vaginitis

The commonest cause of infective vaginitis is bacterial vaginosis (formerly bacterial vaginitis, *Gardnerella vaginalis* or *Haemophilus vaginalis*) which accounts for 40–50% of cases of vaginitis.<sup>2,3</sup> *Candida albicans* is the causative agent in 20–30% of cases while *Trichomonas vaginalis* causes about 20% of cases in Australia. The comparable features are outlined in TABLE 106.2. Human papilloma virus infection of vaginal epithelium may cause excess discharge.

## Serious disorders not to be missed

The 'not to be missed' group includes cancer of the vagina, cervix or uterus and STIs, including

**Table 106.1** Vaginal discharge: diagnostic strategy model

Q.	Probability diagnosis
A.	Normal physiological discharge
	Vaginitis: <sup>3</sup>
	<ul style="list-style-type: none"> <li>• bacterial vaginosis 40–50%</li> <li>• candidiasis 20–30%</li> <li>• <i>Trichomonas</i> 10–20%</li> </ul>
Q.	Serious disorders not to be missed
A.	Neoplasia: <ul style="list-style-type: none"> <li>• cancer</li> <li>• fistulas</li> </ul> STIs/PID (i.e. cervicitis): <ul style="list-style-type: none"> <li>• gonorrhoea</li> <li>• <i>Chlamydia</i></li> <li>• herpes simplex—types 1 and 2</li> </ul> Sexual abuse, esp. children Tampon toxic shock syndrome (staphylococcal infection) Streptococcal vaginosis (in pregnancy)
Q.	Pitfalls (often missed)
A.	Chemical vaginitis (e.g. perfumes) Retained foreign objects (e.g. tampons, IUCD) Endometriosis (brownish discharge) Ectopic pregnancy ('prune juice' discharge) Poor toilet hygiene Latex allergy Genital herpes (possible) Atrophic vaginitis Threadworms
Q.	Seven masquerades checklist
A.	Diabetes Drugs UTI (association)
Q.	Is the patient trying to tell me something?
A.	Needs careful consideration; possible sexual dysfunction.

PIDs caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Vaginal discharge is the most common presenting symptom of both of these serious STIs. Occasionally, infections of the endometrium and endosalpinx will produce a discharge that gravitates to the vagina.<sup>1</sup> Benign and malignant neoplasia anywhere in the genital tract may produce a discharge. Usually it is watery and pink or blood-stained.

Inspection should include vigilance for fistulas that may be associated with malignancy, inflammation or post-irradiation.

## Pitfalls

It is common to overlook the problem caused by hygienic preparations. Apart from the vaginal tampon, which may be retained (knowingly or otherwise), there is a variety of preparations that can induce a sensitivity reaction. These include deodorant soaps and sprays and contraceptive agents, especially spermicidal creams. Ironically, the various preparations used to treat the vaginitis may cause a chemical reaction.

Endometriosis of the cervix or vaginal vault may cause a bloody or brownish discharge.

## Seven masquerades checklist

Of this group, diabetes mellitus leading to recurrent 'thrush', drugs causing a local sensitivity, and urinary tract infection have to be considered (see TABLE 106.1).

## Psychogenic considerations

This question needs to be answered, especially if the discharge is normal. The problem could be related to sexual dysfunction or it may reflect a problematic relationship, and the issue may need to be explored diplomatically. Vaginal discharge is an embarrassing problem for the patient and any discussion needs to be handled thoroughly and sensitively. A relevant sexual history may satisfactorily solve the problem.

## The clinical approach

### History

The history is important and should include:

- nature of discharge: colour, odour, quantity, relation to menstrual cycle, associated symptoms
- exact nature and location of irritation
- sexual history: arousal, previous STIs, number of partners and any presence of irritation or discharge in them
- use of chemicals, such as soaps, deodorants, pessaries and douches
- pregnancy possibility
- drug therapy
- associated medical conditions (e.g. diabetes)

### Examination

Optimal facilities for the physical examination include an appropriate couch and good light, bivalve Sims specula, sterile swabs (preferably with transport media), normal saline, 10% potassium hydroxide (KOH), slides and cover slips and microscope. Inspection in good light includes viewing the vulva,

**Table 106.2** Characteristics of discharge for important causes of abnormal vaginal discharge<sup>2</sup>

Infective organism	Colour	Consistency	Odour	pH (normal 4–4.7)	Associated symptoms
<i>Candida albicans</i>	White	Thick (cream cheese), lumpy	None	<4.5	Itch, soreness, redness
<i>Trichomonas vaginalis</i>	Yellow–green	Bubbly, profuse (mucopurulent)	Malodorous, fishy	5–6	Soreness
Bacterial vaginosis	Grey	Watery, profuse, bubbly, homogenous	Malodorous, fishy	5–6	Irritation (sometimes)
Cervicitis	Yellow–green (coming from cervix)	Thick (mucopurulent)	Variable—usually malodorous	4–4.7	Signs of PID

Source: After Weisberg<sup>2</sup>

introitus, urethra, vagina and cervix. Look for the discharge and specific problems such as polyps, warts, prolapses or fistulas. To differentiate between vaginal and cervical discharge, wipe the cervix clear with a cotton ball and observe the cervix. A mucopurulent discharge appearing from the endocervix may be the clue to an STI such as *Chlamydia* and gonorrhoea. Perform a pH test and a wet film.

Pitfalls to keep in mind include:

- The patient may have had a bath or a ‘good wash’ beforehand and may need to return when the discharge is obvious.
- A retained tampon may be missed in the posterior fornix, so the speculum should slide directly along the posterior wall of the vagina.
- *Candida* infection may not show the characteristic curds, ‘the strawberry vagina’ of *Trichomonas* is uncommon and bubbles may not be seen.

Acetic acid 2% is useful in removing the discharge and mucus to enable a clearer view of the cervix and vaginal walls.

Investigations

- pH test with paper of range 4 to 6
- Amine or ‘whiff’ test: add a drop of 10% KOH to vaginal secretions smeared on glass slide
- Wet film microscopy of a drop of vaginal secretions

A full STI work-up

- First-pass urine and ThinPrep samples—for *Chlamydia* and gonorrhoea NAAT (PCR)
- Swabs from the cervix for *Chlamydia*, *N. gonorrhoeae*:
  - swab mucus from cervix first
  - swab endocervix
  - place in transport media

- Pap test
- Viral culture (herpes simplex):
  - scrape base of ulcer or, ideally, derroof a vesicle
  - immediately immerse in culture medium
  - transport rapidly to laboratory
- Group B *Streptococcus*:
  - swabs from endocervix, urethra, rectum

Preparation of a wet film

To make a wet film preparation<sup>2</sup> (see FIG. 106.1), place one drop of normal saline (preferably warm) on one end of an ordinary slide and one drop of 10% KOH on the other half of the slide. A sample of the discharge needs to be taken with a swab stick, either directly from the posterior fornix of the vagina or from discharge that has collected on the posterior blade of the speculum during the vaginal examination. A high vaginal swab is required for *C. albicans*. A small amount of the discharge is mixed with both the normal saline drop and the KOH drop. A cover slip is placed over each preparation. The slide is examined under low power to get an overall impression, and under high power to determine the presence of lactobacilli, polymorphs, trichomonads, spores, clue cells and hyphae. A summary of various findings on wet film examination is presented in TABLE 106.3. Lactobacilli are long, thin Gram-positive rods; clue cells are vaginal epithelial cells that have bacteria attached so that the cytoplasm appears granular and often the entire border is obscured. They are a feature of bacterial vaginosis. Trichomonads are about the same size as polymorphs; to distinguish between the two, one needs to see the movement of the trichomonad and the beating of its flagella under high power of the microscope. Warming the slide will often precipitate movement.

Refer to FIGURE 106.2.

FIGURE 106.1 Wet film method

## Vaginal discharge in children

Most newborn girls have some mucoid white vaginal discharge. This is normal and usually disappears by 3 months of age. From 3 months of age to puberty, vaginal discharge is usually minimal.<sup>4</sup> Staining on a child's underclothes may be due to excess physiological discharge, especially in the year before the menarche.<sup>1</sup> Vulvovaginitis is the most common gynaecological disorder of childhood, the most common cause being a non-specific bacterial infection.

## Vaginal discharge in the elderly

Vaginal discharge can occur in the elderly from a variety of causes, including infective vaginitis, atrophic vaginitis, foreign bodies, poor hygiene and neoplasia. It is important to exclude malignancy of the uterus, cervix and vagina in the older patient.

## Atrophic vaginitis

In the absence of oestrogen stimulation the vaginal and vulval tissues begin to shrink and become thin and dry. This renders the vagina more susceptible to bacterial attack because of the loss of vaginal acidity. Rarely, a severe attack can occur with a very haemorrhagic vagina and heavy discharge:

- yellowish, non-offensive discharge
- tenderness and dyspareunia

FIGURE 106.2 Relative sizes of various cells or organisms as seen in a wet smear

- spotting or bleeding with coitus
- the vagina may be reddened with superficial haemorrhagic areas

## Treatment

local oestrogen cream or tablet (e.g. Vagifem).

The tablet is preferred as it is less messy

or

zinc and castor oil soothing cream

Note: perform a careful speculum examination.

## \$ Vaginal candidiasis

Infection with the fungus *Candida albicans* is a common and important problem with a tendency to recurrence. However, with the widespread use of over-the-counter antifungals, resistant non-*albicans* species, such as *C. glabrata* (in particular), *C. parapsilosis* and *C. tropicalis* are becoming more common.<sup>5</sup> Microbiological investigation may clarify diagnosis and is essential in recurrent or refractory cases.

## Clinical features

- Intense vaginal and vulval pruritus
- Vulval soreness

Table 106.3 Wet film examination

	Lactobacilli	Polymorphs	Epithelial cells	Clue cells	Other
<b>Normal</b>	+	None or occasional	+	—	
<b>Candidiasis</b>	+	None or occasional	+	—	Spores/hyphae
<b>Trichomoniasis</b>	Absent or scant	Numerous	+	—	Trichomonads
<b>Bacterial vaginosis</b>	Absent or scant	Numerous	+	2–50%	

Source: After Weisberg<sup>2</sup>

- Vulvovaginal erythema (brick red)
- Vaginal excoriation and oedema
- White, curd-like discharge (see FIG. 106.3)
- Discomfort with coitus
- Dysuria

### Factors predisposing to vaginal candidiasis<sup>1</sup>

#### Endogenous

- Diabetes mellitus
- AIDS syndrome
- Pregnancy
- Debilitating diseases

#### Exogenous

- Oral contraceptives (but cessation of the OCP does not usually improve candidiasis)
- Antibiotics
- Immunosuppressants
- Orogenital/anogenital intercourse
- IUCD
- Tight-fitting jeans
- Nylon underwear
- Humidity/wet bathing suit

**FIGURE 106.3** Vaginal candidiasis showing typical adherent, thick, milky-white vaginal discharge

### Treatment<sup>6,7,8</sup>

For the first attack of candidiasis it is appropriate to select one of the range of vaginal azoles therapies (clotrimazole, butoconazole, miconazole) for 1–7 days. There appears to be no significant difference between azoles. Nystatin is best reserved for recurrent cases or if there is local reaction to the azoles. Some therapists prefer creams to tablets and pessaries because cream can be applied to any tender vulval area, but a tablet and cream can be used simultaneously, especially for a heavy infection.

Gentian violet (0.5% aqueous solution) is useful for rapid relief, if available.

### Recommended initial regimen<sup>7,8</sup>

clotrimazole 500 mg vaginal tablet as a single dose or 100 mg for 6 nights  
±  
clotrimazole 2% cream applied to vulvovaginal and perineal areas 8–12 hourly (for symptomatic relief)

An alternative regimen, especially for recurrent infections:

nystatin pessaries twice daily for 7 days  
and/or  
nystatin vaginal cream (100 000 U per 5 g) twice daily for 7 days

If patient intolerant of vaginal therapy, use fluconazole 150 mg (o) as a single dose

### Recalcitrant cases (proven by microscopy and if not pregnant) or recurrent and chronic cases<sup>6</sup>

fluconazole 50 mg (o) once daily  
or  
itraconazole 100 mg (o) once daily

The time to achieve remission varies from 2 weeks to 6 months.

*Note:* A male sexual partner does not usually require treatment.<sup>5</sup> If symptomatic (usually balanitis in an uncircumcised male), treat with clotrimazole 1% + hydrocortisone 1% topically, 12 hourly until 2 weeks after symptoms resolve.

### *Candida glabrata*<sup>7</sup>

A significant number of cases of recurrent vulvovaginal candidiasis are due to non-albicans species of *Candida*. *Torulopsis glabrata* is the commonest non-albicans species, which exhibit reduced susceptibility to azoles. In resistant infections use boric acid 600 mg

(in a gelatin capsule) intravaginally for 10 to 14 days. Do not use in pregnancy.

### Advice to patients with vaginal candidiasis<sup>8,9</sup>

- Bathe the genital area gently for symptomatic relief. In preparing for the antifungal preparation, use 1–3% acetic acid or sodium bicarbonate solution (1 tablespoon to 1 litre of water).
- Dry the genital area thoroughly after showering or bathing.
- Wear loose-fitting, cotton underwear.
- Avoid wearing pantyhose, tight jeans or tight underwear or using tampons.
- Avoid having intercourse or oral sex during the infected period.
- Do not use vaginal douches, powders or deodorants or take bubble baths.

### § *Trichomonas vaginalis*

This flagellated protozoan, which is thought to originate in the bowel, infects the vagina, Skene's ducts and lower urinary tract in women and the lower genitourinary tract in men. It is transmitted through sexual intercourse and is relatively common in the female after the onset of sexual activity. The most sensitive and specific test available (if necessary) is PCR.

#### Clinical features

- Profuse, thin discharge (grey to yellow–green in colour) (see FIG. 106.4)
- Small bubbles may be seen in 20–30%
- Pruritus
- Malodorous discharge
- Dyspareunia
- Diffuse erythema of cervix and vaginal walls
- Characteristic punctate appearance on cervix

#### Treatment<sup>5,6</sup>

oral metronidazole 2 g as a single dose (preferable) or 400 mg bd for 5 days (if relapse)  
or

tinidazole 2 g as a single dose (see TABLE 106.5)

- Use clotrimazole 100 mg vaginal tablet daily for 6 days during pregnancy
- Attention to hygiene
- The sexual partner, whether male or female, must be treated simultaneously
- The male partner should wear a condom during intercourse
- For resistant infections a 3–5 day course of either metronidazole or tinidazole may be necessary<sup>10</sup>

FIGURE 106.4 *Trichomonas vaginitis* showing profuse, thin, greyish discharge with erythema of the vaginal walls

### § Bacterial vaginosis

Bacterial vaginosis is a clinical entity of mixed aetiology characterised by the replacement of the normal vaginal microflora (chiefly *Lactobacillus*) with a mixed flora consisting of *Gardnerella vaginalis*, other anaerobes such as *Mobiluncus* species, and *Mycoplasma hominis*. This accounts for the alkalinity of the vaginal pH.

#### Clinical features

- A grey, watery, profuse discharge (see FIG. 106.5)
- Malodorous
- No obvious vulvitis or vaginitis
- Liberates an amine-like, fishy odour on admixture of 10% KOH (the amine whiff test)
- Clue cells
- ± Dyspareunia and dysuria
- ± Pruritus (uncommon)

#### Treatment<sup>8</sup>

Refer to TABLE 106.4.

FIGURE 106.5 Bacterial vaginosis

metronidazole 400 mg (o) bd for 7 days  
(or 2 g stat)

or

0.75% vaginal gel applied at bedtime for 5 days

Clindamycin 300 mg (o) bd for 7 days or 2% clindamycin cream can be used for resistant infections or during pregnancy. Normal vaginal pH can be restored using a variety of topical douches such as povidone iodine solution (1 tablespoon per litre of water), vinegar (3–4 tablespoons per litre of water), topical Aci-Jel or a milky solution of yoghurt to restore *Lactobacillus* levels. Consider screening and treating female sexual partners.

There is no evidence that treatment of the male sexual partner reduces the recurrence rate or provides any significant benefit.<sup>11</sup> The STI treatment guidelines of the US Centers for Disease Control state explicitly that such treatment is of no proven benefit.<sup>12</sup>

**Table 106.4** Oral treatment for bacterial vaginosis and *Trichomonas* infections

Length of treatment	Generic name	Oral dosage
1 day (statim dose)	tinidazole	500 mg × 4
	metronidazole	400 mg × 5
7 days (for recurrent)	tinidazole	500 mg daily
	metronidazole	400 mg bd

## § Group B *Streptococcus* vaginosis

Group B *Streptococcus* (*S. agalactiae*) is a commensal in up to 40% of healthy humans. It is a problem if detected in the pregnant woman because of serious infection in the neonate. In certain at-risk circumstances, such as premature rupture of the membranes or a previous infected neonate, give:

benzylpenicillin 1.2 g IV stat, then 600 mg IV  
4 hourly until delivery (see CHAPTER 109)

In the non-pregnant woman give amoxycillin 500 mg (o) tds for 7 days if there is significant pyogenic infection.

## § Retained vaginal tampon

A retained tampon, which may be impacted and cannot be removed by the patient, is usually associated with an extremely offensive vaginal discharge. Its removal can cause considerable embarrassment to both patient and doctor.

### Methods of removal

Using good vision the tampon is seized with a pair of sponge-holding forceps and quickly immersed under water without releasing the forceps. A bowl of water (an old plastic ice-cream container is suitable) is kept as close to the introitus as possible. This results in minimal malodour. The tampon and water are immediately flushed down the toilet if the toilet system can accommodate tampons. An alternative method is to grasp the tampon with a gloved hand and quickly peel the glove over the tampon for disposal.

## § Tampon toxic shock syndrome: staphylococcal infection

This rare, dramatic condition is caused by the production of staphylococcal exotoxin associated with tampon use for menstrual protection. The syndrome usually begins within 5 days of the onset of the period.

The clinical features include sudden onset fever, vomiting and diarrhoea, muscle aches and pains, skin erythema, hypotension progressing to confusion, stupor and sometimes death.

### Management

Active treatment depends on the severity of the illness. Cultures should be taken from the vagina, cervix, perineum and nasopharynx. The patient should be referred to a major centre if 'shock' develops. Otherwise the vagina must be emptied,

ensuring there is not a forgotten tampon, cleaned with a povidone iodine solution tds for 2 days, and flucloxacillin or vancomycin antibiotics administered.

- These women should not use tampons in the future.

### Prevention

- Good general hygiene with care in handling and inserting the tampons.
- Change the tampon 3–4 times a day.
- Use an external pad at night during sleep.

### When to refer

- Evidence of sexual abuse in children (to an experienced sexual assault centre)
- Recurrent, recalcitrant infections
- Presence of cancer or fistula
- Staphylococcal toxic shock syndrome

### Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Vaginal thrush
- Vulvovaginal irritation in children

### Practice tips

- Failure of treatment may be due to diagnostic error, therapeutic error, sexual re-infection, chemical sensitivity to vaginal tablets, drug resistance or depressed host immunity.
- Patients with an infective cause appreciate the use of patient education material, especially that including preventive measures.
- Advise patients subject to vaginal infection about simple hygiene measures to keep the area dry and cool: avoid nylon underwear, pantyhose, tight jeans, wet swimsuits, perfumed soaps and vaginal deodorisers.
- A serious sequela is subsequent dyspareunia and vaginismus. The patient should be advised to have sufficient lubrication, such as K-Y Gel, to avoid distressing psychosexual problems.

# 107 Vulvar disorders

*Genital skin is very sensitive. This sensitive organ needs protection from chemical and physical damage. The genital area is also affected by the way you feel and symptoms can appear worse at times of stress.*

EXTRACT FROM PATIENT INFORMATION SHEET, 'THE DO'S AND DON'TS OF GENITAL HYGIENE',  
DERMATOLOGY/VULVAL DISEASES CLINIC, MERCY HOSPITAL FOR WOMEN, MELBOURNE

The dermatoses are the predominant cause of vulvar problems and this chapter focuses mainly on the important female genital skin conditions.

The vulva is that part of the female external genitalia lying posterior to the mons pubis, comprising the labia majora, labia minora, clitoris, vestibule of the vagina, vaginal opening and bulbs of the vestibule.<sup>1</sup>

The vaginal vestibule is an almond-shaped opening between the lines of attachment of the labia minora. The clitoris marks the superior angle and the fourchette the inferior boundary. It is approximately 4–5 cm long and 2 cm in width.<sup>1</sup> The four main structures that open into the vestibule are the urethra, vagina and the two secretory ducts of Bartholin's glands. The surface is composed of delicate, stratified squamous epithelium.

The genital area is affected by dermatoses found elsewhere on the skin but management is rendered more complex by the sensitivity and thinness of the skin, a tendency to superinfection, in addition to the psychological problems, including the often-resultant dyspareunia.

The vulval area, which is innervated by nerves arising from L1–2 and S2–4 nerve roots, is sensitive to noxious stimuli but the vagina is not sensitive to pain.<sup>2</sup> Topical creams, soaps, perfumes and other toilet products irritate the vulva easily—it is an area prone to contact dermatitis.

Clinical manifestations of vulvar disorders include itching, pain, irritation, white mucosal patches, lichenification, erosions and intertrigo<sup>3</sup> (see the diagnostic strategy model presented in TABLE 107.1).

## Key facts and checkpoints

- If a dermatosis is suspected, check the skin on the body.
- Provoked vestibulodynia (vulvar vestibular syndrome) is a distressing, reasonably common

condition that gives superficial dyspareunia. Diagnosis is by an abnormal response to light touch, even by a cotton bud.

- The vestibule can exhibit pearly papules (the equivalent of pearly penile papules) that look like tiny regular warts—they are normal.
- Urinary incontinence or faecal incontinence may be the basis of the problem in the vulvar area. It can be misdiagnosed as urinary tract infection.
- Avoid using topical mixed steroids and antimicrobial applications (e.g. Kenacomb) to treat vulvar dermatoses.
- Approximately 20% of women carry *Candida albicans* as genital flora but less than 5% suffer from repeated or intractable clinical candidiasis.
- Not all itching and burning of the vulva and vagina is *Candida* infection. Swabs should be taken for diagnosis before committing to treatment empirically.
- The cause of vulvar irritation may be multifactorial (e.g. atopic dermatitis or *Candida* with irritant or allergic contact dermatitis from applications).
- Be alert for malignant melanoma and be aware that an area of benign pigmentation with well-demarcated edges and bluish discolouration called melanocytosis vulvae can develop.

## § Dermatitis

As expected, the various common forms of dermatitis collectively represent the prime cause of a pruritic irritating vulvar skin disorder. They classically present with itching, burning and soreness initiated by scratching leading to white plaques of lichen simplex chronicus. The manifestations can vary from symptoms without a rash to a poorly defined rash without the above symptoms.

The causes of vulvar dermatitis are:

- atopic dermatitis
- irritant contact dermatitis

- allergic contact dermatitis
- seborrhoeic dermatitis
- corticosteroid-induced dermatitis
- psoriasis

**Table 107.1** Vulvar discomfort/irritation: diagnostic strategy model

Q.	Probability diagnosis
A.	Atopic dermatitis Chronic vulvovaginal candidiasis Irritant contact dermatitis (e.g. panty liners, douches, bubble baths) Allergic contact dermatitis (e.g. perfumes, topical antimicrobials) Fissuring from the above dermatoses Trauma—'dry' coitus
Q.	Serious disorders not to be missed
A.	Neoplasia <ul style="list-style-type: none"> <li>• squamous cell carcinoma:</li> <li>• melanoma</li> <li>• lymphomas, etc. → pruritus</li> </ul> Infection: <ul style="list-style-type: none"> <li>• streptococcal vulvovaginitis</li> <li>• herpes simplex virus; herpes zoster virus</li> </ul> Provoked vestibulodynia
Q.	Pitfalls (often missed)
A.	Lichen sclerosus Urinary incontinence → ammoniacal vulvitis Faecal soiling Tinea cruris Trichomonal vaginitis Atrophic vaginitis Aphthous ulcers Dysaesthetic vulvodynia Psoriasis Lichen planus Infestations: <ul style="list-style-type: none"> <li>• threadworms</li> <li>• pubic lice</li> <li>• scabies</li> </ul>
Q.	Seven masquerades list
A.	Depression Diabetes Drugs Spinal dysfunction (dysaesthesia) UTI
Q.	Is the patient trying to tell me something?
A.	Common: psychosexual problems.

## Principles of management<sup>4</sup>

- Take an appropriate history, including atopy, skin diseases.
- Check allergens and irritants (e.g. panty liners, soap, bubble bath, perfumed toilet paper, douches, perfumes, condoms, tea-tree oil).
- Check for heat and friction (e.g. synthetic or tight underwear, tight denim jeans, sporting costumes/tights, sweating, vigorous activity—bicycle riding).
- Check gynae-urological history (e.g. oestrogen status, faecal or urinary incontinence, vaginal discharge, 'thrush').
- Check psychosexual history (e.g. dyspareunia, partnership issues, depression).
- Carefully inspect the vulva plus the rest of the skin, scalp and nails. Look for lichenification (see **TABLE 107.2**).
- Appropriate investigations: low vaginal swab (? *Candida albicans*), Pap test, perhaps patch testing and vulval biopsy for a rare, premalignant or suspected malignant condition, especially if thickening or textural change.

**Table 107.2** Causes of common vulvar signs

White patches	Lichen simplex (lichenification) Lichen sclerosus Lichen planus Leucoplakia Cancer
Erosions and ulcers	Herpes simplex or zoster Excoriated lichen sclerosus Erosive lichen planus Cancer Aphthous ulcers Various uncommon dermatoses Contact dermatitis Excoriated scabies
Intertrigo	Atopic dermatitis <i>Candida albicans</i> Seborrhoeic dermatitis Tinea Erythrasma Psoriasis

**Treatment<sup>3,4</sup>**

- Provide supportive education and counselling.
- Correct underlying factors (e.g. tight clothes, incontinence, anal discharge, overused topical medications and cosmetics).
- Treat any secondary infection.
- Use aqueous cream moisturiser as cleanser.
- Start with potent class III topical steroid and follow with 1% hydrocortisone until resolution.

**§ Psoriasis<sup>5</sup>**

Psoriasis can affect the genital or perianal area (especially the natal cleft) and appears as a glazed, beefy red plaque without the classic scale seen elsewhere. There may be minimal or no sign of psoriasis on the skin of the body.

The main symptom is itching. It is usual to take swabs to rule out infection.

**Treatment<sup>5</sup>**

- Avoid irritants and use a soap substitute.
- First apply a potent topical steroid (e.g. methylprednisolone aceponate)—continue until resolution of rash.
- Second (when controlled) apply LPC 2% in aqueous cream bd, slowly increasing the strength up to 8%. If not tolerated, use ichthammol 2% in aqueous cream.

*Note:* Maintenance with topical steroids—hydrocortisone 1% or resume potent agent for a flare-up.

**§ Lichen planus<sup>6</sup>**

Genital lichen planus is relatively uncommon but may affect both the vulva and vagina and can occur in association with oral lesions. Vulvar lesions appear as whitish reticulated papules and plaques. A delicate white lacy pattern at the periphery of the lesion is a distinctive feature. Erosions may occur.

Symptoms include irritation, pruritus, vaginal discharge, dyspareunia (if erosions) and postcoital bleeding.

Differential diagnoses of vulvar lichen planus include other causes of desquamative and erosive lesions, such as lichen sclerosus, pemphigus vulgaris, bullous and cicatricial pemphigoid and erythema multiforme.

A biopsy is required to make the diagnosis. Treatment is difficult. Potent topical steroids provide symptomatic relief and there is a variety of treatment trials, including topical cyclosporin or oral methotrexate.<sup>5</sup>

**§ Lichen sclerosus<sup>4,5</sup>**

Also known as lichen sclerosus et atrophicus (see FIG. 107.1), this uncommon chronic inflammatory dermatosis of unknown aetiology (perhaps an autoimmune disorder) presents as well-defined white, finely wrinkled plaques that almost exclusively affect the anogenital skin, although they can occur anywhere on the body. Lichen sclerosus spares the vagina. It can run a chronic and complicated course with development of squamous cell carcinoma (SCC) in about 4% a concern. The differential diagnosis is atrophic vaginitis.

**DxT** genital pruritus + soreness + white wrinkled plaques → lichen sclerosus

**FIGURE 107.1** Lichen sclerosus et atrophicus of vulva in a 55-year-old woman. This shows white sclerotic plaques and epidermal atrophy

**Clinical features**

- Bimodal peak: prepubertal girls, perimenopause
- Mean age of onset in adult women is 50 years
- Pruritus is main symptom
- Soreness, burning, dyspareunia

## Examination

- Variable distribution
- White wrinkled plaques
- Purpuric and ulcerated areas
- May show figure of 8 pale perianal and perivaginal area

## Complications if untreated

- Vulval atrophy and labial (even clitoral hood) fusion, introital stenosis
- Lifetime risk of SCC 2–6%

## Management<sup>5</sup>

- Best in consultation with a dermatologist.
- Confirm diagnosis by biopsy (tend to avoid in children).
- Based on potent topical corticosteroids (e.g. betamethasone dipropionate 0.05% ointment or cream applied bd for 4 weeks, then daily for 8 weeks, with applicator—show patients where to apply, using a mirror).
- Reduce to a potent topical steroid once daily for next 3 months, then reduce to hydrocortisone 1% ointment or cream applied daily for long term.
- Lifelong surveillance with 6-monthly check-up.
- A similar topical program is used in children.

## INFECTIONS

### § Chronic vulvovaginal candidiasis

This is different from acute candidiasis and remains difficult to treat because there may be a localised hypersensitivity to *Candida*.

### Clinical features

- Chronic vulval itch–scratch cycle
- Burning, swelling—premenstrual exacerbation
- Dyspareunia
- Discharge not usually present
- Aggravated by courses of systemic antibiotics

### Management<sup>5</sup>

- Cease hormone contraceptives e.g. OCP
- Swab—low vaginal—with each suspected episode, especially if discharge
- Aim for symptom remission with continuous antifungal treatment:
  - topical vaginal antifungals (imidazoles or nystatin), *or*
  - daily oral antifungals (monitor liver function tests) until symptoms clear—ketoconazole

200 mg/day (beware of hepatotoxicity) or fluconazole 50 mg/day, or itraconazole 100 mg day (then weekly for 6 months)

- Relieve itching with hydrocortisone 1% (do not use stronger preparations)
- Use nystatin pessaries in pregnancy

### § Group B *Streptococcus* (GBS)

GBS is commonly carried in the vaginal flora of healthy women. Very rarely it may produce symptomatic vulvovaginitis with a constant irritating discharge and a beefy red, sore vulva and vagina. Diagnosis is based on Gram stain and culture of a vaginal swab.

### Treatment<sup>5</sup>

clindamycin 2% vaginal cream nocte for 14 nights

*or*

phenoxymethylpenicillin 500 mg (o) 12 hourly for 14 days

*or*

oral antibiotic as indicated on sensitivity testing (e.g. amoxycillin or roxithromycin)

### § Tinea

Tinea causes an annular spreading rash with an active border that spreads from the labia to the thigh (see tinea cruris, CHAPTER 122). A problem is the development of tinea incognito from the application of topical steroids. This lacks central clearing but the active margin can be seen. Skin scrapings are necessary for diagnosis. Treatment is with a topical imidazole (avoid nystatin) or oral agents if resistant or extensive.

### § Pruritus vulvae

The causes of an itchy vulva to consider are:<sup>7</sup>

- candidiasis (rash, cottage cheese discharge):
  - broad-spectrum antibiotics
  - diabetes mellitus
  - contraceptive pill
- poor hygiene and excessive sweating
- tight clothing
- sensitivity to soaps, bubble baths, cosmetics and contraceptive agents
- overzealous washing
- local skin conditions:
  - psoriasis
  - dermatitis/eczema (uncommon cause)

- post-anal conditions (e.g. haemorrhoids)
- infestations:
  - threadworms (children)
  - scabies
  - pediculosis pubis
- infections (other than candidiasis):
  - *Trichomonas*
  - urinary tract infection
  - genital herpes, genital warts
- menopause: due to oestrogen deficiency (atrophic vaginitis)
- topical antihistamines
- vulval carcinoma
- psychological disorder (e.g. psychosexual problem, STI phobia)

If labia minora, consider lichen sclerosus.  
Treatment is according to the causation.

### Management

This depends on the primary cause (e.g. candidiasis, incontinence), which should be treated effectively.

### General measures (advice to patients)<sup>3</sup>

- Attend to hygiene and excessive sweating.
- Avoid overzealous washing.
- Take showers of no more than 5 minutes duration.
- Avoid water too hot (lukewarm preferable).
- Avoid toilet soap—use a soap alternative (e.g. aqueous cream, Cetaphil lotion) and wash it off with water only.
- Use soap alternatives (e.g. Dove, Neutrogena) for rest of body.
- Pat the skin dry after the shower (avoid harsh drying).
- Keep the genital area dry and wash thoroughly at least once a day.
- Do not wear tight pantyhose, tight jeans or tight underwear, or use tampons.
- Do not use vaginal douches, powders or deodorants.
- After the toilet, wipe gently with a soft, non-coloured, non-perfumed toilet paper.
- Apply a good moisturiser (e.g. Hydraderm or 5% peanut oil in aqueous cream).

### Treatment

- For pruritus, apply cool moisturising cream (kept in refrigerator) when there is an urge to scratch.
- Apply prescribed steroid ointment to the rash.

## VULVOVAGINITIS IN PREPUBERTAL GIRLS

Vulvovaginitis is the most common gynaecological disorder of childhood. It can affect women of any age but is particularly common in girls, especially between the ages of 2 and 8 years. It is a type of dermatitis of the vulva and the vagina.

### § Mild vulvovaginitis

Symptoms of this very common problem include:

- discomfort and soreness
- vulval itching
- redness
- discharge—usually a slight yellow discharge on the underwear
- dysuria

FIGURE 107.2 Typical area of inflammation of vulvovaginitis in girls

It is important not to confuse it with a urinary infection when the child is clearly uncomfortable due to stinging on urination.

The cause is usually due to a low-grade inflammation in an area with a possible underlying dermatological disorder such as atopic dermatitis, psoriasis and lichen sclerosus, leading to sensitivity to various irritants such as soaps and urine.

Affected girls are often 'atopic'.

The causal factors include:

- thin vaginal mucosa (the normal prepubescent state)
- dampness from synthetic fibre underwear, tight clothing, wet bathers, obesity
- lack of hygiene

- frequent self-handling, especially with irritation
- irritants (soap residue, bubble baths, antiseptics, chlorinated water)
- 'sandbox' vaginitis: girls sitting and playing in sand or dirt may develop irritation from particulate matter trapped in the vagina

### Management

- Explanation and reassurance to parents
- Avoidance of the above causal factors, especially wet bathers, synthetic underwear, bubble baths, perfumed soaps and getting overweight
- Attention to good, supervised toileting practice
- Attention to bathing and drying
- Regular warm baths (rather than showers)

It is worth soaking the child in a warm shallow bath containing half a cup of white vinegar.

Alternatively, bicarbonate of soda (10 g/10 L water) can be used.

Soothing creams such as soft paraffin creams and nappy rash creams such as zinc and castor oil cream should be applied three times daily as a short-term measure. If a powder is required, use zinc oxide (e.g. Curash). Consider an oestrogen cream.

### § Moderate/persistent vulvovaginitis

The symptoms may be more intense with increased itching, burning and discharge.

#### Important causes to consider<sup>8</sup>

- 'Sandbox' vaginitis
- Skin disorders, especially atopic dermatitis and lichen sclerosus (look for skin problems elsewhere on body)
- Foreign body: consider if a bloody, malodorous vaginal discharge
- Candidiasis—uncommon but consider if antibiotic therapy or possibility of diabetes
- Sexual abuse (uncommon but must not be missed)
- Pinworm infestation (*Enterobius*) (see FIG. 15.5 in CHAPTER 15)
- Sexually transmissible organisms—usually postpubertal

### Examination

A careful general examination should be performed only if considered appropriate. In infants the best examination method is to place the child on her mother's lap with the legs held well abducted. Lateral traction applied to the labia allows the hymen orifice

to be examined. Look for vulval or vaginal infection. Aspirate vaginal secretion with a medicine dropper for appropriate cultures. A Pap test is advisable for a persistent problem since a sarcoma is a possibility.

An older child can be placed in one of two suitable positions:

- 1 supine, legs apart in a frog-leg position, with bottom of feet touching (generally preferred)
- 2 prone, knee/chest position. This allows a better view of the hymenal orifice but many children do not like this position

A rectal examination may be performed to try to feel for suspected foreign bodies in the vagina.

### Taking a swab<sup>8</sup>

If the discharge is profuse and offensive, take an introital swab (do not take a vaginal swab). Infective vulvovaginitis in girls is almost always due to a Group A beta-haemolytic streptococcus.

Treat with an appropriate antibiotic.

### Treatment of dermatitis

Most cases of vulval dermatitis will respond to short courses of 1% hydrocortisone ointment or cream, provided aggravating factors are removed.

### § Labial adhesions (labial agglutination)

Labial fusion is caused by adhesions considered to be acquired from vulvovaginitis after which sometimes the medial edges of the labia minora become adherent. The adhesions are certainly not present at birth. Labial fusion is regarded as a normal variant and usually resolves spontaneously in late childhood. Provided the child is able to void easily, no treatment other than reassurance is needed.

For significant adhesions, treat as follows:

- oestrogen cream once a day until resolution (usually 2 to 6 weeks). Once the fusion has separated, ongoing treatment with soap avoidance, topical lubricants (e.g. Vaseline) and 1% hydrocortisone
- the fusion may re-form and have to be re-treated as necessary

Occasionally a minor surgical procedure (sometimes under general anaesthetic) to separate the labial adhesions may be required. However, such measures are not generally recommended.

## VULVODYNIA

Vulvodynia describes the symptom of pain (burning, rawness or stinging) and discomfort, where no obvious cause can be found. Itch is not a feature. Causes include provoked vestibulodynia (vulvar vestibular syndrome), dysaesthetic vulvodynia and various infections (e.g. herpes simplex virus). Virtually every condition of the vulva can be painful at times; even dermatitis can become painful if scratching or splitting leads to open areas and ulceration.

### § Provoked vestibulodynia<sup>2,4</sup>

#### Definition

**Vestibular hypersensitivity** Severe vulvar or vestibular pain on touch or entry into the vagina.

Also referred to as vulvar vestibular syndrome (VVS) or vestibulitis, it is a very important disorder for the GP to be aware of in the woman with a typical history of introital dyspareunia. It is a difficult problem to treat. The characteristic feature is severe pain with vestibular touch, including attempted vaginal entry (early dyspareunia). The vestibule is very sensitive, featuring an inappropriate response to light touch. In many instances the cause of the primary condition is not apparent and a history of possible sexual abuse or other psychological provoking factors should be diplomatically elicited. Some patients can develop the problem after years of pain-free sex.<sup>6</sup> It is the most common cause of dyspareunia in the premenopausal female.

Secondary causes include inflammatory triggers such as irritant contact dermatitis and infection. This establishes a conditioned response.

Spontaneous resolution has been reported in up to 50% of cases. Prognosis appears to be reasonably good but depends to some extent on the premorbid personality of the patient.<sup>3</sup>

**DxT** young + nulliparous + dyspareunia → provoked vestibulodynia

#### Clinical features

- Delayed diagnosis (average 2–3 years)<sup>4</sup>
- Sexually active women in 20s and 30s
- Family history

- Pain provoked by intercourse, tampon insertion, tight underwear
- Superficial 'entry' dyspareunia
- Sexual dysfunction
- Tender vestibule on pin point light pressure
- Erythema (usually minute red spots) around Bartholin's duct openings (consider *Candida*)

#### Diagnosis

Inappropriate tenderness to light touch with a cotton bud.

#### Management<sup>4</sup>

- Investigate underlying cause and treat it
- Patient education, counselling and support
- Physiotherapy—rehabilitation of pelvic floor musculature by increasing awareness and increasing elasticity of the tissues of the vaginal opening
- Reassure that the condition is self-limiting
- Encourage use of oil-based lubricants
- Use bland emollients or 2% lignocaine gel prior to intercourse
- If *Candida* present, treat with fluconazole 150 mg (o) weekly for 6 weeks

#### Options

- Biofeedback technique
- Tricyclic antidepressants (start low, e.g. amitriptyline 10–20 mg nocte then up to 100 mg—best option)
- Gabapentin
- Intralesional therapy:
  - triamcinolone
  - interferon
- Vestibulectomy (last resort):
  - excise tender vestibular tissue

### § Dysaesthetic vulvodynia<sup>2,9</sup>

The typical patient with this neuropathic pain problem is a middle-aged to elderly woman who presents with a constant burning pain of the labia. It typically builds up during the course of the day. Examination is often unrewarding. The underlying cause may be pudendal neuralgia (may be secondary to pudendal nerve block), referred spinal pain or simply unknown.<sup>10</sup>

Herpes simplex infection needs to be excluded.

Treatment options include antidepressants and gabapentin.

## § Bartholin's cyst

A Bartholin's gland swelling follows obstruction of the duct and presents as a painless vulval swelling at the posterior end of the labia majora, close to the fourchette. A simple, non-infected cyst can be left alone and may resolve spontaneously. If it becomes infected an abscess may result, causing a painful, tender, red vulval lump. It may resolve with antibiotics or discharge spontaneously. Otherwise drain and perform a micro and culture. The usual organism is *E. coli*. If the cyst persists and becomes large, a surgical marsupialisation procedure, which allows permanent drainage, can be performed (see FIGS 107.3a, b).

FIGURE 107.3 (a) Bartholin's cyst: starting the marsupialisation procedure, (b) Postoperative appearance

## Practice tip

- Always biopsy a focal lesion on the vulva<sup>6</sup>

# 108 Basic antenatal care

*An examiner, no lover of females, thrust a femur into her hand.*

*'How many of these have you got?' he demanded.*

*'Five.'*

*'How do you come to that conclusion?' he asked contemptuously.*

*'I have two of my own, the one in my hand, and the two of my unborn child.'*

ANONYMOUS ANECDOTE

Pregnancy and childbirth are very important and emotional events in the lives of women and their families. Their care during and after pregnancy is one of the most satisfying aspects of the work of the family doctor, who generally chooses breadth of knowledge rather than depth of knowledge. The changing trend towards specialisation has meant a change of role for the city practitioner and now shared obstetric care is a commonly practised routine. The quality of care that can be given in family practice is often superior to that offered in the hospital antenatal clinic, partly because of the continuing personal care offered by the family doctor.<sup>1</sup>

Antenatal care presents preventive medicine opportunities par excellence and is the ideal time to develop an optimal therapeutic relationship with the expectant mother. The opportunities for anticipatory guidance should be seized and education about the multitude of possible sensations during pregnancy (such as heartburn, backache, leg cramps, various fears and anxieties) should be addressed. In other words, an optimal communication system should be established between the expectant couple and the health care system.

Early diagnosis of high-risk pregnancy is important but of little value unless followed by normal attendance for antenatal care.

The information presented here is a basis for the shared care strategy where family doctors share basic antenatal care with consultants and have a ready referral strategy for high-risk pregnancies.

The basic aim of antenatal care is to assess the risk of harm to mother and baby and apply the appropriate level of surveillance to minimise or eradicate harmful effects.

## Preconception care

Preconception care is to be commended to the woman contemplating pregnancy and her family doctor is well

placed to provide general health care and screening as well as genetic counselling.

General advice should include optimal nutrition and diet, weight control, regular exercise and discouragement of smoking, alcohol and drugs. *Listeria* infection is a problem if contracted, with fetal mortality being 30–50%. Protection is afforded by good personal and food hygiene. For those who ask, advise avoidance of unpasteurised dairy products, soft cheeses, cold meats, raw seafoods, chilled ready-to-eat foods and takeaway foods.

Folic acid (0.5 mg tablets) is now generally recommended to commence about 3 months prior to conception, continuing to 12 weeks postconception. For women at increased risk, such as those on drugs known to increase fetal abnormalities or those with a past or family history of congenital abnormalities and also pre-pregnancy diabetes, the dose is 5 mg/day for at least 1 month and preferably 3 months pre-conception.<sup>2</sup> Examination should include blood pressure, cardiac status, urinalysis and cervical smear.

Rubella serology should be estimated and, if required, immunisation 4 weeks prior to conception should be initiated. Test for seroconversion 6–8 weeks later. Vaccination should be avoided in early pregnancy, and pregnancy avoided for 28 days after rubella vaccination.

Ask about a history of varicella and, if necessary, consider serology and vaccination.

Vaccinations to consider are:

- Boostrix (diphtheria, tetanus, pertussis)
- MMR (measles, mumps, rubella)
- Varicella
- Influenza (to protect against infection in the second and third trimester)

Genetic counselling based on past obstetric or family history, advanced maternal age or other factors should be considered. This applies especially

to Down syndrome, neural tube defect, congenital heart disease, cystic fibrosis, fragile X syndrome and sickle cell anaemia.

### Checkpoint summary: advice to patients

- Stop smoking and avoid passive smoke.
- Stop alcohol and other recreational drug use.
- Reduce or stop caffeine intake.
- Practise safe sexual health.
- Review current medications with your GP.
- Follow a healthy diet.
- Avoid being overweight.
- Take folic acid for 3 months before conception.
- Have a good exercise routine.
- Ensure rubella immunity.
- Have a regular breast check and Pap test.
- Eat freshly cooked and prepared food.
- Consider genetic and family history.
- Consider health insurance cover.
- Consider and discuss future family planning.

## The initial visit

It is important to book the patient into hospital at the first visit and into the antenatal outpatient department if appropriate. It is mandatory to make an accurate estimation of the expected due date—the use of ultrasonography can help.

### History checkpoints<sup>3,4</sup>

- Confirm the pregnancy by the menstrual history and by urine or serum human chorionic gonadotrophin (hCG), if necessary.
- Previous obstetric history:
  - gestation, length of labour, mode of delivery, birthweight of each baby
  - consider previous problems: fetal or neonatal abnormalities or deaths; pre-term or growth-restricted infants
  - abortions: determine if there has been any termination of pregnancies or first or second trimester spontaneous abortions
- Medical history:
  - check for past evidence of diabetes, tuberculosis, anaemia, rubella, rheumatic fever, heart or kidney disease, jaundice, depression, transfusions and rhesus status
- Family history:
  - features to consider are multiple pregnancies, hypertension and diabetes

- if any of these pertain to first-degree relatives, consider glucose tolerance testing
- Psychosocial history:
  - this is very important and includes an assessment of the emotional attitude and possible intimate partner violence
- Drug history:
  - includes intake of nicotine, alcohol, aspirin, illicit drugs, OTC drugs and prescribed drugs
- Important points to consider:
  - establish date of confinement (see obstetric calendar in FIG. 108.1)
  - if maternal age >37 years or NT indicates an increased risk of a fetal chromosomal abnormality, discuss maternal screening tests and amniocentesis or chorionic villus sampling or other relevant tests
  - consider unusual causes for severe nausea and vomiting (e.g. hydatidiform mole, cerebral tumour)
  - investigate possible exposure to rubella
  - if vaginal bleeding: if Rh negative, send blood sample for Rh antibodies—if absent, give one ampoule anti-D gammaglobulin within 72 hours of first bleed

## Examination

During the initial examination assess the patient's general physical and mental status. Examine the following:

- general fitness, colour (? anaemia)
- basic parameters: height, weight (calculate BMI), blood pressure, pulse, urinalysis (protein and glucose). A woman is hypertensive if the systolic BP  $\geq 140$  mmHg and/or diastolic BP is  $\geq 90$  mmHg<sup>3</sup>
- head and neck: teeth, gums, thyroid
- chest: including breasts/nipples
- abdomen: palpate for uterine size and listen to fetal heart (if indicated)
  - Perform the four classic techniques of palpation (applies to later visits):
  - 1 Fundal palpation
  - 2 Lateral abdominal palpation
  - 3 Pawlik palpation
  - 4 Deep pelvic palpation
- legs: note oedema or varicose veins

Speculum examination: perform a Pap test if not performed in preceding 2 years and swab (if indicated by abnormal vaginal discharge).

Pelvic examination (optional): confirm uterus size and period of gestation by bimanual palpation.

The calculation is made from the first day of the last menstrual period

Or: (approximately) subtract 3 from months and add 7 to days e.g. 19/8/89

+ 7 - 3

26/5/90

Or: Naegele's rule—add 7 days, 9 months

FIGURE 108.1 Obstetric calendar to determine expected due date

## Antenatal screening

The recommendations for antenatal screening of asymptomatic women are the source of debate with evidence-based medicine calling into question traditional tests. TABLE 108.1 reflects the recommendations of the RANZ College of Obstetricians and Gynaecologists.<sup>5,6</sup> Debate continues about screening for syphilis, group B *Streptococcus* in late pregnancy, thyroid function, hepatitis B and C and ultrasound.

### First trimester combined screening test<sup>3</sup>

- Maternal serum screening (MSST)<sup>7</sup> (9–13 weeks, 11 is ideal):
  - Free  $\beta$ -hCG
  - PAPP-A
 If MSST performed at 11 weeks and combined with NT one week later, it enables the risk of trisomy-21 and trisomy-18 to be defined and compared with age-related risk
- Nuchal translucency (NT) ultrasound (usually 12–13 weeks)

## Second trimester MSST

- performed at 15–16 weeks (if desired)

It is less useful for risk of trisomy-21 and 18, but the  $\alpha$ -fetoprotein assessment does define the risk of a neural tube defect.

This screening is to identify risk for a chromosomal abnormality and other fetal abnormalities (see also CHAPTER 18). Genetic testing for recessive disorders such as cystic fibrosis and thalassaemia can be discussed at this time.

Recently, free fetal DNA testing has been available in Australia and overseas. It is performed on a maternal blood sample taken at about 10–12 weeks gestation and allows the diagnosis of chromosome and gene abnormalities in the fetus, in addition to the sex of the baby.<sup>7</sup> If positive, amniocentesis or chorionic villus biopsy would usually be required for confirmation.

## Visits during pregnancy

The box below is a summary of standard antenatal practice.

**Table 108.1** Routine antenatal screening\*3,5,9

Recommended	Consider
First visit	
Full blood count and s. ferritin	• vitamin D
Blood group	• varicella serology
Rhesus and antibody screen	• haemoglobin electrophoresis (if indicated)
Rubella antibody status	
Cervical cytology if previous > 12 months	
HBV and HCV serology	
HIV serology (after counselling)	
Syphilis serology (TPHA)	
MSU and dipstick urine	
Discuss:	
First trimester combined screening test + NF test	
Ultrasound—18–20 weeks	
Subsequent visits	
Oral glucose challenge test or OGTT (now preferred to OGC because more accurate)—28 weeks	• 18-week morphology scan
Rubella anti—D immunoglobulin 28 and 34 weeks (Rh-negative mother)	
FBC—36 weeks	
Group B <i>Streptococcus</i> (GBS) swab—36 weeks	

### A common routine schedule (if all appears normal)

- Initial in first trimester: 8–10 weeks
- Up to 28 weeks: every 4–6 weeks
- Up to 36 weeks: every 2 weeks
- 36 weeks–delivery: weekly

### Guidelines for OGTT

- First visit—if previous gestational diabetes or strong family history
- About 20 weeks—as above + normal initial test
- About 26 weeks—for all other patients

The average number of visits is 12 but the need for this number is being questioned, with some authorities recommending as few as six visits.

A systematic review of seven RCTs found no difference in the detection of pre-eclampsia, urinary tract infection, low birthweight or maternal mortality when a schedule of reduced antenatal visits was compared with the traditional routine.<sup>5,8</sup> However, a sensible approach would be to plan visits according to need and circumstances in a flexible way.

For each visit record:

- weight (to calculate gain)
- blood pressure
- urinalysis (protein and sugar)—many clinics repeat at each visit only if there is proteinuria at the first visit or if signs of hypertension, kidney disease or pre-eclampsia develop. See **TABLE 108.2**
- uterine size/fundal height
- fetal heart (usually audible with stethoscope at 25 weeks and definitely by 28 weeks): detected by Sonicaid (or similar) from 18–20 weeks<sup>3</sup>
- fetal movements (if present)
- lie, presentation and position of fetus (third trimester)
- presence of any oedema

Record day of first fetal movements (i.e. ‘quickening’) (ask patient to write down the dates):

- primigravida: 17–20 weeks
- multigravida: 16–18 weeks

**Table 108.2** Causes of proteinuria in pregnancy

Urinary tract infection  
Contamination from vaginal discharge  
Pre-eclampsia toxemia  
Underlying chronic kidney disease

### Fundal height

The relative heights of the uterus fundus are shown in **FIGURE 108.2**. The uterus is a pelvic organ until the twelfth week of pregnancy. After this time it can be palpated abdominally. At about 20–22 weeks it has reached the level of the umbilicus and reaches the xiphisternum between 36 and 40 weeks. If the symphysis fundal height is more than 2 cm different from that expected for the gestation, the cause of this should be evaluated by ultrasound examination. Palpation of the fundal height is affected by obesity and tenseness of the abdominal wall.

**FIGURE 108.2** Fundal height in normal pregnancy (in weeks); the height of the fundus is a guide to the period of gestation. Nulliparas experience lightening at about 36 weeks when the fundal height usually reverts to the 34-week level.

## Management of specific issues

### Nutrition advice

A healthy diet is very important and should contain at least the following daily allowances:

- 1 Eat most:
  - fruit and vegetables (at least 4 serves)
  - cereals and bread (4–6 serves)
- 2 Eat moderately:
  - dairy products—3 cups (600 mL) of milk or equivalent in yoghurt or cheese
  - lean meat, poultry or fish—1 or 2 serves (at least 2 serves of red meat per week)
- 3 Eat least:
  - sugar and refined carbohydrates (e.g. sweets, cakes, biscuits, soft drinks)
  - polyunsaturated margarine, butter, oil and cream

Bran with cereal helps prevent constipation of pregnancy.

If the ideal diet is followed, iron, vitamin and calcium supplements should not be necessary, although most patients prefer to take OTC vitamin and mineral preparations (e.g. iron, folic acid, multivitamins, iodine). Do not diet to lose weight. It is usual to gain about 12 kg during pregnancy.

Less weight gain is recommended for women who are overweight pre-conception.

### Smoking, alcohol and other drugs

Encourage patients to avoid all street drugs, alcohol, tobacco and caffeine (ideally). If they find this impossible, encourage the following daily limitations:

- 1 standard drink of alcohol
- 1 cup of coffee or 2 cups of tea

Other household members should also stop smoking as passive smoking may be harmful to mother and child.

There is convincing evidence that promotion of smoking cessation programs during pregnancy is effective, with improved outcomes, including reduction in preterm birth rates and low birthweight rate.<sup>10</sup> The fetal alcohol syndrome is a leading cause of mental impairment, so it is best to abstain.

Mothers taking illicit drugs, especially opioids and amphetamines, require identification, counselling, treatment and surveillance for the neonatal abstinence syndrome in the newborn child.

### Breastfeeding

Mothers-to-be should be encouraged to breastfeed. Give advice and relevant literature. They can be directed to a local nursing mothers' group for support and guidance if necessary.

### Antenatal classes

Referral to therapists conducting such classes can provide advice and supervision on antenatal exercises, back care, posture, relaxation skills, pain relief in labour, general exercises and swimming. Enrolment with the partner is recommended.

### Normal activities

Mothers should be reassured that pregnancy is a normal event in the life cycle and that normal activities should be continued. Housework and other activities should be performed to just short of getting tired. The importance of getting sufficient rest and sleep should be emphasised.

### Sex in pregnancy<sup>11</sup>

Coitus should be encouraged during pregnancy but with appropriate care, especially in the 4 weeks before delivery. Restriction would only seem necessary if there has been an adverse obstetric history or there are major complications in the current pregnancy such as antepartum haemorrhage.

The couple should be encouraged to be loving to each other and communicate their feelings freely, as the need for affection and physical contact is important. Coital techniques can be modified as the pregnancy progresses—posterior entry and the female superior position are quite suitable.

## Travel

Pregnant women should avoid standing in trains. They should avoid international air travel after 28 weeks and travel after 34 weeks is usually not permitted. Patients should be counselled to wear a seat belt during car travel. Refer to **CHAPTER 14** for travel sickness in pregnancy.

## Psychosocial and emotional stress

Antenatal visits provide an ideal opportunity to become acquainted with the 'real' person and explore issues that help the patient. Provide whole person understanding with appropriate help and reassurance where necessary. Areas to be explored include support systems, attitudes of patient and partner to the pregnancy, sexuality, expectation of labour and delivery, financial issues, and attitudes of parents and in-laws.

## Weight gain in pregnancy

Although a standard weight gain is given as 12 kg over 40 weeks of pregnancy, it is common for some women in Australia to gain up to 20 kg without adverse effects.<sup>4</sup> Encourage sensible weight control.

Normal weight gain is minimal in the first 20 weeks, resulting in a 3 kg weight gain in the first half of pregnancy. From 20 weeks onwards there is an average weight gain of 0.5 kg per week. From 36 weeks the weight gain usually levels off.<sup>4</sup>

## Fetal movement chart

If daily fetal movements exceed 10 and the regular pattern has not changed significantly, then usually the fetus is at no risk. However, if the movements drop to fewer than 10 per day, the patient should be referred to hospital for fetal monitoring.

## Possible exposure to rubella

When contact with a possible case of rubella occurs during pregnancy it is essential to establish the immune status of the patient. If she is already immune no further action is necessary. If her immune status is unknown, perform a rubella IgG titre and IgM and repeat the IgG and IgM titres in 2–3 weeks.

## § Vaginal bleeding in early pregnancy<sup>12</sup>

This is a common problem in the first trimester in particular. At least 10% of normal pregnancies will have an episode and about 15% of recognised pregnancies will miscarry. If the bleeding is light to moderate and the pain mild or absent the question is 'Can a viable pregnancy continue or is there an ectopic pregnancy or a threatened miscarriage?'

- <6 weeks: Do serial quantitative HCG levels, which should double every 2 days (ultrasound usually unhelpful). If rise is too slow it means a non-viable pregnancy (? in tube or uterus). If hCG >1500 IU/L transvaginal ultrasound should be arranged as, if the pregnancy is progressing normally and within the uterine cavity, it will usually be seen.
- 6–8 weeks: Ultrasound will define an intra-uterine pregnancy and exclude an ectopic.
- >8 weeks: Normal ultrasound is reassuring since miscarriage rate is only 3% unless the amount of intrauterine blood is large.

*Note:* Rest is not necessary for threatened miscarriage.

A small bleed between 18–24 weeks indicates possible cervical 'weakness' and warrants a speculum or vaginal examination plus fetal assessment.

Be aware that an incomplete abortion can cause cervical shock (pelvic pain and fainting). Products of conception must be removed from the cervical os.

Consider the antiphospholipid syndrome for recurrent miscarriage and arrange antibody testing (see **CHAPTER 32**). Refer to a specialist for full assessment if 3 consecutive miscarriages have occurred.

## Threatened miscarriage

If a threatened miscarriage occurs, check the blood group and test for rhesus antibodies in maternal serum. If the mother is Rh-negative and no antibodies are detected, give one ampoule of anti-D gammaglobulin intramuscularly if the woman actually miscarries (not for threatened abortion). Assess her pelvis to rule out an ectopic pregnancy and, if indicated and the  $\beta$ -hCG is >1500 IU/L, perform pelvic scanning to confirm viability of the fetus or the presence of an extra-uterine gestation.

## § Pregnancy sickness<sup>13</sup>

- Nausea and vomiting occur in more than 50% of women

- Almost always disappears by the end of first trimester
- Mild cases can be dealt with by explanation and reassurance; it is preferable to avoid drug therapy if possible
- Simple measures:
  - small, frequent meals including ginger up to 1 g daily
  - a fizzy soft drink, especially ginger drinks, may help
  - ensure adequate hydration, including sucking ice chips and drinking small amounts of fluid
  - avoid stimuli such as cooking smells
  - take care with teeth cleaning
  - avoid oral iron
- Medication (for severe cases):
  - pyridoxine 25–50 mg bd or tds
  - if still ineffective add metoclopramide 10 mg tds

### § Hyperemesis gravidarum

This is severe vomiting in pregnancy, which may result in severe fluid and electrolyte depletion. It occurs in about 1 in 100 pregnancies.

#### Associations

- Normal complication
- Hydatidiform mole
- Multiple pregnancy
- Urinary infection

#### Management

- Test urine—MCU (micro-culture of urine); ketones: if +ve, admit to hospital
- Ultrasound examination
- Test electrolytes, urea, LFTs
- Bed rest
- Nil orally
- Fluid and electrolyte replacement
- Pyridoxine 50–100 mg daily IV/oral
- Metoclopramide 10 mg IV → 10 mg (o) tds (if necessary); if ineffective, ondansetron 4–8 mg IV 8–12 hourly
- Return to oral intake

### Heartburn

Gastro-oesophageal reflux is a major source of discomfort to women in the latter half of pregnancy. Non-pharmacological treatment such as frequent small meals, avoidance of bending over and elevation of the head of the bed are the mainstays of treatment. Smoking, alcohol and caffeine (coffee, chocolate, tea) intake should be avoided. Regular use of antacids is

effective (e.g. alginate/antacid liquid—Gaviscon, Mylanta Plus—10–20 mL) before meals and at bedtime. H<sub>2</sub>-receptor antagonists or PPIs may be necessary.

### Cramps

Pregnant women are more prone to cramp. If it develops they should be advised simply to place a pillow at the foot of the bed so that plantar flexion of the feet is avoided during sleep. Prolonged plantar flexion is the basis of the cramps. Quinine, including tonic water, should be avoided. There is no evidence that calcium supplements help cramps during pregnancy.<sup>14</sup>

### Varicose veins

These can be troublesome as well as embarrassing. Wearing special supportive pantyhose (not elastic bandages) is the most comfortable and practical way to cope, in addition to adequate rest.

### Haemorrhoids

Haemorrhoids in the later stages of pregnancy can be very troublesome. Emphasising the importance of a high-fibre diet to ensure regular bowel habit is the best management. Painful haemorrhoids may be eased by the application of packs soaked in warm saline or perhaps haemorrhoidal ointments containing local anaesthetic.

### Dental hygiene

Dental problems can worsen during pregnancy so special care of teeth and gums, including a visit to the dentist, is appropriate. Continuation of cleaning with a softer brush is recommended.

### Back pain

Back pain, especially low back pain, is common during pregnancy and special back care advice can help women cope with this problem, which can become debilitating. Advice about lifting, sitting and resting using a firm mattress, and avoiding high-heeled shoes, will help.

Physical therapy administered by a skilled therapist can be extremely effective for pregnant patients but certain safety rules should be followed:

- First trimester: use normal physical therapy and advise exercises.
- Second trimester: use supine side lying rotation and sitting techniques only; advise exercises.
- Third trimester: avoid physical therapy (if possible); encourage exercises.

### Guidelines for treatment

- Keep mobilisation and manipulation to a minimum.
- Use stretching and mobilisation in preference to manipulation.
- Safeguard the SIJs in the last trimester.
- Encourage active exercises as much as possible.
- Avoid medications wherever possible.
- Give trigger point injections (5–8 mL 1% lignocaine) around the SIJs if necessary.

### Exercise guidelines

Advise the patient that walking is an excellent exercise. For additional exercise activity:

- exercise at a mild to moderate level only
- avoid overheating and dehydration
- allow for a long warm-up before exercise and a long cool-down
- choose low-impact or water exercise
- stop if there are adverse symptoms (e.g. any pain, bleeding, faintness, undue distress)
- avoid scuba diving and sky diving

### Carpal tunnel syndrome

Splinting of the hand and forearm at night might be beneficial. If desperate, an injection of corticosteroid into the carpal tunnel can be very effective (check drug category for risk relative to dates). Sometimes operative division of the volar carpal ligament is necessary. Most problems subside following delivery.

### Hypotension

This is due to increased peripheral circulation and venous pooling. If bleeding is eliminated, advise to avoid standing suddenly and hot baths. It may cause syncope. Fainting may occur when the woman lies on her back in the latter half of pregnancy (supine hypotension). Avoid lying on the back—lie on the left side.

### Pruritus

Generalised itching (pruritus gravidarum) is usually associated with cholestasis due to oestrogen sensitivity in the third trimester. Order LFTs and, if not serious, reassure and prescribe a soothing skin preparation (e.g. aqueous cream  $\pm$  glycerol). If LFTs markedly abnormal or if pruritus is severe, the risk of fetal death is increased and special care and assessment is required.

### Obesity<sup>15</sup>

Obesity is associated with increased obstetric morbidity, including difficult labour and potential anaesthetic risks. Encourage weight loss diet with the aid of a dietitian.

### Breathlessness of pregnancy<sup>16</sup>

Consider physiological breathlessness of pregnancy in a woman with unexplained dyspnoea. It starts in the second trimester, is constant and aggravated by exercise and emotional stress. No special treatment is needed or helpful. The breathlessness usually settles 6–8 weeks after delivery.

### Mineral supplements in pregnancy

#### Iron

Iron is not routinely recommended for pregnant women who are healthy, following an optimal diet and have a normal blood test. Those at risk (e.g. with poor nutrition, vegan diet) will require supplementation.

#### Folic acid

Folic acid is advised for *all* women contemplating pregnancy, starting about 3 months prior to conception and continuing until 12 weeks after conception. Dose: 0.5 mg (o) daily.<sup>12</sup> In those at risk (e.g. previous neural tube defect and history of epilepsy), the dose is 5 mg per day.<sup>15</sup>

#### Vitamin B12

Vitamin B12 is essential for the developing fetus and if deficiency is known or suspected (e.g. vegetarian/vegan diet), test and give injections of B12 if deficient.

#### Iodine

It is recommended, for pregnant and lactating women and those planning a pregnancy, to take 150 mcg of supplementary iodine as soon as possible by using iodised salt for cooking and a multivitamin that includes iodine.

#### Vitamin D

There may be a case for routine testing but it is advisable to test women who are dark-skinned, veiled and at risk.<sup>17,18</sup> If deficient (<25 nmol/L) or insufficient (25–50 nmol/L), aim to keep vitamin D levels >70 nmol/L with cholecalciferol 1000–2000 IU daily.<sup>19</sup>

### Advice on when to seek medical help

- If contractions, unusual pain or bleeding occur before term
- If the baby is less active than usual: fetal movements should not decrease close to term

- If the membranes rupture (with fluid loss)
- The onset of regular contractions 5–10 minutes apart if >34 weeks gestation but earlier if possible premature labour occurring between 22 and 34 weeks gestation

 NHS Fetal Anomaly Screening Programme <[www.fetalanomaly.screening.nhs.uk/](http://www.fetalanomaly.screening.nhs.uk/)>  
 The Royal Women's Hospital <[www.thewomens.org.au](http://www.thewomens.org.au)>

*After autopsies I concluded that the newborn died of childbed fever, or in other words, they died from the same disease as the maternity patients . . . from hands contaminated with cadaverous particles brought into contact with the genitals of delivering maternity patients. If those particles are destroyed chemically, so that in examinations patients are touched by fingers but not by these particles, the disease must be reduced. To destroy cadaverous matter adhering to hands I used chlorine liquida . . . starting in May 1847 . . .*

*When I look back upon the past, I can only dispel the sadness which falls upon me by gazing into the happy future when the infection will be banished.*

IGNAZ SEMMELWEIS (1818–65), AUTOBIOGRAPHICAL INTRODUCTION

*Semmelweis discovered the infectious nature of puerperal fever and how physicians transmitted it, but was not believed at the time. He died in a mental institution.*

## Urinary tract infection

Urinary tract infection includes pyelonephritis, cystitis and asymptomatic cases (see CHAPTER 25).

### § Acute pyelonephritis

This infection, usually due to *Escherichia coli*, is one of the most common infective complications of pregnancy. Symptoms include fever, chills, vomiting and loin pain. Bladder symptoms such as frequency and dysuria are commonly absent. The patient should be hospitalised and usually requires intravenous antibiotic therapy and possibly rehydration.

#### Treatment

amoxycillin 1 g IV 6 hourly for 48 hours, then 500 mg (o) 8 hourly (if bacteria sensitive) for 14 days<sup>1, 2</sup>

- Alternatives: cephalosporins (e.g. ceftriaxone 1 g IV and cephalexin 500 mg (o))

### § Acute cystitis

Patients with acute cystitis typically have dysuria and frequency. Treat for 10–14 days.

#### Treatment

cephalexin 250 mg (o) 6 hourly<sup>2</sup>

or

amoxycillin/potassium clavulanate (500/125 mg) (o) 12 hourly

or

nitrofurantoin 50 mg (o) 6 hourly, if a beta-lactam antibiotic is contraindicated

*Note:* Nitrofurantoin is contraindicated in the third trimester of pregnancy as it may lead to haemolytic diseases in the newborn. Cotrimoxazole and sulphonamides should be avoided. Amoxycillin is recommended only if susceptibility of the organism is proven.

- A high fluid intake should be maintained during treatment

### § Asymptomatic bacteriuria<sup>1</sup>

- 5–10% of pregnant asymptomatic women have positive cultures during pregnancy.
- Approximately 5% of such women subsequently develop pyelonephritis during pregnancy with an increased risk of preterm labour, mid-trimester abortion and pregnancy-induced hypertension.
- Ideally all women should be screened for bacteriuria at their first visit.
- Less than 1% will subsequently develop bacteraemia.

#### Treatment

Treatment is recommended according to culture sensitivities. It is preferable to delay it until the first trimester has passed (see CHAPTER 25).<sup>2</sup>

## Puerperal infection

Puerperal infection is defined as a wound infection of the genital tract arising as a complication of childbirth. It especially involves the placental site in the uterus and laceration or incisions of the birth canal. Chorioamnionitis is infection of the placenta

and membranes usually from normal vaginal flora (e.g. Group B *Streptococcus* (GBS), *E. coli*). It is worth recalling that Lancefield group A *Streptococcus* infection was the outstanding cause of septic maternal death before the introduction of penicillin. GBS has only recently been identified as a human pathogen.<sup>3</sup> It is carried by 15–20% of pregnant women in the vagina, usually without causing maternal problems or symptoms. Routine testing for GBS is recommended at 36 weeks because:

- if antibiotics are not given to carriers (the 15–20% who carry GBS) in labour, 50% of babies become colonised and 1% of these are severely affected and often die<sup>4</sup>
- the onset can be early or late in the neonate with a severe clinical presentation of rapid deterioration with septic shock. High-risk situations are premature rupture of the membranes, especially preterm, early labour and maternal intrapartum fever and also vaginal delivery
- if antibiotics are given in labour (at least 2 hours prior to delivery) fetal colonisation and infection almost never occurs

### Intrapartum GBS prophylaxis<sup>3</sup>

Indicated for GBS carrier in current pregnancy and previous baby with early onset disease. During labour:

benzylpenicillin 1.2 g IV statim then 600 mg IV 4 hourly until delivery (clindamycin 600 mg IV 8 hourly if hypersensitive to penicillin)

### Intra-uterine sepsis (overt or suspected)<sup>3</sup>

Maternal puerperal GBS infection usually has the following features:

- high fever >38°C on any 2 days from days 1 to 14
- tachycardia (maternal and fetal)
- endometritis—offensive or purulent discharge
- maybe abdominal pain, collapse or delirium if severe (indicates chorioamnionitis)

Swab the genital tract and culture and order FBE (neutrophilia + leucocytosis).

If the woman is febrile but not clinically ill, treat with amoxycillin + clavulanate 875/125 (o) bd for 5–7 days. If septic treat with:

amoxycillin 2 g IV 6 hourly  
plus  
gentamicin 4–6 mg/kg IV daily  
plus  
metronidazole 500 mg IV 12 hourly

## Vaginal candidiasis

*Candida* (thrush) is common in pregnancy since pregnancy is a predisposing factor to the growth of the fungus. Treatment follows conventional lines with topical creams and vaginal tablets as described in CHAPTER 106. Clotrimazole is a first-line treatment. Oral medication with fluconazole or itraconazole should be avoided.

## TRANSMISSIBLE VIRAL INFECTIONS

### 📌 Rubella

#### Key facts and checkpoints

- Fewer than 5% of women are not immune (IgG negative) and many are immigrants.
- Take blood for IgG antibodies—no concerns if negative.
- Rubella IgM indicates recent infection, rises 7–10 days after infection, and a real risk if pregnant.
- Reinfection can occur even after vaccination so test all pregnant contacts.
- Congenital rubella features are described in CHAPTER 93.
- Effects on fetus:<sup>5</sup>
  - <8 weeks gestation—up to 85% infected with all clinically affected
  - <12 weeks gestation—50–80% infected with 65–85% clinically affected
  - 13–16 weeks—30% infected with 1:3 sensorineural deafness
  - 16–19 weeks—10% infected—clinical effects rare, possible deafness
  - >19 weeks—no apparent risk<sup>4</sup>

#### Diagnosis

- Fourfold rise in IgG titres or rubella specific IgM antibody. If initial test –ve repeat in 2 weeks.

#### Vaccination

- Routine vaccination advisable—gives 95% protection<sup>6</sup>
- Do not vaccinate during or within 3 months of a proposed pregnancy
- If inadvertent vaccination in early pregnancy—negligible risk to fetus<sup>5</sup>
- Any IgG negative woman should be offered immunisation in the puerperium if no maternal infection. There is no specific immunoglobulin available

## § Varicella/chickenpox

### Key facts and checkpoints

- Greatest risk if infection is in first trimester and very late pregnancy (see **CHAPTER 93**).
- Does not apply to herpes zoster (shingles).
- Establish diagnosis by IgG antibody test.
- Fetal varicella syndrome is rare—includes limb abnormalities, microcephaly, optic atrophy, mental impairment, IUGR—but it appears to occur in 3% of pregnancies where the mother contracts varicella.<sup>7</sup>

Contacts: if there is no history of clinical varicella do an IgG antibody test in mother. If seronegative give varicella zoster immunoglobulin (VZ-Ig) immediately (within 48 hours of contact). Also give VZ-Ig to immunocompromised patients.

Maternal infection in early pregnancy: greatest risk <20 weeks gestation. Give a course of an antiviral (e.g. acyclovir, valaciclovir); consider ultrasound.

Maternal infection in late pregnancy:<sup>8</sup> greatest risk is 5 days before delivery and up to 4 weeks after delivery—30% fetal mortality if infected. Consider VZ-Ig for baby if <7 days before delivery and up to 4 weeks after. Isolate mother from baby until not contagious.

## § Parvovirus B19

### Key facts and checkpoints

- This virus causes ‘slapped cheek syndrome’ (see **CHAPTER 93**) and can be mistaken for rubella.
- The non-immune are at risk.
- A risk of transplacental infection exists throughout pregnancy.
- Screen for immunity with parvovirus B19 IgG antibodies (reassure if positive).
- Screen for infection with acute and convalescent sera for IgM antibodies.
- Miscarriage rate is 4% <20 weeks.<sup>9</sup>
- If infection occurs in the third trimester it may cause stillbirth due to severe fetal anaemia.
- Fetal parvovirus syndrome is anaemia-hydrops fetalis with cardiac failure and possibly death.

If infection occurs during pregnancy, refer for fetal monitoring by ultrasound—if hydrops, consider early blood transfusion.

## § Cytomegalovirus

### Key facts and checkpoints

- CMV is the commonest cause of intra-uterine infection.

- It is the commonest viral cause of birth defects.
- Primary infection is usually asymptomatic.
- The fetus is most vulnerable in early pregnancy.
- Specific IgM antibody implies acute infection.
- The risk from maternal infection is about 40%.
- The incidence of congenital CMV is about 0.3%.
- Effects variable and unpredictable—can be severe or mild (see **CHAPTER 28**).
- Up to 30% of CMV-affected infants have mental impairment.
- In up to 50% the effects are restricted to hearing loss.
- There is no therapy or preventive strategy to alter the disease.
- Routine testing is not recommended.

If fetal infection is likely or suspected consider referral and amniocentesis.

## § Hepatitis B

### Key facts and checkpoints<sup>9</sup>

- Women should be screened for hepatitis B during pregnancy.
- +ve HBsAg indicates acute infection.
- +ve anti-HBs indicates recovery and immunity.
- +ve HBeAg indicates high infectivity but low transmission in utero.
- Vertical transmission, usually during labour, is the concern.
- There is a higher risk (90%) if mother is HBeAg seropositive.
- Infected infants have a 90% risk of becoming chronic carriers with liver disease.

### Prevention (immunisation)

At delivery or ASAP give newborn babies of carrier mothers both hepatitis B vaccine and immunoglobulin (HBIG). This gives efficacy of about 90–95%. Follow up with booster doses of vaccine at 2, 4 and 6 (or 12) months.

## § Hepatitis C

HCV screening is recommended at the first antenatal visit for those from significant risk groups. If positive, the transmission rate to fetus is 5% and much higher if there is maternal infection during pregnancy.<sup>4</sup> Evidence is unclear whether HCV transmission occurs during breastfeeding. Screen infants at risk at 12 months and treat positive cases accordingly under specialist care.

## SEXUALLY TRANSMITTED INFECTIONS

### § Genital herpes

Both primary genital herpes (in particular) and recurrent herpes pose a risk to the neonate. The risk from primary infection is greatest if it occurs after 28 weeks gestation. Risk factors for intrapartum infection include primary infection, multiple lesions, premature rupture of the membranes and premature labour. The main problem is vertical transmission during labour.

#### Management<sup>10</sup>

- Perform a cervical swab for PCR testing for HSV infection in patients with previous infection or those with apparent infection in pregnancy.
- Consider prophylactic antiviral (e.g. acyclovir) for mother from 38 weeks until time of delivery—to try to prevent recurrent herpes in late pregnancy.
- Arrange caesarean section if:
  - there are active lesions present (cervix/vulva) at time of delivery or within preceding 4 days
  - membranes ruptured <4 hours
- If vaginal delivery, give acyclovir to the neonate (check with neonatal paediatrician).

### § Genital warts

Although estimates indicate that up to 70% of the world's adult population carry one or more strains of human papilloma virus, the risk of transmission of the virus from the maternal genital tract to the fetus is very low.<sup>4</sup> Caesarean section is rarely indicated for obstruction from or the presence of gross numbers of cervical warts.

### § Syphilis

#### Key facts and checkpoints<sup>4</sup>

- Incidence 2:1000
- Usually transmitted in second trimester
- May cause fetal death; congenital infection with mental handicap
- Tests—VDRL, TPHA, FTA-Abs

#### Treatment

- Acquired early syphilis including latent <12 months: benzathine penicillin 1.8 g IM as single dose
- Late latent syphilis (incubation period >12 months): benzathine penicillin 1.8 g IM once each week for 3 doses
- Treat the partner

### § HIV

The fetal infection rate from an HIV-positive mother is about 15–25%,<sup>11</sup> unless appropriate ART has been given.

If screening detects an HIV-positive mother, both she and her newborn infant require antiretroviral therapy. Consult with a specialist experienced in treating HIV infection.

Breastfeeding is inadvisable because it doubles the risk of vertical transmission.

The risk of transmission can be reduced to <5%.<sup>11,12</sup>

- by treatment with zidovudine prescribed for the mother antenatally and during labour and to the neonate for the first 6 weeks postpartum
- by elective caesarean, and
- by avoiding breastfeeding

### § Chlamydia/gonorrhoea

Both gonorrhoea and chlamydia urethritis can transmit infection to the fetus, causing neonatal conjunctivitis, which develops in the first 2 weeks of life. Chlamydia can also cause neonatal pulmonary infection such as pneumonia, which usually appears at 2 or 3 months of age. PCR testing of maternal urine as appropriate and eye swabs from the neonate are advisable. Treat according to antibiotic guidelines.

## INFECTIONS TRANSMITTED FROM CONTAMINATED FOOD

### § Toxoplasmosis

#### Key facts and checkpoints

- Incidence in pregnancy in Australia less than in Europe
- Caused by *Toxoplasma gondii*—a parasite found in cat (and ? possum) faeces and raw meat
- Acquired by close contact with infected cats or eating uncooked or undercooked meat
- About 2:1000 maternal infection rate with about 30% passed to fetus
- Most maternal cases are asymptomatic
- Greater risk to fetus before 20 weeks gestation
- Congenital toxoplasmosis rare, but may result in various CNS and eye abnormalities. Refer to **CHAPTER 28**
- May cause IUGR, miscarriage, stillbirth
- Overall up to 90% of infected babies escape long-term damage<sup>13</sup>
- Diagnosis by serological tests

Treatment in pregnant patients is with a combination of spiramycin, pyrimethamin and sulfadiazin (check with a consultant).

## § Listeriosis

### Key facts and checkpoints

- Infection is caused by a Gram-positive bacterium.
- There is a high risk of fetal mortality (30–50%) if contracted in pregnancy.
- May cause recurrent abortion, stillbirth, premature labour.
- Maternal symptoms include fever, headache, myalgia, rigors, vomiting, diarrhoea, abdominal pain. Suspect if persistent high fever/flu-like illness. Refer for expert advice.
- Non-pregnant women are usually asymptomatic.
- Transmission to fetus mainly in later pregnancy with a high risk.
- Infection is usually by infected food (e.g. soft cheese, pate, milk esp. unpasteurised, raw seafoods, smoked seafoods, coleslaw).
- Investigations—mainly blood culture, also amniotic fluid, cervical swab culture.
- Newborn may acquire pneumonia, liver abscesses, meningitis, sepsis.
- Maternal listeriosis is treated with amoxycillin.

### Practice tips

- Well-proven transplacental vertically transmissible pathogens include cytomegalovirus, rubella, syphilis, toxoplasmosis and varicella.
- The best serological evidence of recent infection is IgG seroconversion so the first specimen should be collected ASAP after the onset of symptoms.
- Many relevant viral and protozoal infections such as CMV, toxoplasmosis, parvovirus, and rubella can be asymptomatic.

### Preventive advice for toxoplasmosis and listeriosis

- Protection is afforded by good personal and food hygiene.
- Avoid eating the products listed.

- Only eat well-cooked meat/poultry—thoroughly cook all food of animal origin.
- Carefully wash soil from raw vegetables and fruit.
- Reheat leftover foods and ready-to-eat food until steaming hot.
- Always thoroughly clean utensils and food surfaces after preparing uncooked food.
- Pregnant women should get another person to clean cat litter boxes daily and wear disposable gloves for handling soil likely to be contaminated with cat faeces.
- Carefully wash hands after gardening or handling raw meats.

# 110 High-risk pregnancy

*Grace the wyffe of William Baxter, beinge aboute three weeks before her tyme, was brought in bed the first day of December of two children, their bellies were growne and joyned together, from their breastes to their navells, and their faces were together.*

JOHN RICHARDSON, GIVING DETAILS OF SIAMESE TWINS, BORN IN 1655

## Definition<sup>1</sup>

A high-risk pregnancy is one in which the fetus is at increased risk of stillbirth, neonatal morbidity or death, and/or the expectant mother is at increased risk for morbidity or mortality.

High-risk pregnancies may be predicted before conception in some women, especially those with serious medical problems and a poor obstetric history. Others at high risk can be identified at the first antenatal visit; other high-risk pregnancies develop during the course of pregnancy. The first antenatal visit is the most important visit and demands time and care to make an accurate assessment.

The primary goal in obstetric care is to avoid maternal and perinatal morbidity and mortality (in particular) wherever possible through appropriate risk management, including proactive strategies.

## Maternal mortality

The WHO definition of maternal mortality is the death of a woman during pregnancy, childbirth or in the 42 days of the puerperium, irrespective of duration or site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management. This excludes deaths from assisted reproductive technology where pregnancy has not resulted, but includes incidental causes of deaths. In Australia the classification comprises direct maternal deaths, indirect obstetric deaths (where diseases such as diabetes, cardiovascular and kidney are complicated by pregnancy) and incidental deaths such as road accidents, suicide and malignancy.<sup>2</sup>

The maternal mortality ratio is the number of deaths per 100 000 confinements. In first world countries it is approximately 10. The latest triennium statistics for Australia was 8.4 deaths per 100 000 confinements—8 for non-Indigenous Australians and 21.5 for ASTI people (c.f. Africa approx. 900).<sup>2</sup>

The main causes of direct maternal deaths in Australia are (in order):

- amniotic fluid embolism
- thrombosis and thromboembolism
- haemorrhage
- hypertensive disorders of pregnancy
- cardiac conditions
- anaesthetic-associated deaths

Contributing factors among those who died from haemorrhage are delays in diagnosis, treatment to arrest the haemorrhage and giving blood transfusion. Intracerebral haemorrhage was the main cause of death in hypertensive disorders.

Some Australian obstetric statistics for 2003:

- average age of all mothers was 29.5 years
- spontaneous vaginal births—60.3%
- caesarean section (CS) rate—28.5%
- instrumental delivery rate—10.7%
- multiple pregnancies—1.7%

## Perinatal mortality

The perinatal mortality is the total number of deaths of children within 28 days of birth (early neonatal deaths) plus fetal deaths at a minimum gestation period of 20 weeks or a minimum fetal weight of 400 g expressed per 1000 births.<sup>3</sup>

In Australia the perinatal mortality for 2011 was 9.9:1000 births with 7.4 fetal and 2.6 neonatal. The major factors<sup>4</sup> associated with perinatal mortality in NSW are very premature birth, congenital abnormalities and hypoxia during the antenatal period or in labour. A review of perinatal deaths occurring in 2003 in Australia found that 30.9% of perinatal deaths (or 45.7% of stillbirths) were unexplained antepartum deaths. Common causes included spontaneous preterm labour (<37 weeks gestation)—16%, congenital abnormality—16%, antepartum haemorrhage—7.4%. For neonatal deaths, extreme prematurity was the most common cause of

death (44.8%), followed by congenital abnormality (19.3%) and neurological disease (12.5%).<sup>4</sup>

A UK study of survival rates of extremely premature infants from birth to discharge from hospital was <23 weeks (0%), 23 weeks (18%), 24 weeks (41%) and 25 weeks (52–63%) with an ongoing improvement from 24 weeks.<sup>5</sup>

## Accurate determination of expected due date of delivery

It is vital to determine the expected due date of delivery (EDD) based on the exact time of the last normal menstrual period (sometimes misleading), the fundal height, the time of first fetal movements and, if in doubt, ultrasound assessment (see FIG. 108.1 in CHAPTER 108). The earlier that ultrasound is performed after 6–7 weeks of gestation, the more accurate the determination.

## High-risk obstetric patients

Guidelines for high-risk pregnancy are presented in TABLE 110.1.

Recognition of these high-risk pregnancies is important for the family doctor involved in shared care. Common categories that require special surveillance are:

- elderly primigravida (aged >35 years)
- grand multigravida (fifth or greater pregnancy, especially if >35 years)
- those with a poor obstetric history
- previous CS
- severely disadvantaged social problem (e.g. sole teenage parent with drug problem)
- hypertension ± chronic kidney disease
- obesity (BMI >30)
- short stature
- diabetes mellitus
- prolonged infertility or essential drug or hormone treatment
- heavy smoking or alcohol intake and illicit drugs

The onset during pregnancy of the following also requires surveillance:

- little or no weight gain during the first half of the pregnancy
- complications such as pre-eclampsia, multiple pregnancies or those with antepartum haemorrhage
- abnormal presentation
- abnormal fetal growth—growth restriction or macrosomia

Diabetes is always a concern and may manifest in pregnancy. Glucose screening testing is now performed routinely in many hospitals at 26–28 weeks gestation.

## Hypertensive disorders in pregnancy<sup>6,7</sup>

Hypertensive disorders complicate about 10% of all pregnancies. Pregnancy may induce hypertension in previously normotensive women or may aggravate pre-existing hypertension. Pre-eclampsia, which in fact complicates 2–8% of pregnancies, can occur at any time in the second half of pregnancy or even just following delivery.

### Types

Hypertension without proteinuria  
Pre-eclampsia—hypertension + proteinuria  
Pre-eclampsia—hypertension + oedema + proteinuria  
Eclampsia—hypertension + convulsions

A classification of hypertensive disorders in pregnancy:

- *Pregnancy-induced hypertension.*
  - SBP >140 mmHg and DBP >90 mmHg, occurring for first time after 20th week of pregnancy and regressing postpartum
- or
- Rise in SBP >25 mmHg or DBP >15 mmHg from readings before pregnancy or in first trimester
- *Mild pre-eclampsia.* BP up to 170/110 mmHg in absence of associated features (see following)
- *Severe pre-eclampsia.* BP >170/110 mmHg and/or associated features, such as kidney impairment, thrombocytopenia, abnormal liver transaminase levels, persistent headache, epigastric tenderness or fetal compromise
- *Essential (coincidental) hypertension.* Chronic underlying hypertension occurring before the onset of pregnancy or persisting postpartum
- *Pregnancy-aggravated hypertension.* Underlying hypertension worsened by pregnancy

Test for pre-eclampsia: spot urinary albumin-creatinine ratio, or 24-hour urinary protein excretion.

**Table 110.1** Guidelines for specialist obstetric consultation

	Major risk factors Obstetric consultation mandatory	Other risk factors Consultation should be considered
<b>Past problematic obstetric history</b>	Previous caesarean section (CS) Incompetent cervical os 2nd trimester spontaneous abortion Rhesus/other blood group incompatibility Thromboembolic disease Premature labour	Multiple spontaneous or elective abortions Premature delivery Previous stillbirth Neonatal death Grand multigravida
<b>Problems related to current pregnancy</b>	Pre-eclampsia Rhesus/other blood group incompatibility Significant vaginal bleeding Placenta praevia Postmaturity (especially if > 41 weeks) Multiple pregnancy Polyhydramnios Need for amniocentesis: <ul style="list-style-type: none"> <li>• genetic concerns</li> <li>• abnormal AFP</li> <li>• other</li> </ul>	Recurrent urinary infections Abnormal uterine growth Inadequate maternal weight gain Hypertension
<b>General factors</b>		Age >35 years; <18 years Obesity BMI >30 at first visit Pre-pregnancy weight <45 kg Psychosocial problems Short stature <152 cm Smoking >10/day
<b>Maternal disorders</b>	Diabetes mellitus SLE Sickle cell anaemia or other haemoglobinopathy Thrombophilia	Anaemia: Hb <100 g/L Cardiovascular disease Chronic kidney disease Alcohol or drug abuse Genital herpes
<b>Perinatal problems</b>	Premature labour Postmaturity (>41 weeks) Disproportion Malpresentation Placental insufficiency	Non-vertex presentation (at term) Fetal arrhythmia Membranes ruptured >18 h
<b>Inadequate antenatal care</b>		Late presentation (after 20 weeks) No antenatal care Failed or poor attendance

## Risk factors

The following are risk factors for pregnancy-induced hypertension:

- nulliparity/primigravida
- family history of hypertension/pre-eclampsia
- chronic essential hypertension
- diabetes complicating pregnancy
- obesity
- donor sperm or oocyte pregnancy
- multiple pregnancy
- hydatidiform mole
- hydrops fetalis
- hydramnios
- kidney disease
- autoimmune disease (e.g. SLE)

Clinical features of superimposed pre-eclampsia include hypertension, excessive weight gain, generalised oedema and proteinuria (urinary protein >0.3 g/24 hours). Late symptoms include headache (related to severe hypertension), epigastric pain and visual disturbances.

## Risks of severe pre-eclampsia/hypertension<sup>7</sup>

### Maternal risks (poor control)

- Kidney failure
- Cerebrovascular accident
- Cardiac failure
- Coagulation failure

### Risks to baby

- Hypoxia
- Placental separation
- Premature delivery

## Management

The optimal treatment is delivery, and induction of labour needs to be timed appropriately—based on parameters such as the BP level and the development of proteinuria. The BP level should be kept below 160/100 mmHg because at this level intra-uterine fetal death is likely to occur and there is a risk of maternal stroke.

### Antihypertensive drugs<sup>6</sup>

Contraindicated drugs are ACE inhibitors and diuretics. There is no place for the use of diuretics alone unless cardiac failure is present.

Commonly used medications:

- beta blockers (e.g. labetalol, oxprenolol and atenolol) (used under close supervision and after 20 weeks gestation)

- methyldopa: good for sustained BP control
- nifedipine

Labetalol, hydralazine and diazoxide are useful for rapid control of BP in hypertensive crises (e.g. hydralazine 5 mg IV bolus every 20–30 minutes or continuous infusion).

## Guidelines for urgent referral/admission to hospital

### Maternal factors

- Progressing pre-eclampsia including development of proteinuria
- Inability to control BP
- Deteriorating liver, blood (platelets), kidney function
- Neurological symptoms and signs (e.g. headache, drowsy and confused, twitching, rolling eyes, vomiting, visual disturbances, hyper-reflexia, clonus)
  - i.e. imminent eclampsia

### Fetal factors

- Abnormal cardiotocograph (CTG) indicating fetal distress
- Intra-uterine growth retardation

Refer to eclampsia ward under specialist care.

## Treatment of severe pre-eclampsia: prevention of convulsions

- Control BP: use IV hydralazine or diazoxide—don't suppress to <140/80 as this can induce fetal hypoxia
- Magnesium sulphate 50% 4 g IV (given over 10–15 minutes) followed by an infusion 1 g/hour for a minimum of 24 hours (if normal kidney function)<sup>8,9</sup>
- Corticosteroid therapy IM for fetal lung maturity if gestation ≤ 34 weeks

Monitor fetus and maternal BP, urine output, urine protein, coagulation profile.

*Note:* The best treatment is termination of pregnancy with early delivery—by CS or vaginal delivery if favourable circumstances. There is a risk of fitting at delivery and after delivery (usually <24 hours).

### Treatment of convulsion<sup>9</sup>

- Secure airway and ventilate if necessary—give intranasal oxygen.
- Magnesium sulphate as above; if further fit use bolus of 2 g MgSO<sub>4</sub>.<sup>8</sup> Consider an alternative—IV diazepam or clonazepam.

- Strict fluid balance required.
- Monitor and treat any coagulopathy, pulmonary oedema.
- Avoid ergometrine in the third stage.
- Be prepared for a possible postpartum haemorrhage.

*Note:* Be aware of the risk of more fits over the next 24–48 hours.

### HELLP syndrome

Haemolysis Elevated Liver enzymes Low Platelets is a severe form of pre-eclampsia occurring in 20% of these patients. Treat as for severe pre-eclampsia with early delivery.

## MEDICAL CONDITIONS IN PREGNANCY

### § Anaemia

During the course of a normal pregnancy the haemoglobin level should remain above 110 g/L. Anaemia is defined as a haemoglobin <110 g/L. Levels below this, particularly less than 100 g/L, require investigation. Total iron demands during pregnancy are 725 mg, especially during the third trimester.

Risks for anaemia include poor diet, multiple pregnancy, recent pregnancy and starting with anaemia.

Important types of anaemia in pregnancy:

- iron deficiency (approximately 50%)
- megaloblastic anaemia (usually due to folic acid deficiency)
- thalassaemia (most commonly  $\beta$ -thalassaemia)

### Management

- If anaemia is found, measure serum ferritin level, MCV, red cell folate and serum vitamin B12 as indicated
- Treatment is according to cause:
  - iron deficiency: ferrous sulphate 0.9 g (o) daily  
iron infusion may be required
  - megaloblastic anaemia: folic acid 5 mg (o) bd
  - thalassaemia: no treatment is possible but partner also needs to be screened

*Note:* A blood transfusion is rarely required.

### § Diabetes mellitus

Diabetes mellitus, especially type 1, in pregnancy requires meticulous management skills to minimise the morbidity and perinatal wastage associated with diabetes. Optimal management demands a

team approach from the compliant patient, GP, obstetrician, diabetic physician, diabetic nurse-educator and dietitian.

### Effects on the fetus

- Large for dates (macrosomia), fetal abnormalities (neural tube, cardiac, kidney, vertebral, etc. defects), hypoxia and intra-uterine death (IUID), miscarriage, malpresentation, IUGR, preterm delivery

### Postnatal

- Early hypoglycaemia, respiratory distress syndrome, jaundice<sup>10</sup>

### Effects on the mother

- Increased risk of pre-eclampsia, diabetic ketoacidosis, polyhydramnios, intercurrent infection, psychological effects, first trimester miscarriage, obstructed labour (shoulder dystocia), placental abruption, CS<sup>9</sup>

## Management

### Pre-pregnancy

- Education on lifestyle management and counselling, review of results, dietary compliance with controlled weight gain, medication especially insulin, advice as in **CHAPTER 108**, including folate
- Aim for diabetic control: fasting blood sugar 4–7 mmol/L: HbA1c <7%

### During pregnancy

- Early referral to a diabetic physician and obstetrician is best management.
- Assess basic parameters—blood sugar (usually 4 times a day), HbA1c, BP, kidney function inc. 24-hour urinary protein, urine, electrolytes.
- Reassess insulin requirements as pregnancy advances ( $\uparrow \times 2$ –3).
- Screen for fetal morphology and growth: ultrasound at 18 weeks then 4 weekly and as required; cardiotocography as required—usually weekly from 32–34 weeks until delivery.
- Aim to deliver at term at latest:
  - vaginally if optimal control
  - CS if large fetus (>90th weight percentile or >4000 g) or evidence of fetal distress or breech presentation
- In labour monitor fetus with CTG and keep maternal blood glucose levels normal with intermittent insulin injections.

- Cease insulin infusion and ↓ insulin to pre-pregnancy regimen immediately after delivery; organise contraception; avoid oral hypoglycaemics during breastfeeding.

## § Gestational diabetes

Gestational diabetes is the onset or initial recognition of abnormal glucose tolerance during pregnancy. If suspected a diagnostic oral glucose (75 g) tolerance test is indicated. It should be performed in the first trimester (if a strong family history or previous gestational diabetes) but at about 26 weeks if all is apparently normal as a screening test.

Diagnosis: fasting blood glucose >5.5 mmol/L  
or  
2-hour level >8.5 mmol/L

The same risks to mother and fetus such as macrosomia, IUFD, congenital malformations, hyaline membrane disease and neonatal hypoglycaemia as for pre-existing diabetes are applicable.<sup>11</sup>

*Note:* Glycosuria in pregnancy is unhelpful for screening because it is common in pregnancy and lacks specificity.

## Principles of management

These are the same as for pre-existing diabetes (above). If insulin is required antenatally, cease insulin postpartum.

Aim to deliver vaginally at term at the latest, unless earlier delivery is indicated by obstetric complications.

## Post delivery

Follow up GTT at 6 weeks and then every 5 years. Gestational diabetes is likely in subsequent pregnancies and there is a 30% risk of developing diabetes in later life—even <10 years.

## § Thyroid disorders

Hypothyroidism in pregnancy is uncommon and usually mild. It is associated with infertility. It is associated with a higher rate of fetal loss, miscarriage, fetal abnormalities and IUGR. TFTs should be checked at first presentation if past history is relevant and at 36 weeks. Optimal dosage of thyroxine replacement should be monitored by thyroid function tests. Normal maintenance dosage is usually increased to meet increased needs in pregnancy and should be increased from the onset of pregnancy.

Hyperthyroidism in pregnancy is usually caused by Graves disease, but the outcomes are generally

good with most remaining euthyroid throughout pregnancy.

If untreated there is an increased risk of maternal and fetal complications. Propylthiouracil is usually the preferred agent. Patients should be referred for specialist management.

## § Cardiac disorders

### Key facts and checkpoints

- Maternal cardiac disease is not common in pregnancy.
- The highest risk of maternal mortality is where pulmonary blood flow cannot be increased (e.g. pulmonary hypertension, Eisenmenger syndrome).
- Cardiac output rises in pregnancy.
- Syncope and dyspnoea may be a pointer to a cardiac disorder.
- Murmurs are common—90% are physiological. Refer if in doubt.
- Patients with an existing cardiac condition require combined specialist cardiologist/obstetrician care.
- Antibiotic prophylaxis is important for those with structural cardiac problems (e.g. valvular problems), most congenital malformations.
- Patients with an increased risk of bacterial endocarditis (especially with rheumatic heart disease) require an antibiotic cover in labour of penicillin and gentamicin.
- Aim for spontaneous vaginal delivery at term if possible.
- As a rule avoid lithotomy, ergometrine, sympathomimetic drugs.
- Watch fluid balance, especially after delivery.
- Administer oxygen during labour and early postpartum.

## § Kidney disease

### Key facts and checkpoints<sup>12,13</sup>

- Outcome in chronic kidney disease depends on severity of pre-pregnancy kidney function and blood pressure. Good control of hypertension is essential.
- Pre-eclampsia is more common, requiring cautious monitoring.
- Mild kidney failure usually has very good outcomes.
- ↑ maternal and fetal complications in moderate failure (s. creatinine 0.125–0.25 mmol/L) and severe kidney failure (>0.25 mmol/L).

- Pregnancy uncommon in dialysis patients. If so, there can be many problems requiring increased use of dialysis.
- Refer these patients and admit if hypertension becomes poorly controlled or marked proteinuria ( $>2$  g/24 hours) is present.
- Aim for delivery at 38–40 weeks at the latest. Delivery is usually required before this time.
- In kidney transplant patients the risk of early miscarriage is  $\uparrow$ —surviving pregnancies have  $>90\%$  success.  $\uparrow$  risk hypertension and pre-eclampsia but low chance of kidney rejection. Pelvic site of transplant is not a problem.

## § Systemic lupus erythematosus

### Key facts and checkpoints

- Pregnancy does not seem to cause exacerbations of SLE.
- SLE can adversely affect pregnancy according to disease severity.
- Increased incidence of spontaneous abortions and stillbirths—related to lupus anticoagulant and anticardiolipin antibodies (see CHAPTER 32).
- $\uparrow$  risk pre-eclampsia, prematurity, IUGR, perinatal mortality.
- Neonatal lupus syndrome includes blood disorders and cardiac abnormalities in the neonate.
- Increased maternal morbidity—kidney complications, pre-eclampsia.

### Management

- Careful preconception counselling—plan pregnancy in remission phase.
- Refer for review of drugs.
- Many investigations required under specialist supervision including lupus antibodies, APTT, FBE, kidney function, ultrasound scans.
- Corticosteroids (e.g. prednisone) are mainstay of therapy.
- Low dose aspirin (100 mg daily) if anticardiolipin antibodies present, to prevent onset of pre-eclampsia or IUGR.
- Low molecular weight heparin may be used as alternative to aspirin and in presence of prolonged APTT.
- Timing of delivery according to assessment of progress and status of fetus.
- Watch for flare-up postpartum (may require increased prednisolone).

## § Thrombocytopenia in pregnancy

The two most common causes of significant thrombocytopenia (TCP) in an otherwise normal pregnancy blood film are gestational thrombocytopenia and immune thrombocytopenia. Other causes that need to be considered are SLE, anti-phospholipid syndrome (APS), drug-induced thrombocytopenia and HIV infection.

### Gestational thrombocytopenia

In up to 4% of pregnancies, mild TCP in the range 75–150 nL develops, usually in the third trimester. Because of the increasing hazard of epidural anaesthesia in platelet counts under 75/nL, a 2-week course of prednisolone is often prescribed at 37–38 weeks gestation, aiming for a platelet count in excess of 100/nL at the time of delivery. It is prone to recur in subsequent pregnancies.

### Immune TCP

Although less common than gestational ITP, it is clinically more significant since it is typically severe and arises earlier in pregnancy. ANA factor and other antibody studies are necessary to exclude SLE and APS. Platelet-specific antibodies are found in at least 50% of ITP patients. Life-threatening cases ( $<10$  nL) require hospitalisation and corticosteroid therapy or IV immunoglobulin (if unresponsive).

### Fetal ITP

Fetal ITP results from the transplacental passage of maternal IgG anti-platelet antibody into the fetal circulation. The risk of severe fetal ITP is increased in severe ITP. The platelet count should be followed carefully postpartum. If severely reduced, IV immunoglobulin and even platelet transfusion may be required (even in utero if necessary).

## § Jaundice specific to pregnancy

Specific types of jaundice related to pregnancy are rare. Viral hepatitis accounts for 40% of all cases of jaundice during pregnancy. Severe pre-eclampsia, eclampsia and hyperemesis gravidarum may cause hepatic damage with jaundice. Two interesting specific conditions are cholestatic jaundice of pregnancy and acute fatty liver of pregnancy—the latter condition is now very rare.

### Cholestasis of pregnancy

This condition is due to an oestrogen sensitivity. The symptoms, which are mild, include low-grade jaundice and pruritus during the latter half of pregnancy. It

can be associated with fetal distress, fetal death and preterm delivery. Refer for monitoring of fetus with a view to deliver if problematic. This is usually at or before about 38 weeks gestation. Perform LFTs and consider vitamin K supplements. Drug treatment is generally unrewarding.

The condition clears up rapidly after delivery, but it often recurs in future pregnancies and if the patient is prescribed oral contraceptives, which are contraindicated.

### Acute fatty liver of pregnancy

This is a serious condition of unknown aetiology and may follow the administration of hepatotoxic agents, especially in the more debilitated patient. Acute fatty liver presents in the last trimester with symptoms of fulminant hepatitis—jaundice, vomiting, abdominal pain, headache and possibly coma. It has a high mortality (about 50%) and necessitates urgent delivery, usually by caesarean section, which may be life-saving for mother and baby.

### § Epilepsy in pregnancy

Although the outcome is successful (normal pregnancy with healthy baby) for more than 90% of epileptic women, there is a slightly increased risk of prematurity, low birth weight, perinatal mortality, defects and intervention. About 25% of women have an increased number of seizures, due mainly to a fall in anti-epileptic drug levels with a small increased frequency during labour and the puerperium. On the other hand 25% have a reduction in frequency. It is important to take oral folic acid supplementation (5 mg daily) during pre-pregnancy and up to 12 weeks gestation, and to share the care with the patient's neurologist, who can advise on the most appropriate anti-epileptic and dosage for the patient.

All anti-epileptic drugs are potentially teratogenic, with different drugs being related to different defects: phenytoin has been related to cleft lip and palate and congenital heart disease, while sodium valproate (in particular) and carbamazepine (although considered safer) have been associated with spina bifida. All anti-epileptic drugs are excreted in breast milk but in such reduced concentrations as not to preclude breastfeeding. For subsequent contraception a higher dose oestrogen pill is recommended because the anti-epileptic agent usually increases liver enzyme activity.

### § Multiple sclerosis

Patients with multiple sclerosis usually manage very well in pregnancy, which appears to have a stabilising

effect on the disorder. Preventive advice against urinary tract infections is advisable and spinal anaesthesia should be avoided.

### Antepartum haemorrhage

*Definition:* Bleeding from the genital tract after the 20th week of gestation and before the onset of labour.

If haemorrhage occurs at less than 24 weeks treat as for threatened miscarriage. If it occurs after 26 weeks admit to hospital for management. Remember to give anti-D gammaglobulin if the mother is Rh-negative. Do not perform a vaginal examination. The main causes are placental, namely placenta praevia (unavoidable APH) and placental abruption (accidental). Placental abruption in particular has a high risk of causing fetal death *in utero* with coagulopathy complications.

### Placenta praevia

The placenta has a low attachment onto the lower uterine segment and may cover the cervix. Incidence is about 1%. Rather than classify placenta praevia according to grades I–IV it is best to divide it into 'minor' and 'major' grades. Presentation usually includes painless bleeding at 28–30 weeks gestation. There is a high presenting part on palpation.

### Principles of management

- Resuscitate the mother as required—insert IV line and cross-match blood.
- Assess fetus with ongoing serial growth scans.
- Confirm diagnosis by ultrasound.
- Aim to prolong pregnancy, especially if minor grade, to reduce prematurity.
- If major grade, admit to hospital for observation with a view to rest and watchful expectancy, and subsequent delivery by CS (the safest approach).
- Give anti-D prophylaxis if the mother is Rh D-negative.
- Seek an opinion whether vaginal birth is a safe option to consider with a marginal placenta praevia.

If bleeding restarts or continues, arrange termination by CS.

Caesarean section is always required for major placenta praevia. Vaginal delivery may be possible in a specialist unit after careful assessment recommends a trial of labour in a patient with a minor degree of praevia where the fetal head lies below the lower edge of the placenta. Elective caesarean section is usually performed at about 37 weeks gestation but may be required earlier if there is continuous bleeding, two

large bleeds (>1L), 3 small bleeds (<1L), membrane rupture, premature labour or evidence of possible fetal compromise.

## Placental abruption<sup>12</sup>

Placental abruption (incidence 1%) is retroplacental bleeding from a normally situated placenta resulting in detachment of a segment of decidua from the uterine wall. The patient presents with mid-abdominal pain, bleeding PV, and a tense and tender uterus (large for dates) and signs of hypovolaemic shock. The cases can vary from mild to severe. It is the commonest obstetric cause of coagulopathy.

### Principles of management

- Admit to hospital for full assessment of mother and baby. Rest in bed with toilet privileges.
- Resuscitate and restore circulatory blood volume if necessary. Give blood until patient recovers and 'shocked' uterus recovers (four times the measured loss is generally needed). Coagulation products may be necessary.
- Perform tests—FBE, coagulation profile, Kleihauer test to define any feto-maternal haemorrhage, blood for cross-matching, kidney function, electrolytes.
- Cardiotocography (CTG) for fetal assessment, especially accurate heart activity. May need to maintain continuous CTG. Fetal death is the rule with severe placental abruption.
- Ultrasound examination of uterus and contents, to exclude placenta praevia and presence/size of any retroplacental clot.
- Rest in bed and pain relief if required.
- Give course of corticosteroids if <34 weeks to mature the baby's lungs as urgent delivery may be necessary.
- Introduce Foley catheter to monitor urine output.

The objective is to aim for vaginal delivery, especially if the baby is dead. Induce when the condition is stable to prevent further retroplacental bleeding. This is normally done by rupturing the membranes and using a Syntocinon drip. Use ergometrine in the third stage unless there is evidence of pre-eclampsia. Caesarean section has been recommended where the baby's life is immediately threatened, but this is hazardous in the presence of coagulopathy.

## Vasa praevia

Vasa praevia is a rare cause of APH due to rupture of fetal blood vessels. It coincides with rupture of the membranes and it is a vital diagnosis to make as it

can lead rapidly to fetal exsanguination. Diagnosis is by a characteristic ominous pattern on CTG and the Apt test. Emergency delivery is indicated.

## § Primary postpartum haemorrhage

Primary postpartum haemorrhage is loss of >500 mL of blood within 24 hours of delivery. A severe PPH is defined as >1000 mL blood loss.

### Causes

- Uterine atony
- Retained placenta/placental fragments
- Soft tissue laceration of genital tract (e.g. episiotomy, cervical tear)
- Ruptured or inverted uterus
- Coagulation disorder

### Principles of management

- Rub up the uterine fundus and give oxytocic agents.
- Resuscitate.
- Stop the bleeding.
- Make the diagnosis—inspect placenta/speculum examination of genital tract.
- Catheterise (a full bladder can aggravate the problem).
- An urgent examination and exploration under general anaesthetic may be necessary.

### Treatment<sup>13</sup>

- IV access—commence crystalloid IV fluids
- Tests: FBE, cross-match blood, coagulation profile
- High-flow oxygen by mask
- IV oxytocin (Syntocinon) 10 IU followed by 40 IU in IV infusion of Hartman solution
- If continuing heavy bleeding ergometrine 0.25–0.5 mg IM or IV + 10 mg metoclopramide IV
- Consider 1 mg (5 tablets) of misoprostol per rectum
- If retained placenta—deliver with cord traction or manual removal
- If continuing heavy bleeding—bimanual compression for 3 minutes
- Treat any coagulation disorder (e.g. fresh plasma/platelet transfusion)

If a persistent atonic uterus is not controlled by oxytocics, 1–2.5 mg doses of intramyometrial prostaglandin F<sub>2</sub>-α can be injected through the abdominal wall. Life-saving measures can include insertion of a Bakri balloon for tamponade,<sup>14</sup> uterine artery ligation, internal iliac artery ligation (usually bilateral) or hysterectomy.

## Blood group isoimmunisation

Blood group or red cell isoimmunisation is primarily related to Rhesus D (RhD) isoimmunisation leading to haemolytic disease of the newborn from the effect of the development of anti-D antibodies.<sup>10</sup> These antibodies develop from feto-maternal haemorrhage/transfusion in RhD-negative women carrying an RhD-positive fetus.

Effects of haemolytic disease on the fetus includes hydrops (oedema), FDIU.

Effects on the neonate include anaemia, heart failure, jaundice and hepatosplenomegaly.

Screening Rh negative mothers: at presentation, 28 weeks, and 34–36 weeks.

Do not perform screening if anti-D has been given.

## Rhesus immunoprophylaxis

Indications for giving anti-D Ig to the RhD-negative mother free of immune anti-D:

- after spontaneous miscarriage at any stage of pregnancy
- after threatened miscarriage
- after delivery of an RhD-positive baby
- following termination of pregnancy or ectopic pregnancy
- following any sensitising event during pregnancy that may provoke a transplacental haemorrhage (e.g. amniocentesis or CVS, APH, external cephalic version, significant closed abdominal trauma)
- prophylactically at 28 and 34 weeks in an apparently normal pregnancy

## Kleihauer test

This is a test on maternal blood after a sensitising event to detect the degree of feto-maternal transfusion and whether increased anti-D Ig is required.

## ABO incompatibility

This usually occurs when the mother is group O and the baby A or B and can occur in the first pregnancy without a tendency to become increasingly severe in subsequent pregnancies. A small number of babies have mild jaundice while severe haemolytic consequences are rare.

## Thromboembolism in pregnancy

Pregnancy is associated with an increased risk of thromboembolism with an incidence of about 1% of deep venous thrombosis (DVT). Untreated DVT carries about 15% risk of pulmonary embolism.

DVT or pulmonary embolism should be suspected in a woman in the antenatal or postpartum period who complains of pain or swelling in the leg, mild unexplained fever, dyspnoea or chest pain (see CHAPTER 133).

Risk factors include past history of DVT, prolonged bed rest, operative delivery, multiparity, postpartum surgical procedure, anaemia, inherited thrombophilia disorders or antiphospholipid antibodies. If a DVT is suspected, low molecular weight heparin is recommended until investigation and specialist advice are obtained.

## § Hydatidiform mole<sup>10</sup>

Hydatidiform mole is an overgrowth of gestational trophoblastic tissue. The moles may be complete (no fetal tissue) or partial (some fetal tissue). Incidence 1:1400 pregnancies. There is a risk that some persistent gestational trophoblastic may become invasive and penetrate the uterus and metastasise to the lungs. One in 20 progress to develop choriocarcinoma.

## Presentation

- Bleeding in early pregnancy ± passage of grape-like debris
- May be exaggerated symptoms of pregnancy (e.g. hyperemesis)
- Uterus large for dates

## Management

- Investigations: FBC, blood group and cross-match, hCG level (very high), ultrasound pelvis (typical 'snow-storm' appearance), chest X-ray
- Suction curette with oxytocin drip
- Consider hysterectomy if patient has completed family planning
- Register in the trophoblastic registry

## Follow-up

- Chest X-ray: ? metastatic disease
- Weekly serum (or urine) hCG until zero (usually takes 8–12 weeks), then monthly for 12 months
- Avoid pregnancy for 12 months after hCG levels normal
- The oral contraceptive pill is appropriate
- Later a putrid vaginal discharge indicates malignancy
- Refer for possible cytotoxic therapy (e.g. methotrexate and folinic acid) if hCG does not become normal or the process is >3 months, or it becomes elevated again and a new pregnancy has been excluded

## Multiple pregnancy

This is associated with increased risks to mother and children.

### Facts

- Spontaneous incidence<sup>9,11</sup>: twins 1:80; triplets 1:80<sup>2</sup> (1:6400); quads 1:80<sup>4</sup>
- Increased incidence with clomiphene-induced ovulation and IVF
- Twins: monozygotic (identical) 30%, dizygotic 70%
- Conjoint twins are a special problem
- Predisposing factors: family history, previous twins, infertility treatment, race esp. black Africans, age
- Diagnosis: hyperemesis, ultrasound, polyhydramnios, large for dates, palpation two fetal heads/three poles  $\pm$  many limbs, two different hearts heard
- Presentation twins: first twin cephalic 70%, both cephalic 40%, cephalic + breech 30%

### Complications

- Maternal: increased risk anaemia; symptoms of pregnancy (e.g. morning sickness, varicose veins); pre-eclampsia  $\times 3$ ; antepartum and postpartum haemorrhage; malpresentation; cord prolapse; CS
- Fetal/neonatal: increased risk abnormalities, preterm delivery (premature labour, premature rupture membranes); intra-uterine growth restriction of one fetus; twin-twin transfusion; perinatal mortality  $\times 5$ ; prematurity; malformations  $\times 2-4$ ; (also those of mother)

### Principles of management

- Increased supplements (iron/folic acid), nutrition requirements and rest
- Increased frequency of antenatal visits and associated care (e.g. weekly visits from 28 weeks)
- Education and counselling about increased incidence of above (e.g. preterm birth)
- Early referral to self-help groups
- Ultrasound examination at 28 weeks, then serial scans to check fetal growth of both babies. Monozygotic twins need a scan every 2–3 weeks from 16 weeks until delivery to recognise evidence of twin-to-twin transfusion syndrome (TTTS)
- Intensive fetal monitoring
- If threatened premature delivery admit to hospital for rest; consideration of tocolytics to gain time and antenatal corticosteroids for fetal lung maturation

- Aim to deliver at 38 weeks if possible either by vaginal delivery (if favourable conditions such as normal growth and double cephalic presentations) or CS (e.g. malpresentation first twin, conjoint twins)
- As a rule, elective CS is favoured at 37 or 38 weeks
- Careful attention to third stage—risk of haemorrhage

### § Preterm labour

Preterm or premature labour is confirmed labour after 20 weeks and before 37 weeks gestation. The incidence is 5–10% (average 7%) of all deliveries and is associated with 85% of neonatal deaths, especially if delivery occurs before 26 weeks. There is often a past history. Causes of spontaneous preterm labour:

- unknown (approx. 40%)
- multiple pregnancy
- cervical incompetence
- polyhydramnios
- uterine abnormality
- maternal medical conditions (e.g. diabetes, drug abuse, infection)
- antepartum haemorrhage

The patient may present with regular contractions or premature rupture of the membranes.

### Management

- Admit to an obstetric unit.
- Consider tocolysis (inhibition of uterine contractions) with atosiban, nifedipine (preferred) or  $\beta$ -sympathomimetic agents (salbutamol, ritodrine, fenoterol).
- Give corticosteroid (e.g. betamethasone, hydrocortisone) for  $\uparrow$  fetal lung maturity (maximum benefit 26–32 weeks).

### § Premature rupture of membranes

Premature rupture of the membranes (PROM) is rupture of the membranes with amniorrhoea before labour commences.

Preterm PROM (PPROM) is rupture of the membranes at  $<37$  weeks gestation.

### Key facts and checkpoints

- 50% of PPROM progress to labour within 24 hours (80% within 7 days).
- Smoking is a risk factor for PROM.
- Differential diagnosis of PROM includes profuse vaginal discharge, incontinence of urine—20% false alarms for amniorrhoea (amniorrhexis).

- A vaginal examination should not be performed.
- Signs of infection (chorioamnionitis): maternal fever, tachycardia, ↑ WCC, ↑ CRP, signs of fetal distress.
- Don't give antibiotics if cervical smears and culture normal.

### Management guidelines

- Perform routine examination including vital signs.
- Speculum examination—liquor pools in posterior fornix.
- Do not perform a vaginal examination.
- Admit to hospital.
- Take vaginal—cervical smears for culture.
- Give prophylactic antibiotics (erythromycin) until culture results indicate that no infection is present.
- Perform WCC or CRP every 2–3 days.
- Continuous observations.
- If no evidence of infection continue the pregnancy; deliver if signs of infection.
- CTG every second day or daily.
- Give corticosteroid therapy if delivery prior to 34 weeks likely.
- Induce if CTG abnormal or infection present or develops.
- Induce if not in labour by 36 weeks.

### § Prolonged pregnancy

Prolonged pregnancy is pregnancy lasting longer than 42 weeks. The due date is based on pregnancy lasting 40 weeks when 65% will proceed to spontaneous labour within the next week.

Normal delivery is between 37 and 42 weeks.

At 41 weeks check CTG and amniotic fluid index (AFI)—allow to proceed if normal.

Induce labour at 42 weeks as perinatal mortality rate is  $\uparrow \times 2$  from 42–43 weeks and more so after 43 weeks. Induction is probably best achieved using prostaglandin E2 vaginal gel, or oral or vaginal misoprostol, followed by ARM if labour does not follow the use of prostaglandin alone.

Many hospitals now favour induction between 10 and 14 days after the estimated due date.

## INTRA-UTERINE GROWTH DISORDERS

### Fundus greater than dates

Consider the following causes:

- polyhydramnios
- multiple pregnancy
- macrosomic baby >90th percentile—diabetes or history of large babies
- uterine abnormality (e.g. fibroids)
- wrong dates

### Polyhydramnios

#### Clinical features

- Liquor volume: usually >2000 mL
- Multiple risks (e.g. PROM, prem labour, cord prolapse, APH, malpresentation)

#### Causes

- Fetal abnormalities: CNS, upper GIT atresia, ectopic vesicae
- Hydrops fetalis
- Diabetes
- Multiple pregnancy
- Chorionangioma of placenta
- Fetal infection—cytomegalovirus, toxoplasmosis
- Unknown causes

Refer for tests—diabetes, ultrasound.

Refer for specialist advice.

### Fundus less than dates

Consider:

- oligohydramnios—liquor volume usually <500 mL
- small baby
- intra-uterine growth restriction
- wrong dates
- ruptured membranes

Oligohydramnios is associated with conditions such as fetal abnormality, prolonged pregnancy, kidney disease, pre-eclampsia, congenital infections (CMV, toxoplasmosis), PROM and placental insufficiency.

Investigation should include ultrasound, kidney function tests, lupus antibodies and regular CTG. Refer for specialist management.

### Intra-uterine growth restriction<sup>9</sup>

Intra-uterine growth restriction (IUGR) is defined as an estimated birth weight <10th percentile. Apart from the disorders outlined in the preceding topics, causes to also consider for a small baby include previous history of a small baby, racial factors, prematurity, various infections and maternal factors such as smoking, drugs, alcohol, anaemia and nutrition. IUGR is categorised as symmetrical or global—proportionally small or asymmetrical, with lagging abdominal growth.

Sometimes it is difficult to detect IUGR on routine clinical assessments, but most cases are detected when the examiner finds that the symphysis–fundal height is at least 2 cm less than that expected for the appropriate gestation. Other telltale signs include oligohydramnios and reduced fetal movements. Appropriate management is referral for an ultrasound assessment and specialist advice. Ongoing investigations also include umbilical blood flow (36 and 38 weeks) and cardiotocography until delivery.

## § Meconium-stained liquor

### Key facts and checkpoints

- Fresh meconium is dark green and sticky.
- Meconium staining is common post-term (13% all births).
- It is a sign of fetal distress but meconium alone is an inadequate marker of perinatal asphyxia; it is more common for the baby to be normal.
- Cord prolapse is an important cause.
- Aspiration of meconium causes pneumonitis in the neonate.

### Management

- Assess fetal condition with continuous cardiotocography, throughout labour.
- Perform a pelvic examination—assess progress and exclude cord prolapse.
- If all is well, allow labour to proceed to a vaginal delivery.
- If minor abnormality on CTG, measure fetal scalp pH or lactate.

If abnormal—CS or manipulative vaginal delivery.

*Note:* As the head is born, aspirate the oropharynx (visualise the vocal cords) or nose (same applies to CS). The presence of a paediatrician is ideal.

## OTHER HIGH-RISK CONDITIONS

### Malpresentations

The important malpresentations are breech (4% of all babies) and transverse or oblique lie. A primary concern is the high risk of cord presentation and prolapse. The usual standard practice is to perform CS as the best option.

### Breech presentation

The general rule is to deliver by caesarean section (CS), especially since studies have shown that the risk of vaginal delivery was much higher than that associated with CS. However, in selected patients and circumstances, vaginal delivery is safe, especially with spontaneous labour that

progresses appropriately with a normal-sized baby and normal pelvic dimensions. A reasonable rule is to assess a breech presentation at 36 weeks. If spontaneous version to a cephalic presentation has not occurred perform an ultrasound to check the status of the fetus, including its size. If appropriate, an external cephalic version can be attempted (with a small risk of haemorrhage). If unsuccessful, arrange an elective CS at 38–39 weeks or when labour commences or consider a vaginal delivery. However, if in doubt—caesar!

## Transverse or oblique lie (1:300)

These presentations are more common in multigravida. Perform an ultrasound examination to exclude placenta praevia. The lie may convert to a longitudinal one. Should it persist beyond 37 weeks admit to hospital and if it persists or labour commences CS is the best option.

## § Cord prolapse and presentation<sup>12</sup>

When the diagnosis is made on pelvic examination and the cord is still pulsating, push the presenting<sup>9</sup> part away and also push the cord up as far as possible and keep it there by continuous digital pressure. This is a particular problem if the mother is in labour. Place her into the knee–chest position and organise urgent delivery, usually by CS while maintaining the position of the hand. If the woman is fully dilated (second stage) and circumstances are favourable, a vaginal delivery with forceps or vacuum extraction, avoiding cord pressure, can be performed.

## § Malpositions

Important malpositions include occipito-posterior (the commonest), occipito-transverse, face and brow. The general rules to follow are that with good analgesia (e.g. epidural), no evidence of cephalo-pelvic disproportion and no fetal or maternal distress, allow labour to proceed and await events. Aim for a vaginal delivery assisted by instruments if necessary, especially with the occipito-posterior and occipito-transverse positions. A notable exception is the face presentation where the head rotates back into the mento-posterior position making vaginal delivery impossible: CS is necessary. Otherwise CS is also the best option in prolonged labour with maternal exhaustion, obstructed labour, disproportion and fetal distress.

## § Shoulder dystocia<sup>13</sup>

Impacted shoulders causing sudden arrest of delivery after delivery of the baby's head is a terrifying

complication of childbirth requiring expert assistance. Various manoeuvres can be attempted to achieve the widest possible diameter of the pelvic inlet and thus facilitate delivery of the shoulders. (Consider McRoberts manoeuvre<sup>12</sup>—suprapubic pressure, shoulder rotation performed vaginally, delivery of the posterior shoulder.) Sometimes placement of the mother into the knee–chest position can expedite the delivery.

### Inverted uterus

This potentially lethal complication occurs when the fundus of the uterus turns inside out, either partially or completely. If it is complete the inside of the uterine fundus may appear outside the introitus. The placenta is usually still attached to the uterus and often the problem is caused by over-traction of the cord without waiting for firm uterine contractions and placental separation. The easiest way to manage this complication is to return the uterus to its normal position with the cord still attached immediately after the event. If unsuccessful resuscitate and attempt hydrostatic replacement of the inverted uterus.<sup>10</sup> Otherwise surgical intervention will be necessary.

### Considerations for induction

Possible indications for induction:

- post-term (41 weeks or over)—a meta-analysis of 11 RCTs found that there were benefits to both mother and fetus in being induced between 10 and 14 days after the due date<sup>11</sup>
- maternal hypertension
- maternal distress
- diseases of pregnancy (e.g. pre-eclampsia)
- intra-uterine growth restriction
- intra-uterine fetal death
- diabetes mellitus
- isoimmunisation
- unstable lie

### Caesarean section

The CS rate has risen from about 6% in the 1960s to over 20% now and continues to rise. Obstetric indications, among many, are:

- previous CS (commonest)
- failed progress of labour
- cephalo-pelvic disproportion—relative or absolute
- cord prolapse and presentation
- placenta praevia

- fetal distress
- fetal malposition or presentation, especially breech
- failed induction of labour

Complications:

- increased risk of maternal mortality
- anaesthetic complications
- damage to adjacent viscera (e.g. bladder, bowel)
- infection
- adhesions
- need for repeat (maximum of three) CS advised
- increased risk of placenta praevia in subsequent pregnancies

### Trauma: motor vehicle accidents

Abdominal trauma in pregnancy is usually associated with seat-belt restraints during motor vehicle accidents. However, these injuries are far less severe than those that occur when people are not wearing seat belts. Women should be encouraged to wear seat belts and should not be given certificates stating that seat belts should not be worn in pregnancy.

The incidence of placental abruption following accidents is related to the severity of the accident and the extent of the external injuries. Injured patients should be admitted to a unit where cardiotocography can be performed regularly for 48 hours and perinatal intensive care can be provided if needed. Consider anti-D gammaglobulin injection.

### Drugs in pregnancy

Drugs have to be used with great care during pregnancy. An Australian categorisation of drug risk is presented in summary in TABLE 110.2. It is worth noting that  $\beta_2$ -agonists used to treat asthma have a category A rating (no harmful effect recorded).

Drugs to be avoided during pregnancy (known teratogens) include isotretinoin (Roaccutane), misoprostol, phenytoin, thalidomide and warfarin.

### When to refer

If there is a possibility of cervical incompetence; refer for a specialist opinion before 14 weeks, when cervical length assessments will be made by ultrasound every two weeks.

### Referral to specialist centre<sup>15</sup>

The key to an optimal outcome is early identification of the high-risk pregnancy and early referral to a specialist team to supervise the management of

**Table 110.2** Examples of medicines in pregnancy: an Australian categorisation of risk (Australian Drug Evaluation Committee)

	Category*
Iron and haemopoietic agents	
Folic acid	A
Iron preparations (all types)	A
Antihistamines and anti-emetics	
Phenothiazines (e.g. prochlorperazine)	C
Meclozine, cyclizine	A
Other antihistamines	A or B2
Alimentary system agents	
Antacids	A
H <sub>2</sub> -receptor antagonists	B1
Proton pump inhibitors	B3
Cardiovascular	
ACE inhibitor	D
Methyldopa	A
Calcium-channel blockers	C
Beta blockers	C
Digoxin	A
Diuretics (except spironolactone, B3)	C
Glyceryl trinitrate	B2
Analgesics	
Aspirin	C
Paracetamol/acetaminophen	A
Codeine	A
Opioid analgesics	C
Hypnotics, sedatives, antipsychotic agents

*As concerning the bringing up, nourishment and giving of suckle to the child, it shal be beste that the mother give her child sucke her selfe, for the mothers milke is more convenient and agreeable to the infant than any other woman's or other milke.*

THOMAS RAYNALDE, *THE BYRTHE OF MANKYNDE* (1540)

Education for the puerperium and caring for the baby should begin during pregnancy so that a new mother is familiar with the basic principles of motherhood, especially infant feeding.<sup>1</sup> The puerperium is defined as the period of approximately 42 days from the completion of the third stage to the return of the normal physiological state.

The newborn screening test or 'heel prick' test should have been performed on the baby routinely. The testing from a single blood sample should include cystic fibrosis, phenylketonuria, congenital hypothyroidism, galactosaemia and several other uncommon metabolic conditions.

Be mindful of the possibility of neonatal abstinence syndrome in a child exposed to excessive drug and alcohol intake during pregnancy.

Postnatal care really begins with the birth of the baby. Once the airways are cleared the baby should be given to the mother as soon as possible and not taken from her except for essential management.

The mother should remain in the labour ward (if delivered in hospital) for at least an hour after giving birth and until she has passed urine. She should be inspected frequently to exclude the possibility of a silent postpartum haemorrhage and vital signs checked before transferring to a lying-in ward. It is worth remembering that one-third of eclamptic convulsions occur postpartum.

It is important to educate postpartum women on care of the baby and breastfeeding, self-care, hygiene, healing of the genital tract, sexual life and contraception, nutrition and what happens to their bodies and preventive issues. The uterus involutes to non-pregnant size by 6 weeks and the cervical os should be closed by 2–3 weeks post delivery.<sup>2</sup>

### Guidelines for the post-natal ward<sup>1</sup>

- Every mother needs rest but should have full toilet and shower facilities.

- The baby should be in a bassinet beside the mother and may be taken into bed any time the mother likes.
- Room in: the baby should not go to the nursery unless it is sick or the mother requests it.
- In the first 24 hours check pain, perineum, blood loss and BP.
- Subsequently check the same parameters plus temperature, signs of infection, lochia, breast care and psyche.
- Demand feed to appetite.
- A golden rule is that breastfeeding and the supply of mother's milk is a classic case of 'supply and demand'.
- The doctor should listen carefully to what the mother is saying (and not saying) during visits.
- Check that anti-D vaccine was given (if necessary).

## Postnatal consultations

### The two-week consultation

Mother:

- check blood pressure, weight (BMI)
- assess the coping ability of the new mother
- look for signs/symptoms of postpartum depression
- provide encouragement and advice
- check breastfeeding

Baby:

- routine examination
- perform a Phenistix test on the baby's napkin (in case the Guthrie test has been missed in hospital)

### The six-week consultation

This is basically a repeat of the previous consultation and a checklist is presented in [TABLE 111.1](#).

**Table 111.1** Checklist for postnatal check at 4–6 weeks

#### Mother

Pap test (if not performed at first visit)  
 Check rubella status  
 Check hepatitis B status  
 Review antenatal screening tests for follow-up action  
 Check for adequate contraception  
 Check if intercourse has resumed and give advice (if appropriate)  
 Check bowel and urine control  
 Encourage abdominal and pelvic floor exercises  
 Check for back problems  
 Check weight, blood pressure and urine  
 Check breasts  
 Check abdomen (uterus should be impalpable)  
 ? Caesarean wound  
 Check perineum  
 Check psychological health, including coping ability; consider Edinburgh Postnatal Depression Scale  
 Check for postpartum thyroiditis  
 Discuss adequate diet, rest and personal care  
 Perform pelvic examination  
 Check pelvic floor strength  
 Further follow-up if necessary  
 Give Personal Health Record folder to mother

#### Baby

Routine examination  
 Check growth and feeding  
 Educate mother regarding immunisation schedule

## Contraception

The lactational amenorrhoea method (LAM) (CHAPTER 99) is an extremely effective contraceptive for the first six months, but only if the woman remains amenorrhoeic. Because some women ovulate before their periods return, breastfeeding women are usually advised to use an additional method of contraception if they wish to avoid pregnancy.

## Oral contraception

Delay to after 21 days because of the risk of thrombosis (COC) and bleeding (POP).

- The mini pill (progestogen only)  
 norethisterone 350 mcg/day  
 or  
 levonorgestrel 30 mcg/day taken every night
- Transfer to COC when breastfeeding completed (oestrogens can potentially suppress lactation)

IUCD: If used, it should be fitted at or after 6 weeks.<sup>2</sup> Consider referral for etonogestrel (Implanon) implant.

## After-pains<sup>1</sup>

After-pains, which are more common and most intense after the second and subsequent pregnancies, are characterised by intermittent lower abdominal pains, like period pains, which are often worse during and after feeding in the first 2 weeks. They are caused by oxytocin released from the posterior pituitary, which also causes the milk ejection (let-down) reflex of nursing. Suspect endometritis if there is offensive lochia, fever and poor involution of uterus.

Treatment, after examination, is reassurance and analgesics in the form of paracetamol every 4 hours for 3 days or as long as necessary.

## BREASTFEEDING PROBLEMS

### § Insufficient milk supply

Studies have shown that many women wean because of low milk supply. The problem is due mainly to lactation mismanagement such as poorly timed feeds, infrequent feeds and poor attachment. A milk ejection reflex (formerly called 'let-down reflex') is necessary to get the milk supply going. Sometimes this reflex is slow and inhibited by pain from the birth canal or breasts, stress, shyness or lack of confidence about breastfeeding. Another factor in low milk supply is the mother underestimating her production capacity. If there is insufficient supply, the baby tends to demand frequent feeds, may continually suck its hand and will be slow in gaining weight.<sup>1</sup> Also consider tongue tie as a cause, especially if breast attachment is affected (see CHAPTER 92).

Important factors in establishing breastfeeding:

- 1 positioning and attachment of the baby on the breast
- 2 the milk ejection reflex
- 3 supply and demand
- 4 intact milk ducts and sensory nerves
- 5 sufficient glandular breast tissue
- 6 infant being able to feed

The breasts produce milk on the principle of supply and demand. This means that the more the breasts are emptied, the more milk is produced.

Signs of low supply:

- poor weight gain
- dark, hard, infrequent stool
- <6 wet nappies per day

### Advice to the mother

- Try to practise relaxation techniques.
- Put the baby to your breast as often as it demands, using the 'chest to chest, chin on breast' method.
- Feed more often than usual.
- Give at least one night feeding.
- Feed at first signs of baby's readiness to feed.
- Express after feeds, because the emptier the breasts, the more milk will be produced.
- Make sure you get adequate rest, eat well, drink ample fluids (drink to thirst) and get home help.
- If you feel tired go to your doctor for a check-up. (Consider investigations: FBE, iron studies, TFTs, blood glucose, vitamins B12 and D,  $\beta$ -hCG.)

### Red flag

- Beware of the sleepy baby who does not demand enough and may quietly starve.

### Lactation stimulation

Lactation can be improved by more frequent breastfeeding and correct position and attachment. Consider domperidone as a galactagogue for increasing milk supply.

- domperidone 10 mg (one tablet) tds for 2–4 weeks, reducing slowly once an adequate breast-milk supply is established <[www.thewomens.org.au/clinicalguidelines](http://www.thewomens.org.au/clinicalguidelines)>

### Engorged breasts

Engorgement occurs when the milk supply comes on so quickly that the breasts become swollen, hard and tender. There is an increased supply of blood and other fluids in the breast as well as milk. The breasts and nipples may be so swollen that the baby is unable to latch on and suckle. Once again, lactation mismanagement is a key factor. If a newborn is attached properly and feeds often and liberally engorgement should not happen.

### Advice to the mother

- Feed your baby on demand from day 1 until the baby has had enough.
- Finish the first breast completely; maybe use one side per feed rather than some from each breast. Offer the second breast if the baby appears hungry.
- Soften the breasts before feeds or express with a warm washer or shower, which will help to get the milk flowing.

- Avoid giving the baby other fluids.
- Express a little milk before putting the baby to your breast (a must if the baby has trouble latching on) and express a little after feeding from the other side if it is too uncomfortable.
- Massage any breast lumps gently towards the nipple while feeding.
- Apply cold packs after feeding and cool washed cabbage leaves (left in the refrigerator) between feeds. Change the leaves every 2 hours.
- Wake your baby for a feed if your breasts are uncomfortable or if the baby is sleeping longer than 4 hours.
- Use a good, comfortable bra.
- Remove your bra completely before feeding.
- Take ibuprofen or paracetamol regularly for severe discomfort.

Regular feeding and following demand feeding is the best treatment for engorged breasts.

### § Suppression of lactation<sup>3,4</sup>

Women may seek suppression of lactation for a variety of reasons such as weaning the baby, not wishing to breastfeed initially, or after stillbirth.

### Mechanical suppression

The simplest way of suppressing lactation once it is established is to transfer the baby gradually to a bottle or a cup over a 3-week period. The decreased demand reduces milk supply, with minimal discomfort. If abrupt cessation is required, it is necessary to avoid nipple stimulation, refrain from expressing milk and use a well-fitting bra. Use cold packs and analgesics as necessary. Engorgement will gradually settle over a 2–3 week period.

### Hormonal suppression

Hormonal suppression can be used for severe engorgement but only as a last resort. It is more effective if given at the time of delivery but may produce side effects. Avoid oestrogens.

cabergoline 1 mg (o) statim (once only)

### § Drugs affecting lactation

Drugs that can affect lactation or a breastfed infant are listed in [TABLE 111.2](#). Most drugs can be compatible and tolerated but check with prescribing guidelines. Consider risk versus benefit.

**Table 111.2** Drugs taken by nursing mother that can affect breastfed infant or lactation

**Antibiotics:**

- aminoglycosides
- chloramphenicol
- nitrofurantoin
- metronidazole
- tetracycline
- sulphonamides

**Antihistamines**

**Antineoplastics/cytotoxics\***

**Benzodiazepines**

**Bromocriptine**

**Combined oral contraceptive/oestrogens**

**Ergotamine\***

**Gold salts**

**H<sub>2</sub>-receptor antagonists (e.g. cimetidine, ranitidine)**

**Illicit drugs (e.g. cocaine, cannabis, LSD)\***

**Lithium**

**Methotrexate\***

**Quinidine**

**Laxatives (e.g. senna)**

**Alcohol (no harmful effects unless taken in excess)**

**Nicotine (increased respiratory distress in infants exposed) but if necessary NRT is preferable to smoking**

\*Indicates contraindicated drugs

## § Nipple problems with breastfeeding

**Causes of nipple trauma:**

- attachment problems (commonest)
- infection—bacterial, ‘thrush’ or viral
- vasospasm
- dermatitis (e.g. contact dermatitis)

### Sore nipples<sup>4</sup>

Sore nipples are a common problem, thought to be caused by the baby not taking the nipple into its mouth properly, often because of breast engorgement. The problem is preventable with careful attention to the feeding position of the baby. A well-attached baby sucking strongly should not cause nipple trauma.

#### Advice to the mother

It is important to be as relaxed and comfortable as possible (with your back well supported) and for your baby to suck gently.

- Try to use the ‘chest to chest, chin on breast’ feeding position.
- Vary the feeding positions (make sure each position and attachment is correct).
- Start feeding from the less painful side first if one nipple is very sore.

- Express some milk first to soften and ‘lubricate’ the nipple. (Avoid drying agents such as methylated spirits, soap and tincture of benzoin, and moisturising creams and ointments, which may contain unwanted chemicals and germs.)
- Gently break the suction with your finger before removing the baby from the breast. (Never pull the baby off the nipple.)
- Apply covered ice to the nipple to relieve pain.
- Keep the nipples dry by exposing the breasts to the air and/or using a hair dryer on a low setting.
- If wearing a bra, try Cannon breast shields inside the bra. Do not wear a bra at night.

*Note:* Raynaud phenomenon can affect the nipple and cause painful breastfeeding. It is often mistaken for *Candida albicans* infection.

### Cracked nipples

Cracked nipples are usually caused by the baby clamping on the end of the nipple rather than applying the jaw behind the whole nipple. Not drying the nipples thoroughly after each feed and wearing soggy breast pads are other contributing factors. Untreated sore nipples may progress to painful cracks.

#### Symptoms

At first, the crack may be so small that it cannot be seen. The crack is either on the skin of the nipple or where it joins the areola. A sharp pain in the nipple with suckling probably means the crack has developed. Feeding is usually very painful, and bleeding can occur.

#### Advice to the mother

Cracked nipples nearly always heal when you get the baby to latch onto the breast fully and properly. They usually take only 1–2 days to heal.

- Follow the same rules as for sore nipples.
- Do not feed from the affected breast—rest the nipple for 1–2 feeds.
- Express the milk from that breast by hand.
- Feed that expressed milk to the baby.
- Start feeding gradually with short feeds.
- A sympathetic expert such as an ABA breastfeeding counsellor will be a great help if you are having trouble coping. Consider use of a nipple shield only after seeking face-to-face expert advice
- Take paracetamol or ibuprofen just before feeding to relieve pain.

## Inverted nipples

An inverted nipple is one that inverts or moves into the breast instead of pointing outwards when the baby tries to suck from it. When the areola is squeezed, the nipple retracts inwards.

### Treatment<sup>4</sup>

The best approach is good preparation with prolonged breast contact and feeding prior to milk 'coming in' and knowledgeable helpers giving advice and confidence. If a baby continues to have ongoing problems with attachment, a nipple shield may be helpful.

## MASTITIS

Mastitis, which has a high incidence (up to 20%), is basically cellulitis of the interlobular connective tissue of the breast (see **CHAPTER 100**). Usually restricted to lactating women, it is caused mainly by a cracked nipple or poor milk drainage. Not all mastitis is infective. Many instances are related to milk not being drained adequately and will improve if appropriate breastfeeding technique is followed. A blocked duct or ducts may be the cause. It is a serious problem and requires early treatment. Breastfeeding from the affected side can continue as the infection is confined to interstitial breast tissue and doesn't usually affect the milk supply.

*Note:* Mastitis must be treated vigorously—it is a serious condition. Refer to **CHAPTER 100**.

### § Bacterial mastitis

#### Clinical features

- A lump and then soreness (at first)
- A red, wedge-shaped, possibly tender, area
- Fever, tiredness, muscle aches and pains

#### Management

Prevention (in lactation).

*Rule:* 'Heat, rest and drain the breast'.

- Keep feeding and frequently.
- Maintain free breast drainage.
- Attend to breast engorgement and cracked nipples.

If symptoms persist >24 hours or patient is unwell obtain breast milk culture and commence antibiotics.<sup>5</sup>

- Antibiotics: resolution without progression to an abscess will usually be prevented by antibiotics: dicloxacillin 500 mg (o) qid for 7–10 days

or

flucloxacillin 500 mg (o) qid for 7–10 days

or

cephalexin 500 mg (o) qid for 7–10 days

If severe cellulitis:

flucloxacillin/dicloxacillin 2 g IV 6 hourly

- Ibuprofen or paracetamol for pain

### Instructions to patients

- Keep the affected breast well drained.
- Continue breastfeeding: do it frequently and start with the sore side or begin feeding from the normal side until the milk comes and then switch to the sore side.
- Heat the sore breast before feeding (e.g. hot shower or hot face washer).
- Cool the breast after feeding: use a cold face washer from the freezer.
- Massage any breast lumps gently towards the nipple while feeding.
- Empty the breast well: hand express if necessary.
- Get sufficient rest.
- Keep to a nutritious diet and drink ample fluids.

### § Candida mastitis

#### Clinical features

- Painful breasts—often exquisite pain especially during and after feeding
- No fever
- Nipple pain and sensitivity
- Usually but not always bilateral
- Nipples can be pink and shiny
- ± Pink haloes around the base of the nipple
- Breasts usually normal: no heat, lumps or tender points

*Note:* May follow a course of antibiotics. Swabs are of limited value.

#### Treatment

fluconazole 150 mg (o) every second day for 3 doses<sup>5</sup> then oral nystatin (o) tds for 10 days  
miconazole gel qid to nipple after feeds

Treat the baby with oral nystatin drops or miconazole oral gel.

#### Maternal diet

- Remove refined carbohydrates especially sugar- and yeast-containing foods for at least 6 weeks.

## § Breast abscess

If tenderness and redness persist beyond 48 hours and an area of tense induration develops, then a breast abscess may have formed. It can be treated with needle aspiration or may require surgical drainage under general anaesthesia.

For a description of surgical and other management refer to [CHAPTER 100](#).

## § Secondary postpartum haemorrhage<sup>2,6</sup>

Primary PPH is presented in [CHAPTER 110](#).

Secondary postpartum haemorrhage is any bright bleeding from the birth canal 24 hours or more after delivery. It may vary from very slight to torrential and may occur at any time up to 6 weeks postpartum. It tends to peak at 5–10 days.

### Causes

- Retained products of conception (PoC)
- Infection, especially at placental site
- Laceration of any part of the birth canal
- Coagulation disorder

No cause is found in one-third of cases (i.e. idiopathic subinvolution).

### Treatment

**Rule:** An empty and contracted uterus will not bleed.

- Investigation:
  - ultrasound (? retained PoC)
  - cervical swab for smear and culture
  - FBE
- IV oxytocin 10 IU followed by infusion of 40 IU in Hartman solution
- Ergometrine 250 mcg IM or 25–50 mcg slowly IV (if continuing heavy bleeding)
- Consider misoprostol, 4 or 5 × 200 mcg tablets per rectum or otherwise by intramyometrial injection of prostaglandin F2 alpha (caution: specialist supervision)
- Exploration under general anaesthetic if blood loss >250 mL:
  - gentle blunt curettage required in the postpartum uterus (aim to prevent uterine adhesions—Asherman syndrome)
- Arrange blood transfusion if Hb is <100 g/L
- Antibiotics (e.g. amoxycillin/clavulanate + metronidazole + gentamicin while awaiting culture)

- Consider Bakri balloon tamponade and uterine packing for major PPH

**Note:** Referral is necessary after the oxytocin/ergometrine injection. Occasionally a life-saving hysterectomy or ligation of the internal iliac arteries may be necessary.

## Lochia discharge

The discharge of lochia, which is blood and sloughed-off tissue from the uterine lining, should be monitored.

Normal:

- 1 bloody loss = lochia rubra: 2–12 days
- 2 serous loss = lochia serosa: up to 20 days
- 3 white loss = lochia alba
- 4 offensive lochia = endometritis

Lochia loss persists for 4 to 8 weeks. Abnormal lochia rubra indicates a retained placenta. If there is a problem examine with a speculum and take cervical/vaginal swab.

## § Puerperal fever

Puerperal fever is defined as raised temperature of  $\geq 38^{\circ}\text{C}$  from day 1 to day 10. If fever, think of the three Bs—birth canal, breast, bladder. The cause is genital infection in about 75% of patients. Endometritis presents with offensive lochia, abdominal pain and a tender uterus. Other causes include urinary tract infection, mastitis and an intercurrent respiratory infection. Investigations include a vaginal swab for smear, culture and sensitivities (include anaerobic culture) and a midstream specimen of urine for microscopy and culture, blood culture and an FBE. Refer to [CHAPTER 109](#).

### Treatment

amoxycillin/potassium clavulanate plus metronidazole (while awaiting sensitivities)

Beware of severe puerperal sepsis such as Gram-negative septicaemia or *Clostridium welchii* septicaemia and the rare *Bacteroides fragilis*.

## POSTNATAL DEPRESSIVE DISORDERS

It is quite common for women to feel emotional and flat after childbirth; this is apparently due to hormonal changes and to the anticlimax after the long-awaited event. There are three separate important problems:

- 1 postnatal blues
- 2 postnatal adjustment disorder
- 3 postnatal (or postpartum) depression

## § Postnatal blues

'The blues' is a very common problem (occurs in 80%) that arises in the first 2 weeks (usually days 3–10) after childbirth.

### Clinical features

- Feeling flat or depressed
- Mood swings
- Irritability
- Feeling emotional (e.g. crying easily)
- Feeling inadequate
- Tiredness
- Sleep disturbance unrelated to baby's sleep needs
- Lacking confidence (e.g. in bathing and feeding the baby)
- Aches and pains (e.g. headache)

Fortunately 'the blues' is a passing phase and lasts only 4–14 days. Management is based on support, reassurance and basic counselling. Contact friends and relatives to help.

### Advice to the mother<sup>3</sup>

All you really need is encouragement and support from your partner, family and friends, so tell them how you feel.

- Avoid getting tired and rest as much as possible.
- Talk over your problems with a good listener (perhaps another mother with a baby).
- Accept help from others in the house.
- Allow your partner to take turns getting up to attend to the baby.

If 'the blues' lasts longer than 4 days, it is very important to contact your doctor.

## § Postnatal adjustment disorder

- Occurs in first 6 months
- Similar symptoms to 'the blues'
- Anxiety with handling baby
- Psychosomatic complaints
- Fearful of criticism

### Treatment

- Support and reassurance
- Cognitive therapy
- Parentcraft support
- Settles with time

## § Postnatal depression

Some women develop a very severe depression after childbirth. Always consider it in the frequent attender. Symptoms are present for at least 2 consecutive weeks with onset in the first few days postpartum. It should be treated as for major depression. (See CHAPTER 19 for an overview.)

- Occurs in 10–30% women
- In first 6–12 months (usually first 6 months: peaks about 12th week)
- Anxiety and agitation common
- Marked mood swings
- Poor memory and concentration
- Typical depressive features

Use the Edinburgh Postnatal Depression Scale (a score of 12 or more is significant).

### Treatment

- Support, reassurance, counselling
- Group psychotherapy and support group (e.g. <[www.panda.org.au](http://www.panda.org.au)>)
- Couple therapy (must involve partner)
- Postnatal depression support group
- Hospitalisation may be necessary (especially if suicidal or infanticidal ideations)
- Medication—SSRIs (sertraline, paroxetine—agents of choice), amitriptyline, nortriptyline
- Closely monitor any risk of self-harm
- Consider referral if poor response to treatment in 2 weeks

*Note:* Beware of puerperal psychosis with onset usually within first 2 weeks.

## Postpartum psychosis

The most common postpartum psychosis is an affective disorder: mania or agitated depression. It is treatable and requires urgent attention. Symptoms that appear within the first month include unusual behaviour, agitation, delusions, hallucinations, mania and suicidal ideations.

It is rare, occurring in about 1:500 births.

Past history may be a pointer. Suspect if severe depression not responding to treatment. Check thyroid function and organise inpatient psychiatric care. There is an increased risk of further episodes with subsequent pregnancies.

## Other issues in postnatal care

### Sleep deprivation

Give advice and counselling. Use the 'sleep when baby sleeps' rule. Avoid sedatives.

### Tiredness

Tiredness is very common in the first few months after delivery. It may be a presenting symptom of anaemia, depression, hypothyroidism, anxiety or depression (in particular).

Perform FBE, TFTs, blood glucose and urinalysis.

### Postpartum thyroid disturbance (PPTD)<sup>6</sup>

Postpartum thyroiditis may be misdiagnosed as postpartum depression and should always be considered in the tired, apparently depressed woman in the first 6 months after delivery. PPTD is common in women with pre-existing autoimmune thyroid disorders and often flares up in this period. It must be differentiated from new onset or relapsing Graves disease indicated by positive anti-thyroid stimulating hormone receptor antibodies. Women who have had PPTD are at greater risk of developing hypothyroidism within 10 years postpartum.

### Hair loss

Increased hair shedding as telogen effluvium is common about 4–6 months after delivery. Large clumps of hair with white bulbs come out easily with combing or shampooing. Reassure that it reverts to normal in 3–6 months.

### Back pain and coccygodynia

Postnatal backache occurs in about 50% of women and may persist for several weeks. Management includes simple analgesics, massage, exercises, hot or cold packs, education regarding lifting of baby and referral to a physiotherapist for persistent pain.

### Sexual difficulties

Decreased libido is a common problem and often related to sleep deprivation. Decreased libido can also be due to one of the postnatal depressive disorders or to tension in adjusting to the new relationships.<sup>2</sup>

Dyspareunia is common, especially following an episiotomy or vaginal tear, and should be treated symptomatically and with education. Simple lubrication or vaginal oestrogens can help until perineal healing is achieved.

Early intercourse is risky with deaths from air embolism reported in the first 2 weeks. Intercourse is not advisable in the first 6 weeks.

### Elimination disorders<sup>3</sup>

Always enquire how the patient is coping with her bowels and urination. Simple advice such as stool softening and pelvic floor exercises will help. However, serious problems such as faecal incontinence secondary to a fistula from a third-degree tear or urinary retention due to neuropraxia of the pelvic floor can develop and need urgent attention.

### Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Breastfeeding and milk supply
- Establishing breastfeeding
- Mastitis with breastfeeding
- Nipple problems with breastfeeding
- Postnatal depression

# Part 7

## Male health

---

# 112 Male health: an overview

*Call it the 'M-factor', call it maleness, call it what you like—but from infancy onwards, in every age group, males are more likely to die than females.*

ANDREW PATTISON<sup>1</sup>

In recent years, increasing attention has been focused on men's health, mainly because it became evident that the average male's lifestyle was slowly killing him. As doctors we are beginning to understand that a great proportion of male ill-health is related to behavioural and social factors.

An important statistic is the constant discrepancy in average life expectancy (ALE) between the sexes. At present in Australia, the ALE is 79.9 years for males compared with 84.3 years for females.<sup>2</sup>

Since the beginning of the 20th century and even further back this discrepancy has continued. In 1900 the ALE for males was 55.2 years and 58.8 for females.<sup>2</sup> This increased to a difference of 6 years for most of the last century. However, the significant increase in ALE for both sexes has been encouraging.

Men have a significantly greater incidence of medical conditions and problems, such as cardiovascular disease, obesity, alcoholism, HIV and hypertension, as well as having higher rates of accidental death and suicide. The following comparative statistics for Australian society highlight this difference.

## Men's health at a glance<sup>1,2,3</sup>

- Up to 14 years, boys are at least twice as likely to die from accidental injury (e.g. motor vehicle accidents [MVAs] and drowning).
- In the 15–24 years age group, males are three times more likely to die in MVAs and four times more likely to commit suicide. The overall death rate is 3.65 times higher than for females.
- In the 25–65 years age group, males are four times more likely to die from coronary artery disease, three times more likely to die in MVAs, four times more likely to commit suicide, four times more likely to die in other accidents, and twice as likely to die from cancer. The overall death rate is two times that of females.
- The figures are worse in the lower socioeconomic groups. Low-income males are nearly three times

more likely to state that their overall health is poor compared to men with higher incomes.

FIGURE 112.1

Source: Courtesy of Ron Tandberg

- At least four out of five heroin overdose deaths occur in males.
- Aboriginal males' life expectancy is 17 years less than that of non-Aboriginal males. In the 35–45 years age group, the death rate is *eleven* times that of non-Aboriginals.
- Workplace deaths—93% occur in males (who constitute 56% of the workforce).
- Forty-six per cent of Australian marriages end in divorce. The majority of these are initiated by women.

- Ninety per cent of those convicted for acts of violence are males: 80% of the victims are males.
- In Australian schools, 90% of children with documented behavioural problems are males.

(This list has been reproduced with the permission of Andrew Pattison.)

These statistics are very revealing and reflect attitudes to lifestyle. Men smoke more, drink more and indulge in greater risk-taking behaviour in general. Only 5% of men have adequate fruit and vegetable intake.<sup>3</sup>

Young males in particular are more likely than young females to take risks in areas such as conflict or violence, sexual behaviour, drinking, gambling and accident prevention.<sup>4</sup> The main causes of death by age group for Australian males are summarised in TABLE 112.1.<sup>5</sup>

**Table 112.1** Main causes of death by age group for Australian males

Years	No. 1	No. 2	No. 3
1–14	Non-traffic accidents	Traffic accidents	Cancer
15–24	Traffic accidents	Suicide	Non-traffic accidents
25–44	Suicide	Cancer	Non-traffic accidents
45–54	Cancer	Circulatory diseases	Suicide
55–64	Cancer	Circulatory diseases	Suicide
65–74	Circulatory diseases	Cancer	Respiratory diseases
75+	Circulatory diseases	Cancer	Respiratory diseases

## Prostatic disease

Ageing men find disorders of the prostate almost inevitable, as they become aware of lower urinary tract symptoms (LUTS). The usual cause of benign prostatic hyperplasia is now being managed better with  $\alpha$ -blocking agents, such as tamsulosin and 5-alpha reductase inhibitors (such as Dutasteride), which delay the almost inevitable resection of the prostate—a procedure that provokes considerable anxiety in men. Cancer of the prostate is the second commonest cause of death from cancer in men and the

third overall including both sexes, yet its management remains controversial and at times confusing, especially the screening issues (see CHAPTER 116).

## Androgen deficiency<sup>1,2</sup>

Androgen deficiency, which affects about 1 in 200 men under 60 years of age and possibly 1 in 10 older men, is likely to be an underdiagnosed condition. Androgen deficiency should be considered when the following signs and symptoms present:

- *infancy*—micropenis, small testes
- *puberty*—delayed, small testes, failure of growth of larynx or penis, failure of skin of scrotum to thicken and/or pigment, poor muscle development, poor facial, body and pubic hair, marked and persisting gynaecomastia
- *adult*—regression virilisation, mood changes, poor concentration, lethargy, hot flushes, sweats, decreased libido, decreased semen volume, gynaecomastia, osteoporotic fracture, erectile dysfunction (ED)

Androgen deficiency is an uncommon cause of ED, but men presenting with ED should be assessed for androgen deficiency (ED will be discussed in CHAPTER 118). This should be done initially through history and examination rather than a blood test, including examining the size and firmness of the testes. An orchidometer (a series of beads of various sizes to match clinical testicular size) can assist with this and can be obtained through Andrology Australia.<sup>8</sup>

Diagnosis is by at least two testosterone levels taken on different mornings (LH added to the second collection if the first testosterone is low).<sup>6</sup> Other tests may include semen analysis (if fertility is an issue), bone density, karyotype (Klinefelter syndrome—see CHAPTER 18), FSH and iron studies (haemochromatosis).

Abnormal results:

- testosterone <8 nmol/L
- testosterone 8–15 nmol/L with elevated LH

Treatment under consultant guidance is with testosterone replacement with injections, implants, patches or tablets.<sup>6,7</sup>

## Osteoporosis in men<sup>9,10</sup>

While more common in women, osteoporosis still has a high prevalence in men and remains a major health concern for older men. Almost a third of Australian men >60 years of age will suffer an osteoporotic fracture.<sup>9</sup> Yet the identification of osteoporosis in men remains particularly poor, and this may be

because it is considered a predominantly female condition. BMD testing rates for women are four times those of men.<sup>11</sup>

Prevention can be achieved through reducing risk factors where possible. Risk factors include poor dietary calcium, lack of weight-bearing exercise, vitamin D deficiency, hypogonadism, smoking, excess alcohol and medications (corticosteroids used for >3 months, anti-epileptics e.g. phenytoin). Other risk factors for osteoporosis and fractures include a family history of osteoporosis, malabsorption, hypothyroidism, hyperparathyroidism, being underweight and being at risk of falls. Men with risk factors should be screened using BMD testing. Other indications for screening include height loss, kyphosis or back pain suggesting possible vertebral fractures, low-impact fractures and possibly even high-impact fractures.<sup>12</sup>

Investigations can include bone densitometry, FBE, LFTs, testosterone and vitamin D. When identified, osteoporotic men should be encouraged to have adequate dietary calcium, be educated on fall-prevention strategies and encouraged to do weight-bearing exercise. Medication management options include oral bisphosphonates (first-line treatment) and calcium, vitamin D or testosterone if deficient.

## Gynaecomastia

This is a 'true' enlargement of the male breasts, not to be confused with false enlargement of obese men. Gynaecomastia occurs in up to 50% of adolescent boys. Virtually no breast tissue is palpable in normal men.

If present in adult men, look for evidence of testosterone deficiency. Other causes include drugs (e.g. anabolic steroids, oestrogen, digoxin, calcium antagonists, marijuana, spironolactone, amiodarone, tricyclic antidepressants, cimetidine), liver failure, testicular feminisation syndrome and oestrogen-secreting tumours, such as adrenal carcinoma and Leydig cell tumour.

## Sex-linked inherited disorders

Males bear the burden of X-linked recessive gene disorders, which always manifest as there is no normal gene on the additional X chromosome (as there is in the female) to counteract the action of the abnormal gene.

Occasionally a gene can be carried on an autosome but manifests only in one sex. An example is male-pattern baldness, manifesting as an autosomal dominant disorder in males but as a recessive disorder in females.

Examples of X-linked disorders significantly affecting males include:

- haemophilia A and B
- glucose-6-phosphate dehydrogenase deficiency
- Duchenne muscular dystrophy
- retinitis pigmentosa
- Hunter syndrome
- ocular albinism

## Summary

There is an increasing emphasis on and interest in men's health. In 2008, in response to the growing awareness of men's health issues, the first Australian National Male Health Policy<sup>13</sup> was developed. Initiatives that have emerged from and been enhanced by this policy include programs and campaigns that focus on male mental health, work safety, male health in particular risk groups and prevention of chronic disease and injury. Examples include the Men's Sheds, Man Health and Strong Father Strong Family programs. Also available are information sources and links, resources and research on male health issues.

Many of these programs, especially those concerning mental health and psychosocial aspects such as family relationships and risk behaviour, focus on issues such as what it means to be male. Topics explored include the positives of maleness, the behaviours males should be avoiding and personal responsibility.

The GP is in an ideal position to identify, assess and manage significant health problems in males. Men's reluctance to access health services when they need them makes the GP's role all the more important. Opportunities should be grasped to discuss health issues with male patients and foster preventive issues where appropriate.

# 113 Scrotal pain

*Acute scrotal pain in infancy and adolescence should be regarded as torsion of the testis until proved otherwise.*

TEXT, PAGE 1218

Scrotal pain in males can occur in all age groups but the child or adolescent with acute scrotal pain often poses a diagnostic challenge. Serious problems include testicular torsion, strangulation of an inguinoscrotal hernia, a testicular tumour and a haematocele, all of which require surgical intervention.

## Key facts and checkpoints

- Torsion of the testis is not the most common cause of acute scrotal pain in childhood and adolescence, but it is the most important.<sup>1</sup>
- Torsion is also a feature of young men younger than 25 years.
- Testicular pain can be referred to the abdomen.
- Torsion of the testis should form part of the differential diagnosis in a boy or young man who is vomiting and has intense pain in the lower abdominal quadrant inguinal region.
- The loss of a testicle from torsion, an avoidable problem, is a real 'time bomb' and a common reason for litigation for medical negligence.
- The clinical picture of epididymo-orchitis can mimic torsion of the testis so closely that in most boys and young men the diagnosis should be made only at surgical exploration.<sup>1</sup>
- An abnormality predisposing to torsion of the testis is usually present bilaterally; the opposite testis should also be fixed to prevent torsion (orchidopexy).
- Torsion must be corrected as soon as possible to reduce the chance of gangrene and loss of the testis.
- Suspect self-correcting testicular torsion in repeated episodes of severe spontaneously resolving pain. Refer for possible orchidopexy.
- Suspect abscess formation if epididymo-orchitis does not settle with a reasonable course of antibiotics. Surgical drainage may be necessary.
- A varicocele can cause testicular discomfort—examine the patient in the standing position.

## The clinical approach

### History

It is important to determine whether there were any pre-existing predisposing factors or history of trauma.

### Key questions

- Have you noticed any burning of urine or penile discharge?
- Have you had an injury to your scrotal region such as being struck by a baseball, cricket ball or falling astride something?
- Have you travelled overseas recently?
- Have you been aware of a lump in your testicle or groin?
- Have you had an illness lately and have you noticed swelling of the glands in your neck or near your ear (i.e. screening for mumps)?
- Do you have back pain or have you injured your back?

### Examination

Both sides of the scrotum must be examined and contrasted. Inguinal and femoral hernial orifices, the spermatic cord, testis and epididymis must be checked on both sides. The size, lie and elevation in the scrotum of the testis should be assessed, as should the cremasteric reflex. This is done by stroking or pinching the medial thigh, and considered positive if the testicle moves at least 0.5 cm. An absence of the ipsilateral cremasteric reflex is the most sensitive physical finding in testicular torsion but the reflex is often absent in small boys (under 2½ years) without torsion.<sup>2</sup>

The patient should be examined standing and supine. The scrotum and its contents are examined systematically starting with the skin, which may include sebaceous cysts or other dermatological

conditions. A painful testis should be elevated gently to determine if the pain improves.

## Investigations

Investigations that may help diagnose the painful testis in particular include:

- blood cell count
- urine analysis: microscopy and culture
- Chlamydia antigen detection tests
- ultrasound
- technetium-99m scan

## Acute scrotal pain in children and adolescents — ‘the acute scrotum’

This problem is more likely to be encountered in the adolescent, especially after the testis enlarges at puberty (13–16 year olds).<sup>1</sup> A list of causes is presented in TABLE 113.1. Infants, however, can also have torsion of a testis or a testicular appendage.

**Table 113.1** Causes of scrotal pain or swelling

Torsion of the testis
Torsion of a testicular appendage
Epididymo-orchitis
Mumps orchitis
Acute hydrocele
Idiopathic scrotal oedema
Haematoma/haematocele
Testicular neoplasm
Henoch–Schönlein purpura
Strangulated inguinoscrotal hernia
Scrotal skin conditions
Varicocele
Referred pain (e.g. spine, ureteric colic, abdominal aorta)

## Clinical problem

A 15-year-old teenager presents with relatively acute onset of pain in his lower right abdomen and scrotum. He has vomited several times. On examination the right testicle is tender, red and swollen.

## Discussion

The three main differential diagnoses of the acute scrotum in an adolescent are torsion of the testis, torsion of a testicular appendage and acute epididymo-orchitis (see FIG. 113.1). Less commonly the problem would be a haematoma or an acute hydrocele mimicking testicular torsion. This patient, however, must be regarded as having torsion of the testis until proven otherwise. Early operation with torsion is

**FIGURE 113.1** Illustration of torsion of the testis and an appendage: the ‘black’ hydatid of Morgagni is the one most likely to undergo torsion

imperative because if the testis is deprived of its blood supply, infarction is inevitable and excision becomes necessary. Excluding mumps, no pre- or peripubertal youth should be diagnosed as suffering from acute epididymo-orchitis until the testis has been exposed at operation and torsion excluded.

## Torsion of the testis

Torsion usually occurs because of an abnormally narrow anchoring of the testis by the testicular mesorchium posteriorly<sup>1</sup> and the tunica vaginalis (which normally covers only the testicle and epididymis) also covering the bottom end of the spermatic cord. This allows the testicle to have a more mobile and transverse lie, referred to as a ‘bell clapper deformity’, and makes it easier for the testicle to twist around upon its cord. This deformity is almost invariably present on the other testicle, so when surgical correction of the torted testis is done, orchidopexy should always be done on the other side also.

When a testicle torts, time is of the essence. One study suggests that the testicular salvage rate is 90% if detorsion occurs less than 6 hours after the onset of symptoms, but this drops to 50% after 12 hours and <10% after 24 hours.<sup>3</sup>

## Torsion of the testis versus epididymo-orchitis

With torsion of the testicle there is pain of sudden onset, described as a severe, aching, sickening pain in the groin that may be accompanied by nausea and vomiting. With epididymo-orchitis the attack usually begins with malaise and fever and is often

associated with a urinary infection. The testicle soon becomes swollen and acutely tender; however, elevation and support of the scrotum usually relieves pain in this condition (Prehn sign) while tending to increase it with a torsion. A comparison of the clinical presentations is given in **TABLE 113.2**.

Table 113.2	Clinical presentations of torsion of testis and acute epididymo-orchitis	
	Torsion of testis	Epididymo-orchitis
Typical age	Early teens, average range 5–15 years	Young adults Elderly
Onset	Usually sudden but can be gradual	Gradual
Severity of pain	Very severe	Moderate
Associated symptoms	Vomiting Groin pain Possibly abdominal pain	Fever ± Dysuria
Examination of scrotum	Very tender and red Testis high and transverse Scrotal oedema Possibly an acute hydrocele	Swollen, tender and red; can be tender on rectal examination Possibly an acute hydrocele
Effect of gentle scrotal elevation	No change to pain or worse pain	Relief of pain
Investigations	Technetium-99m scan (if available, time permits and diagnosis doubtful)	Leucocytosis Possibly pyobacteria of urine

**Radiology as a diagnostic aid**

Ultrasound, particularly colour Doppler, is useful in distinguishing a cystic scrotal lump (such as a hydrocele) from a solid tumour. Its use to distinguish between a torsion and epididymo-orchitis is controversial as it cannot reliably detect changes that are diagnostic of early torsion. Since the investigation can involve unnecessary delay in treatment it is generally not recommended. A technetium-99m scan can differentiate between the two conditions: in torsion the testis is avascular while it is hyperaemic in epididymo-orchitis.

At surgery the testicle is untwisted and if viable an orchidopexy is performed. A gangrenous testicle is removed (see **FIG. 113.2**).

**FIGURE 113.2** Torsion of the testis resulting in gangrene after 12 hours from onset of pains. The testis was excised and the other normal testis ‘anchored’

**Cautionary tales**

Many testicles are lost because of inappropriate delays with referral for an ultrasound. The patient should be referred immediately to a surgeon or surgical centre. Teenage boys presenting with acute right iliac fossa pain, nausea and vomiting are sometimes misdiagnosed as having acute appendicitis.

**Torsion of a testicular appendage**

Torsion of one of the testicular appendages (most commonly the hydatid of Morgagni) accounts for 60% of cases of acute scrotal pain in children<sup>1</sup> (torsion of the testis accounts for 30%, and epididymo-orchitis, idiopathic and other causes comprise the remaining 10%). Vestigial remnants to the testis or the epididymis are present in 90% of the male population.<sup>1</sup> Torsion of a testicular appendage has a similar presentation to that of torsion of the testis but is less severe (see **FIG. 113.1**).

Torsion of a testicular appendage can be diagnosed by the appearance of a dark blue nodule at the upper pole of the testis called the ‘blue dot sign’(provided that it is not masked by an associated hydrocele).<sup>3</sup>

Surgical exploration may be needed to distinguish this from torsion of the testis.

## SCROTAL PAIN AT VARIOUS AGES

### § Acute epididymo-orchitis

Apart from mumps, acute epididymo-orchitis is usually caused by sexually transmitted pathogens in young males and by urinary tract pathogens in older males. In older men it usually follows urinary tract obstruction and infection or instrumentation of the lower genitourinary tract.

### Investigations

Blood cell count:	leucocytosis
Urine microscopy and culture:	pyuria, bacteria and possibly <i>Escherichia coli</i> a sterile culture suggests the possibility of a chlamydial or gonorrhoeal infection <sup>4</sup>
Tests for <i>Chlamydia</i> :	PCR kits
Ultrasound:	can differentiate a swollen epididymis from a testicular tumour

### Treatment

- Bed rest
- Elevation and support of the scrotum
- Analgesics
- Antibiotics<sup>4</sup>

Sexually active men (especially those <35 years old) should be treated empirically for chlamydial or gonorrhoeal infection:

use ceftriaxone 500 mg (in 2 ml of 1% lignocaine) IM (or 500 mg IV) daily for 3 days

plus

azithromycin 1 g (o) as a single dose

plus

another dose of 1 g azithromycin a week later, or doxycycline 100 mg bd for 14 days

Associated with urinary infection:

trimethoprim 300 mg (o) daily (child 6 mg/kg) for 14 days

or

cephalexin 500 mg (child 12.5 mg/kg) (o) 12 hourly for 14 days

or

amoxycillin/clavulanate 500/125 mg (child 12.5/3.1 mg/kg) (o) 12 hourly for 14 days

or (if resistance to above)

norfloxacin 400 mg (o) 12 hourly for 14 days

If severe infection, administer parenteral gentamicin + ampicillin.

### § Orchitis

Acute orchitis is invariably due to mumps and occurs during late adolescence. Mumps orchitis has become relatively rare with vaccination. It is usually unilateral (see FIG. 113.3) but may be bilateral.

FIGURE 113.3 Mumps orchitis with a swollen tender testicle

## Testicular neoplasm

Testicular tumours can occur at all ages but are more common in young men aged 20–30 years (teratoma) and 25–40 years (seminoma). Sometimes they can mimic an acute inflammatory swelling and present with acute pain. See CHAPTER 114.

## Strangulated inguinoscrotal hernia

It is possible that a supposed testicular torsion may be found to be a strangulated inguinoscrotal hernia, usually an indirect inguinal hernia extending into the scrotum. It can be detected by careful palpation of the base (neck) of the scrotum, feeling for a cough impulse and being unable to 'get above' the swelling.

## Trauma and haematoceles

A diffuse haematoma into the scrotum that causes no significant problems can follow surgery to the inguinal area, a blow to this area or a fracture of the pelvis. These conditions cause extravasation of blood distally. However, a haematocele of the tunica vaginalis can be either acute or an 'old clotted haematocele' following injury, such as a blow to the

testis, or the drainage of a hydrocele. Sometimes it can arise spontaneously. All types of haematoceles require surgical exploration to exclude testicular rupture or a tumour.

Trauma to the scrotum may produce urethral injury and extravasation of urine into the scrotum. This problem requires urgent surgery.

## Problems of scrotal skin

Sebaceous cysts are common and may be infected and require drainage. Less commonly, idiopathic scrotal oedema can present, usually in boys aged 5–10 years. With this condition, scrotal swelling and mild redness and tenderness begin gradually and spread, often across the midline and also possibly beyond the scrotum. Palpation reveals normal, non-tender testes but torsion needs to be excluded in some instances of the swollen red scrotum. Idiopathic scrotal oedema is believed to be allergic in origin, either localised (e.g. insect bite) or globalised as part of urticaria. It sometimes results from exposure to cold water. There may be a tender enlarged draining inguinal lymph node near the external ring.<sup>1</sup> Treatment includes scrotal support, analgesics and antihistamines.

## Referred pain

Pain can be referred to the scrotal region from ureteric colic and quite commonly from disorders of the thoracolumbar spine, notably a disc disruption at the T12–L1 level involving the L1 nerve root. The pain therefore may be referred or radicular. In elderly men, referred pain can arise (uncommonly) from a ruptured abdominal aortic aneurysm or acute aortic dissection.

## When to refer

- Any suspicion of torsion of the testis
- Sudden onset of acute scrotal pain at any age
- A history of recurrent transient testicular pain in a young man

- Presence of a tender testicular lump
- Presence of a haematocele surrounding the testis

*Note:* Referral should be urgent, given the critical importance of time in testicular survival.

## Practice tips

- Acute scrotal pain in infancy and adolescence should be regarded as torsion of the testis until proved otherwise.
- A history of recurrent transient pain (with or without swelling of the testis) in a young person means recurrent torsion. Urgent referral is essential.
- A pitfall is the phenomenon of 'testis redux' in which the descended testis undergoes torsion, is pulled into the superficial inguinal pouch by the cremasteric reflex and then becomes fixed by oedema. Always check both testes are present in the scrotum in boys and young men with inguinal pain.
- The development of an acute hydrocele should be regarded with suspicion.
- Beware of the strangulated inguinoscrotal hernia presenting as a testicular torsion.
- Consider dissecting aneurysm in an older person presenting with testicular pain.

Lumps in the groin are common to both sexes but males are likely to have a greater variety of swellings in this area and several may be associated with scrotal lumps.

## Lumps in the groin

The commonest swellings encountered in the groin or inguinal area are hernias and enlarged lymph nodes. The diagnosis of a hernia is usually straightforward but it must be differentiated from other swellings, including Malgaigne bulgings—these are not true hernias but diffuse swellings in both inguinal regions seen in people with poor lower abdominal musculature.<sup>1</sup> TABLE 114.1 lists the differential diagnoses of groin lumps.

**Table 114.1** Differential diagnoses of a groin mass

Hernia—femoral, inguinal
Malgaigne bulgings
Lipoma
Undescended testis
Spermatic cord swelling—encysted hydrocele, lipoma
Lymph node—localised, generalised
Haematoma (post femoral artery puncture)
Neoplasm—lipoma, others
Psoas abscess
Vascular anomalies:
• saphenous varix
• femoral aneurysm

## Hernias

The commonest types of hernias in the groin are inguinal, femoral and a combination of the two. Rare hernias in the region are obturator, Spigelian (low abdominal), preperitoneal inguinal and prevascular femoral. The basic parts of a hernia are shown in FIGURE 114.1 and important anatomical landmarks in FIGURE 114.2. An indirect inguinal hernia is a hernia

BEN JONSON (1573–1637), *THE STAPLE OF NEWS*

emerging through the deep inguinal ring, originating lateral to the inferior epigastric vessels, following the path of the spermatic cord, and which can traverse the whole length of the inguinal canal (see FIG. 114.3). It may also pass through the superficial inguinal ring into the scrotum—an inguinoscrotal hernia.

Because of their narrow neck and oblique path in the inguinal canal, such hernias are often irreducible and can occasionally lead to strangulation of entrapped bowel.

A direct inguinal hernia originates medial to the inferior epigastric vessels and protrudes through the

**FIGURE 114.1** Basic components of a hernia

**FIGURE 114.2** Key landmarks in the left inguinal region: the deep inguinal ring lies above the mid-inguinal point (between the ASIS and the pubic tubercle); the femoral artery lies below this point

posterior wall of the inguinal canal, and is therefore separate from the spermatic cord (see FIG. 114.4). It is almost always seen in men and rarely descends into the scrotum. Due to a wider neck, strangulation and obstruction are most unusual. It must be emphasised that the distinction between a direct and an indirect inguinal hernia can be very difficult (and of no clinical benefit)<sup>1</sup> and the two may occur together.

**FIGURE 114.3** Left indirect inguinal hernia: it emerges lateral to the inferior epigastric artery and passes into the scrotum medial to the pubic tubercle

A femoral hernia herniates through the femoral ring (also known as the femoral canal), which is the medial component of the femoral sheath. The hernia tends to bulge forward and then upwards as it becomes larger. The neck is lateral to the pubic tubercle (see FIG. 114.5).

**FIGURE 114.4** Left direct inguinal hernia: it emerges medial to the inferior epigastric artery and bulges forward

**FIGURE 114.5** Left femoral hernia: its neck is lateral to the pubic tubercle and it lies below the inguinal ligament

Femoral hernias are often small, usually occur in females and may be unnoticed by the patient. They are particularly liable to produce bowel obstruction or strangulation.

## Guidelines

### Acquired hernia

- Always examine the scrotum and both sides
- Frequently bilateral
- Result from muscular weakness
- Commonest—direct inguinal and femoral
- Predisposing factors:
  - age (more common with increasing age)
  - obesity
  - pregnancy
- Precipitating factors (related to above factors):
  - increased intra-abdominal pressure:
  - difficulty of micturition
  - straining at stool (constipation)
  - chronic cough (e.g. bronchitis)
  - straining or lifting heavy objects
  - nerve damage (e.g. post appendicectomy)
- Complications:
  - intestinal obstruction (see TABLE 114.2)
  - incarceration
  - strangulation
  - sliding

**Table 114.2** Symptoms and signs of hernial obstruction

Colicky abdominal pain
Nausea and vomiting
Constipation and failure to pass flatus
Abdominal distension
High-pitched tinkling bowel sounds
Local tenderness and swelling of the hernia
No expansile cough impulse

## Clinical features

The main symptoms and signs:

- lump
- discomfort or pain:
  - a dragging pain
  - worse after standing or walking
  - referred to testicle (indirect inguinal)
- testicular pain—referred or with compression of the spermatic cord
- expansile impulse on coughing

*Note:*

- A femoral hernia is easily missed in obese patients.
- Larger femoral hernias are often irreducible.
- Always attempt reduction in the recumbent position (direct hernias usually reduce easily).

## Treatment

### Surgery

All symptomatic hernias require repair. Those patients who are not symptomatic (a third of patients with hernias)<sup>1</sup> and who are medically fit should also be offered surgery. This is not so much because of the risk of strangulation (which is rare) but because most patients usually become symptomatic eventually and a watch-and-wait approach delays rather than prevents surgery.<sup>2</sup> Obstructed and strangulated hernias require urgent surgery. The risk of strangulation is greatest with femoral hernias, occasional with indirect inguinal hernias and very rare with direct inguinal hernias.

Open-mesh repair has been the preferred technique by most surgeons.<sup>1</sup> Using mesh (rather than sutured repair only) has been shown to greatly reduce the hernia recurrence rate. Recently, laparoscopic repair has become more popular, with less severe postoperative pain, fewer complications and a faster return to normal activities.<sup>3</sup> However, a surgeon who is still on the 'laparoscopic learning curve' may have a higher rate of hernia recurrence, and patients should be fully informed of the risks and benefits of open and laparoscopic surgery to enable them to choose between procedures.<sup>1</sup>

While generally a very safe procedure, inguinal hernia surgery complications include bruising, numbness, haematoma, infection (1–7%), recurrence and chronic pain (defined as persisting for >3 months after surgery). Chronic pain is the most serious long-term complication of hernia repair and may persist for several years. It may be severe in up to 3% of patients<sup>1</sup> and can require referral to pain clinics or further surgery. An increase in infertility risk and testicular atrophy on the side of the surgery has been noted but is not common.

Most patients return to work after hernia repairs in around 7 days, or 14 days for those doing strenuous work.<sup>1</sup>

### Conservative

Asymptomatic inguinal hernias in patients with associated medical conditions, and who pose a

significant operative risk, such as the frail elderly patient, can be treated with a watch-and-wait approach. Trusses have been used since ancient times to help patients with hernias, but can be difficult for a patient to manage and cannot be recommended as a definitive form of treatment.<sup>4</sup>

## HERNIAS IN CHILDREN<sup>5</sup>

The most common hernias in infants are inguinal hernias and umbilical hernias.

### § Umbilical hernias

#### Clinical features

- Soft, round, skin-coloured lump in umbilicus, occurring in around 15% of infants.<sup>6</sup>
- May increase in size in first few months
- Not painful, not tender to palpate, easily reducible
- Swelling disappears when child asleep
- Usually gradually disappears
- Most disappear by age of 12 months<sup>6</sup>
- Larger ones usually disappear by age of 4 years<sup>6</sup>
- Consider hypothyroidism

#### Management

- Explanation and reassurance
- No treatment required
- Do not tape or strap (may cause strangulation and does not help)
- Refer for repair if still present at age 4 years

### § Inguinal hernia

#### Clinical features

- More common in premature infants and boys
- Present with groin lumps—may be intermittent sightings (e.g. when crying)
- May cause intermittent pain or discomfort
- If irreducible, consider possibility of strangulation

*Note:* Bowel strangulation is a possibility.

#### Management

Rules for surgical intervention:

- general rule is ASAP, especially in infants and for irreducible ones
- reducible herniae—the '6–2' rule:
  - birth–6 weeks: surgery within 2 days
  - 6 weeks–6 months: surgery within 2 weeks
  - over 6 months: surgery within 2 months

## Scrotal lumps

The scrotum contains the testes and distal parts of the spermatic cords, covered by layers of fascia and the dartos muscle. The testes are invested with tunica vaginalis derived from the peritoneal cavity during their descent.<sup>1</sup>

Disorders of the scrotum may be acute or chronic and bilateral or unilateral. Lumps may be cystic, solid or otherwise, such as a varicocele, oedema or hernia. Solid lumps include a testicular tumour, epididymo-orchitis, and torsion of the testes. Cystic lumps include hydroceles, epididymal cysts and spermatoceles. A comparison of scrotal lumps appears in **FIGURE 114.6** and **TABLE 114.3**. Lumps in the scrotum usually develop from deeper structures, particularly the testes and their coverings, rather than scrotal skin.

The cardinal sign of a true scrotal mass is that it is possible to palpate it from above (i.e. get above the lump) (see **FIG. 114.7**).

The patient usually presents with pain or a lump.

## Examination of the scrotum

The scrotum should be examined with the patient supine and then standing. The left testis usually

hangs lower than the right. On inspection note any sebaceous cysts in the scrotal skin (common); scabies if there are very pruritic nodules; and scrotal oedema, which causes taut pitting skin. Careful palpation will elicit the relevant structures in the scrotum. Gently palpate each testis and epididymis between the thumb and the first two fingers. The spermatic cord is palpable as it enters the scrotum after passing through the superficial ring and the testis and epididymis are readily palpable.

After palpation, test for translucency of any swelling in a darkened room by shining the beam of a strong torch from behind the scrotum through the swelling. Transilluminable swellings that light up with a red glow (referred to as a 'Chinese lantern sign') include hydroceles and cysts of the epididymis. Swellings that contain blood or other tissue, such as testicular tumours and most hernias, do not transilluminate.

## Unilateral scrotal swelling

It is important to determine whether the lump is inguinoscrotal or scrotal. It is scrotal if it is possible to get above the lump. If it is not possible to get above the lump then it is a large inguinal hernia or

**FIGURE 114.6** Basic comparison of scrotal lumps

**FIGURE 114.7** Difference between a true scrotal swelling and an inguinoscrotal swelling

a combined hernia and hydrocele (see FIG. 114.7). This palpation should be coordinated with the cough impulse. The next feature to determine is whether the testis and/or epididymis can be palpated or whether they are obscured by a swelling.<sup>5</sup>

### Small testes

Normal testicular size in children and adolescents is 4–14 mL or 15–35 mL in adults (this can be assessed with an orchidometer).<sup>7,8</sup> Small firm testes less than 10 mL are a feature of Klinefelter syndrome. Small

**Table 114.3** Features of scrotal lumps

	Possible clinical setting	Position	Palpation	Trans-illumination
<b>Hydrocele</b>	Any age Primary or secondary: • tumour • infection • torsion	Confined to scrotum Anterior: surrounds testis except posteriorly	Smooth, pear-shaped Lax or tense Testis impalpable, non-tender	Yes
<b>Cyst of epididymis</b> Epididymal cysts and spermatoceles clinically similar	Asymptomatic or dragging sensation	Behind and above testis	Smooth and tense Multilocular swelling Testis easily palpable Appears separate from testis	Yes
<b>Chronic epididymo-orchitis</b>	Non-specific Tuberculosis <i>Chlamydia</i> (Occasional associated small hydrocele)	Behind and above testis	Firm swelling Hard and craggy Normal testis	No
<b>Varicocele</b>	Dragging discomfort	Usually left-sided Along line of spermatic cord Above testis	Soft, like bunch of worms or grapes Collapses when patient supine and testis elevated Testis often smaller	No
<b>Cancer</b>	Young men 20–40 Painless lump Loss of testicular sensation	In body of testis Usually felt anteriorly May be hydrocele	Enlarged firm testis Feels heavy if large Normal epididymis (palpable)	No

soft testes indicate atrophy, which may follow mumps orchitis, oestrogen therapy, androgen deficiency or anti-androgen therapy, hypopituitarism, cirrhosis and other related conditions.

## § Hydrocele

A hydrocele is a collection of clear amber fluid in the tunica vaginalis and can be primary or secondary. If a hydrocele develops it is important to rule out intrascrotal disease, such as a tumour or infection. Ultrasound examination of the scrotum is helpful in assessing the state of the testis in the presence of a hydrocele. Hydroceles may be symptomless or cause dragging discomfort in the scrotum and groin.

## Hydroceles in the neonate<sup>5,9</sup>

Hydroceles present at birth are communicating (failed closure of the processus vaginalis) or (less commonly) non-communicating, where the tunica vaginalis contains fluid, which can sometimes be loculated or cystic. Transillumination will prove that it is cystic but if the diagnosis is in doubt perform an ultrasound. Hydroceles may vary in size from day to day and can appear quite large. They do not extend proximal to the external inguinal ring so it is possible to palpate above them. There is no impulse on crying or straining. Of the 5% of those born with a hydrocele, most will resolve spontaneously within 12 months. If the hydrocele is very large or persists beyond 12 months, surgical intervention should be considered.

## Treatment of a primary hydrocele in adults

If underlying pathology has been excluded, hydroceles can be managed conservatively with reassurance and scrotal support.<sup>10</sup> If the hydrocele is large and uncomfortable, simple aspiration with or without the injection of sclerosing agents can be attempted, but the fluid usually reaccumulates and there is a risk of bleeding or infection with repeated procedures. However, aspiration can prevent fluid accumulation and after two or three times can often cure the problem. This sclerotherapy may be complicated by pain and inflammatory reaction to the sclerosant. Surgery is generally considered a second-line procedure after observation with or without aspiration.

### Practice tip

Consider testicular cancer in a young man presenting with a hydrocele. Perform an ultrasound examination.

## Encysted hydrocele of the cord

This is a localised fluid-filled segment of the processus vaginalis within the spermatic cord. It is palpable as a cystic lump in the upper scrotum above the testis. It characteristically moves down with traction on the testis. Treatment is not usually needed.

## § Epididymal cysts

These are common, often multiple, and are usually found in middle-aged/elderly men. The majority of epididymal cysts are about the size of a pea and contain a clear colourless fluid. If the cysts communicate with the vasa efferentia, a spermatocele filled with whitish fluid containing spermatozoa may form.

Epididymal cysts may be asymptomatic or they may cause discomfort and cosmetic embarrassment and if so can be excised. Fertility may be impaired in patients undergoing bilateral cyst excision.

Aspiration and injection of sclerosant agents can also be used for epididymal cysts.

## § Varicoceles

A varicocele is a varicosity of the veins of the pampiniform plexus (see FIG. 114.6). It is seen in 8–10% of normal males and occurs on the left side in 98% of affected patients, due to a mechanical problem in drainage of the left kidney vein. A relationship with infertility has been observed but its nature is controversial, as is whether repairing varicoceles in subfertile men improves fertility chances.<sup>10</sup>

Most varicoceles are asymptomatic and incidental findings. They can cause a dragging discomfort in the scrotum. Investigation is usually not necessary but an ultrasound is useful where the diagnosis is doubtful or a neoplasm is suspected. Treatment is indicated if it is symptomatic or for infertility. Firm-fitting underpants may relieve discomfort. Surgical treatment is by venous ligation, above the deep inguinal ring. Ligation is indicated if there is any reduction in the size of the left testis.

## § Haematoceles

These can be either acute, resulting from trauma such as a fall astride, sports injury or tapping of a hydrocele, or chronic, where there is no obvious history of injury. Haematoceles are anterior to the testis and not transilluminable. Surgical drainage is required with acute injury where there is a possibility of testicular rupture (associated urethral injury has to be considered); and a tumour has to be excluded with

the chronic type. Pressure atrophy of the testis can occur with injury and is much more common if early drainage is not instigated.

### § Sperm granulomas

- Firm tender lumps
- Post-vasectomy—at cut end of vas

#### Treatment

- Leave to resolve.
- Consider NSAIDs.
- Refer for excision if symptomatic and enlarging.

### § Testicular tumours<sup>11,12</sup>

A mass that is part of the testis, and solid, is likely to be a cancer. Malignant testicular tumours account for about 1–1.5% of malignant tumours in men. They mainly affect fit young men and represent the commonest cancer in men aged 20–40 years in Australia (see TABLE 114.4). Some 90–95% of testicular tumours arise from the germ cells, and for practical purposes are classified into:

- seminomas 40%
- non-seminoma germ cell tumours (NSGCT) 60%

**Table 114.4** Testicular tumours

Tumour	Incidence (%)	Peak incidence (years)
Seminoma	40	25–40
Teratoma	32	20–35
Mixed seminoma/teratoma	14	20–40
Lymphoma	7	60+
Other tumours (e.g. interstitial—Leydig, gonadoblastoma)	uncommon	variable

#### Clinical features

- Young men aged 20–40 years (NSGCTs peak in the third decade of life, seminomas peak in the fourth decade)
- Most common presentation is a painless lump in the body of one testis (only 1–2% present with bilateral tumours)
- Up to a quarter of men have pain at presentation
- Loss of testicular sensation

- Associated presentations (may mask tumour):
  - hydrocele
  - varicocele
  - epididymo-orchitis
  - swollen testis with trivial injury
  - gynaecomastia (teratoma)
  - back and flank pain

#### Risk factors

Those at high risk include those men with:

- cryptorchidism/orchidopexy (testicular dysgenesis syndrome)
- previous testicular cancer
- family history of testicular cancer (brother/father)
- Klinefelter syndrome
- infertility

#### Golden rules

- All solid scrotal lumps are malignant until proved otherwise and must be surgically explored.
- Beware of hydroceles in young adults.
- Tumours can mimic acute epididymo-orchitis—the so-called ‘inflammatory’ or ‘flash fire’ presentation.

If a man has a testicular lump he should visit his GP and have ultrasound screening and baseline tumour markers. If it is cancer, he should:

- be treated in a specialist centre
- undergo careful staging
- have an orchidectomy and adjunct therapy

#### Metastases

Testicular tumours spread by direct infiltration via the lymphatics and the bloodstream. Metastases typically occur in the para-aortic nodes and so may not be detected by abdominal palpation. They are best detected by a CT scan of the abdomen and chest. Metastases also occur in the neck, brain, liver, chest and bones.

#### Investigations

Investigations to aid diagnosis include:

- ultrasound of the testis should always be done as it can detect and diagnose with considerable precision underlying testicular lumps plus any invasion of the tunica
- tumour markers:  $\alpha$ -fetoprotein and  $\beta$ -hCG—indicates teratomas

Investigations for staging include:

- chest X-ray
- CT scanning of abdomen, pelvis and chest for node involvement (any spread is usually direct to the para-aortic nodes)
- lactate dehydrogenase—monitors secondary spread and indicates tumour mass

*Note:* Avoid scrotal needling biopsy because of the potential risk of tumour implantation in the scrotal wall. Avoid scrotal incisions for surgery.

Treatment

The initial treatment is orchidectomy through an inguinal incision with inguinal division of the spermatic cord. Further treatment then depends on the type and staging of the tumour. Early seminomas are given radiation to the ipsilateral lymph nodes or a single dose of chemotherapy. Early NSGCTs undergo active surveillance (tumour markers, CXR, CT scans) but no further treatment. More advanced disease may have further chemotherapy or radiotherapy. The results for NSGCTs in general are not as satisfactory as for seminoma, though prognosis is good for both, with current 5-year relative survival rates of 99% for localised disease (majority of presentations), 96% for regional disease and 74% for distant disease.<sup>13</sup> A comparison of the testicular tumours is summarised in TABLE 114.5.

Surgery should not affect the remaining testis but production of motile and functional sperm may be reduced. However, sperm production can be temporarily or permanently reduced following radiotherapy and chemotherapy. Pretreatment sperm storage may be discussed with the patient, and the psychological implications of testicular cancer need to be carefully monitored. The GP may also play a role in coordinating appropriate active surveillance investigations.

Screening and testicular self-examination

Studies of testicular cancer have shown the benefits of early detection. However, studies to date indicate that there is insufficient evidence to screen routinely for testicular cancer in asymptomatic patients. It is recommended for those at high risk. This screening includes colour Doppler ultrasound and tumour markers. Evidence also indicates that, to date, there is little evidence to show that those performing testicular self-examination are more likely to detect early stage tumours or have better survival than those who do not.<sup>14</sup>

Table 114.5 Comparison of the common testicular cancers

	Seminoma	Non-seminoma (NSGCT)
Typical age	30–40 years	20–30 years
Incidence	40%	60%
Growth rate	Slow	Rapid
Nature	Solid	Mixed—solid + cystic
Stage at presentation	90%—stage 1	60%—stage 1
Tumour markers:		
α-FP	Never	Common
β-hCG	Occasional	Common
Treatment	Inguinal orchidectomy + radiotherapy	Stage 1: orchidectomy Relapse: chemotherapy
Sensitive to chemotherapy	+ + +	+ + +
Sensitive to radiotherapy	+ + +	±

Undescended testes (cryptorchidism)<sup>15</sup>

An undescended testis is one that fails to reach the bottom of the scrotum by 3 months of age. It has stopped in the normal path of descent and can occupy the intra-abdominal, inguinal canal, emergent (just outside the external ring), high scrotal and mid-scrotal positions (see FIG. 114.8). The cause of maldescent is most probably mechanical.

After the indirect inguinal hernia, it is the most common problem in paediatric surgery. The incidence at birth is 4–5% but this falls to 1–2% in the first 3 months of life as testicular descent can continue, though further descent after 3 months is rare. More than two-thirds of undescended testes are located in the superficial inguinal pouch; that is, they are palpable in the groin.

The testis is usually normal at birth but may become secondarily dysplastic if left outside the scrotum.

FIGURE 114.8 Undescended testis: arrested in the line of descent

### Retractile testis

A retractile testis is one that can be manipulated into the scrotum irrespective of the position in which it is first located. It is a common condition and requires no further investigation or treatment. The testis can be present in the scrotum under circumstances such as a warm bath but retracted out of the scrotum when cold. Cremasteric contraction is absent in the first few months after birth and is maximal between 2 and 8 years.

### Ectopic testis

An ectopic testis is one that has left the normal path of descent and cannot be manipulated into the scrotum. It can be found in the perineum, upper thigh (femoral), base of the penis (prepubic), anterior abdominal wall or in the superficial inguinal pouch (see FIG. 114.9). True ectopic testes form only about 2.5% of all undescended testes.

### Ascending testis

An 'ascending' testis is one that was in the scrotum in infancy but subsequently moved back to the groin because the spermatic cord failed to elongate at the same rate of body growth.

### Examination<sup>12</sup>

The examination of the testes should take place in a warm room and relaxed environment. Begin by placing one finger on each side of the neck of the scrotum to prevent a retractile testis from being retracted when palpation is commenced with the other hand. The scrotum is then carefully palpated for a testis. If impalpable the fingertips of one hand are placed just medial to the anterior superior iliac spine and moved firmly towards the pubic tubercle where the other hand waits to entrap the testis should it appear. The diagnosis then depends on carefully determining the range of movement.

FIGURE 114.9 Undescended testis: ectopic

### Practice tip

If the testis is not palpable at birth, review in 3 months. Refer for specialist evaluation if it still cannot be palpated.

### The problem of non-descent

- Testicular dysplasia
- Susceptible to direct trauma (if in inguinal region)
- Risk of malignant change (seminoma) is 5–10 times greater than normal

### Optimal time for surgery

The optimal time for orchidopexy is 6–12 months of age. It is considered to be satisfactory as long as the

testis is in the scrotum by 2 years. The production of spermatozoa is adversely affected in undescended testes from the age of 2 years onwards. Exploration for the uncommon impalpable testis is worthwhile: 50% salvage rate, while in the other 50% either there is no testis or an abnormal and potentially neoplastic testis is removed.

The advantages of early orchidopexy are summarised in TABLE 114.6.

### Hormone injections

Injections of chorionic gonadotrophic hormones are generally not recommended. They are ineffective except for cases of borderline retractile testes.

**Table 114.6** Advantages of early orchidopexy (1 year)

Provides optimal chance of fertility
Corrects indirect inguinal hernias (coexists in 90%)
Reduces risk of trauma
Reduces risk of torsion
Reduces psychological consequences
Probably lessens the risk of malignancy (seminoma)

## Vasectomy

### Dangerous features (beware)

- Unmarried
- Young <35 years old
- No children
- Emotional crisis
- Spouse not involved

### Postoperative

- Avoid strenuous activity and sex for 4–7 days.
- Use alternative contraception until negative semen analysis.
- First semen analysis at 3 months.
- Inform not immediately infertile.
- Need to ejaculate 20 times.

### Complications<sup>16</sup>

- Postoperative bleeding and haematoma 4–22%
- Wound infection <1.5%
- Ongoing pain—around 10%, usually mild but can be severe

- Formation of sperm antibodies ~50%. May be a problem if subsequently requests vasectomy reversal
- Failure rate 1–2: 1000 (can be from tubes not fully tied off, growing back together or a third vas deferens existing)
- Psychological and psychosexual problems

### Other facts

- No difference in ejaculate appearance (sperm makes up 1% ejaculate volume) or sex drive
- No known association with prostate and testicular cancers

## Practice tips

### Inguinoscrotal lumps

General rules for optimal times for surgical repair in children:

- inguinal hernia—ASAP
- umbilical hernia—aged 4 years (most resolve)
- femoral hernia—ASAP
- undescended testes—6 to 12–18 months
- hydrocele—after 12 months if still large; most resolve
- varicocele—leave and review

## Patient education resources

Hand-out sheets from *Murtagh's Patient Education* 6th edition:

- Hernia, inguinal
- Scrotal lumps
- Testicle, undescended
- Testicular cancer
- Testicular self-examination

# 115 Disorders of the penis

*Ironically there is no organ about which more misinformation has been perpetuated than the penis.*

WILLIAM MASTERS & VIRGINIA JOHNSON, *HUMAN SEXUAL RESPONSE* (1970)

The most common penile disorders are those of psychosexual dysfunction and STIs, but there are many other problems and these are most often related to the foreskin.

## DISORDERS AFFECTING FORESKIN AND GLANS

### § Phimosis

Phimosis is tightness of the foreskin (prepuce), preventing its free retraction over the glans penis. The foreskin is normally attached to the glans and is non-retractile in most newborns; it may remain so until puberty.<sup>1,2</sup> The proportion of boys with retractile foreskins is: 40% at 1 year, 90% at 4 years and 99% at 15 years.<sup>3</sup> Forceful retraction of the penis should be avoided until spontaneous separation occurs.<sup>1</sup> Once the foreskin easily retracts, the boy should learn to do this as part of normal washing, ensuring he rinses off any soap and pushes the foreskin back over the glans afterwards.<sup>4</sup>

‘True’ phimosis is caused by forceful retraction, infection or balanitis xerotica obliterans (see later in this chapter).<sup>1,2</sup> Indicators of true phimosis (rather than simple non-retractile foreskin) are:<sup>3</sup>

- foreskin not retractile by the time of established puberty
- previously retractile foreskin becomes non-retractile
- obvious ring of scar tissue at foreskin opening
- inability to visualise the urethral meatus when foreskin opening is lifted away from glans
- ballooning during and after micturition, with pinhole foreskin opening and a squirting urinary stream (though mild ballooning during micturition is common and normal)

### Treatment

Inflammatory phimosis can be treated by local corticosteroid cream (e.g. 0.05% betamethasone valerate cream qid for 2–4 weeks)<sup>3</sup> applied generously to the tight shiny part of the foreskin where inner

skin meets the outer skin. If the tip of the foreskin is inflamed, gently retracting it will cause the inflamed opening to ‘cauliflower’ up so the cream can be applied. A stronger steroid cream can be tried if this fails.

True scarring that fails to respond to steroid creams may require circumcision, though this is uncommon.<sup>1,2</sup> Some patients with true phimosis may have problems once they start to have intercourse and will require circumcision.

### § Paraphimosis

Paraphimosis occurs when a tight foreskin is forcibly retracted over the glans, gets stuck in the sulcus and cannot be pulled forward again. The glans and the foreskin distal to the tight area become swollen and painful (see FIG. 115.1) and this demands urgent resolution.<sup>1</sup> This problem occurs in boys aged 8–12 and the elderly, especially if a mild degree of phimosis is already present. Typically it occurs when the penis is erect or after catheterisation.

### Management

Paraphimosis can usually be corrected without surgery and urgent manual reduction should be attempted first.<sup>3</sup> It is usually performed without anaesthesia but

FIGURE 115.1 Paraphimosis showing retracted, swollen, oedematous foreskin

a penile block (remembering never to use adrenaline in LA), systemic analgesia  $\pm$  sedation or a generous application of 2% lignocaine gel or EMLA cream may be appropriate depending on the geographic location and the clinical circumstances. Local anaesthetic infiltration before manual reduction should be avoided as it increases the swelling.

*Note:* Do not apply ice.

### Method 1

The glans penis and oedematous tissue distal to the constricting ring of foreskin are gently squeezed for several minutes to reduce the oedema. Using a lubricating jelly, manual reduction can then be performed by trying to advance the prepuce over the glans with the index fingers while gently compressing the glans with both thumbs (see FIG. 115.2).

### Method 2

- Take hold of the oedematous part of the glans in the fist of one hand and squeeze firmly. A gauze swab or cool towelette will help to achieve a firm grip (see FIG. 115.3).

FIGURE 115.2 Acute paraphimosis: method of manual reduction

FIGURE 115.3 Acute paraphimosis: squeezing with a swab method

- Exert continuous pressure until the oedema passes under the constricting collar to the shaft of the penis.
- The foreskin can then usually be pulled over the glans.

*Note:* If these simpler methods are successful, educate the patient about proper foreskin management as this may prevent further attacks.

### Method 3

Immediate referral is necessary if manual reduction methods fail. As an emergency, a dorsal slit incision can be made in the constricting collar of skin under local or general anaesthetic (see FIG. 115.4). The incision allows the foreskin to be advanced and reduces the swelling. Circumcision can be considered some days later when the inflammation has settled and any phimosis assessed, but a single episode of paraphimosis is not an absolute indication for circumcision.<sup>3</sup>

FIGURE 115.4 Acute paraphimosis: dorsal slit incision in the constricting collar of skin

## § Balanitis (balanoposthitis)

Balanitis is inflammation of the glans; inflammation of the foreskin is called posthitis and the combination is balanoposthitis, though balanitis is the most commonly used term. Urine trapped under the foreskin converts into ammonia compounds, and an ammoniacal dermatitis (similar to that of nappy rash) causes inflammation. Other causes of inflammation include irritation by soaps and other environmental substances, and trauma such as sexual activity. This inflamed area can become infected with commensal bacteria or fungi leading to infection.<sup>1</sup> Balanitis is common, affecting 6% of uncircumcised and 3% of circumcised males.<sup>3</sup>

Balanitis is actually a collection of disparate conditions with similar clinical presentation and varying aetiologies affecting a particular anatomical site.<sup>5,6</sup> These include:

- Infections—*Candida* (the most common cause), streptococci, anaerobes, staphylococci, *Gardnerella*, herpes simplex
- Inflammatory dermatoses—lichen sclerosis, lichen planus, psoriasis, Zoon balanitis, eczema (including irritant, allergic and seborrhoeic)
- Premalignant—Bowen disease, Bowenoid papulosis, erythroplasia of Queyrat

Men presenting with balanitis should be considered for predisposing conditions such as diabetes or HIV.

### Treatment

Treatment will be dependent on the cause, which will in turn be determined by the clinical picture, patient risk factors and potential culture results. Cultures can be useful, but may also pick up commensals unrelated to the aetiology so cannot always be relied upon.

- Mild cases felt to be caused by an inflammatory dermatosis may be treated with gentle saline bathing, a barrier cream or hydrocortisone 1% cream to tip of penis, and careful washing behind the foreskin.
- If there is a purulent discharge, take swabs for culture.
- Candidal balanitis is suggested by blotchy erythema with small papules that may be eroded, or dry, dull, red areas with a glazed appearance, and associated soreness  $\pm$  itch.

If yeasts present:

- topical nystatin or miconazole or clotrimazole cream

If trichomonads present:

- metronidazole or tinidazole (oral treatment)

If bacterial infection is suspected:

- topical antibiotic ointments under the foreskin using a narrow, longish nozzle (e.g. chloramphenicol)
- severe cases caused by bacterial infection may have purulent discharge with spreading cellulitis down the penile shaft and require oral or intravenous antibiotics

### § Balanitis xerotica obliterans (BXO)

Thickening of the foreskin with skin pallor suggests balanitis xerotica obliterans. There is white, thickened

scarring giving an ‘icing sugar’ appearance to the glans. It results in progressive phimosis, typically in late childhood, usually 10–12 years. It may respond to corticosteroid cream if it is mild, but circumcision is usually indicated.

## Foreskin hygiene

The normal foreskin in infants and children does not need special care and should be retracted for cleaning only after spontaneous separation of the foreskin has occurred. After this, males can practise proper hygiene by gently retracting the foreskin and washing the area as often as washing behind the ears.

### Basic rules

- The foreskin should be retracted only by its owner (or a health professional)
- The foreskin should not be retracted forcibly
- Once retraction has spontaneously occurred, encourage daily retraction and gentle cleansing in the bath or shower

### Instructions to patients

- During a shower or bath slide the foreskin back towards your body (see FIG. 115.5).
- Wash the end of the penis and foreskin with soap and water and then rinse off.
- After washing the area, dry the end of your penis and foreskin and then replace the foreskin.
- If the foreskin has a tendency to become irritated and smelly, slide the foreskin back sufficiently to allow free urination.

## Smegma pearls

Smegma is made up of shed skin cells from the inner aspect of the foreskin. Smegma cysts/deposits (yellow–white lumps beneath the foreskin) can be visible or palpable through the thin foreskin of boys whose foreskins have not retracted. They are sometimes called ‘smegma pearls’, and are normal and need no treatment. They can discharge a white ooze from under the foreskin. They can also be mistaken for sebaceous cysts and may cause concern for the boy or his parents, who can be reassured all is well.<sup>1</sup>

## Circumcision

Circumcision is now performed in 10–20% of Australian males after peaking at 85% in the 1950s.<sup>7</sup> True phimosis not resolving with steroid creams, paraphimosis, recurrent balanitis, BXO or boys at

**FIGURE 115.5** Foreskin hygiene: sliding foreskin back for washing

high risk of UTIs are potential medical indications for circumcision. However, improved personal hygiene and better management of some of these conditions has led to a reduced medical need for circumcision. Apart from these situations and circumcision for

religious reasons, circumcision for social reasons is generally discouraged. A policy statement from the Paediatric and Child Health Division of the RACP recommends against routine infant circumcision.<sup>7</sup>

Circumcision is generally a safe procedure but there are risks of minor complications and some rare but serious complications. In newborns, because of their small blood volume, any bleeding is of major concern and blood loss over 25 mL can be life-threatening.<sup>1</sup> A bleeding circumcision site can be the presentation of a coagulopathy disorder.<sup>3</sup> Also, because of a newborn's relatively poor immunity, septicaemia from coliform infection on the wound site is a risk. If circumcision is done, it is recommended that it be done after 6 months of age and ideally in an operating theatre under general anaesthetic and with careful surgical technique.<sup>1</sup>

Arguments for routine circumcision include a reduction in risk of UTIs (and their complications) in infancy, reduction of sexually transmitted infections (including HIV) and a possible reduction in the risk of penile cancer in men and cervical cancer in their female partners later in life.

Circumcision reduces the risk of UTIs by about 10-fold.<sup>8</sup> However, because of the low baseline risk, 111 circumcisions would be required to avoid one UTI in boys without abnormal urinary tracts.<sup>7</sup> The reduction in STIs including HIV has been shown to be a benefit in males in high-risk populations (such as men in Africa), but this benefit has not been consistently evident in studies in lower-risk populations such as Australia and New Zealand. While there have been some studies showing that circumcision provides a protective benefit against HPV transmission and subsequent cervical cancer risk, the introduction of HPV vaccination is likely to dramatically reduce the baseline risk of these conditions. Cancer of the penis is so rare that the overall benefit offered by circumcision would be very small, and is overshadowed by recent improved penile hygiene in men and management of phimosis. In summary, the RACP guidelines conclude the benefits do not warrant the risks in routine circumstances, but that it is reasonable for parents to weigh up the risks and benefits (after being fully informed), and to make the decision themselves with parental choice being respected.

Complications of circumcision:

- bleeding
- infection (local/septicaemia)
- ulceration of glans/meatus
- meatal stenosis
- penile deformity

Absolute contraindications:

- hypospadias and other congenital abnormalities (the foreskin may be a vital source of skin for subsequent repair)
- chordee (painful dorsolateral curvature of the penis during erection, which interferes with sexual intercourse)
- 'buried' penis
- sick, 'unstable' infants
- family history of bleeding
- inadequate experience of proceduralist

### § Frenuloplasty

A congenitally tight frenulum may lead to a tear during intercourse. Repeated bleeding occurs. Division of the frenulum and suturing in the opposite direction is preferable to circumcision.

### § The 'buried' penis

In the 'buried' penis syndrome (also known as the 'concealed' or 'inconspicuous' penis) the penis is not adequately exposed and looks small. There is failure of skin fixation at the base of the penis with possible excessive prepubic fat pad at the base. It is commonly seen in small children, especially chubby boys, and can cause parental concern. Manually pressing down the fat pad at the base of the penis back towards the pubic bone will allow a more reliable assessment of penile length (and often reassure the parents). This situation usually improves spontaneously over time. In adolescents and adults, a buried penis is usually associated with obesity and rarely can require surgical intervention for cosmetic or functional reasons.<sup>9</sup>

## DISORDERS AFFECTING URETHRAL MEATUS

### § Meatal stenosis

Meatal stenosis or stricture may be congenital or acquired. It may be acquired in the circumcised child due to abrasion and ulceration of the tip of the glans. The incidence can be reduced by the application of moisturising cream for 2 weeks on the glans after circumcision.<sup>1</sup> Uncommon causes are direct trauma during circumcision and irritation from ammoniacal dermatitis. Meatal ulceration predisposes to meatal stenosis. It usually presents as pain during micturition or as slight bleeding on the nappy or underpants. Significant stenosis requires surgical correction by meatotomy.

Catheter trauma is the usual cause in adults.

### § Hypospadias

Hypospadias is a condition where the urethra opens on the underside or ventral aspect of the penis. It occurs in 1 in 350 males. Hypospadias is classified based on the location of the proximally displaced urethral orifice:<sup>2</sup>

- distal–anterior (located on the glans or distal shaft of the penis and the most common type)
- intermediate–middle (penile)
- proximal–posterior (penoscrotal, scrotal, perineal)

There is often associated chordee (a ventral bending of the penis associated with erection) due to a 'bowstring' effect from the lack of tissue on the ventral surface, and also a high incidence of cryptorchidism (10%) and open processes vaginalis or inguinal hernia (9–15%).<sup>2</sup>

Hypospadias may cause the stream of urine to be deflected downwards or splash or drip back along the penile shaft. Unless it is glanular, surgical repair is usually advised, using the available foreskin, and is usually done between 6 and 18 months.<sup>2</sup> Chordee may be corrected at the same time to allow eventual successful sexual intercourse. These boys should not undergo routine circumcision.

## OTHER DISORDERS OF THE PENIS

### § Penile warts

Penile warts are usually multiple fleshy, papillomatous outgrowths, commonly found around the coronal sulcus, the adjacent prepuce and the meatus (see FIG. 115.6). They are caused by human papillomavirus and usually transmitted sexually. Look for warts within the meatus by allowing gentle dilation of the distal urethra with mosquito forceps.

Treatment is aimed at reducing any pain, bleeding, itch or embarrassment. Treatment options include:<sup>10</sup>

- no treatment
- self-applied treatments at home
- treatment at the surgery or a clinic

The following treatments<sup>11</sup> can be used with or without periodic cryotherapy:

- imiquimod 5% cream topically applied to each lesion, 3 times per week at bedtime (wash off after 6–10 hours) until the warts disappear (usually 8–16 weeks)
- podophyllotoxin 0.15% cream or 0.5% paint topically applied to each wart, twice daily for 3 days followed by a 4-day break, then repeat weekly for 4–6 cycles until the warts disappear

**FIGURE 115.6** Penile (genital) warts caused by the human papillomavirus

### § Pearly penile papules

These are very small regular round lumps (actually angiofibromas) that appear on the corona of the glans of the penis (see FIG. 115.7). They are common and are often first noticed by adolescent males who should be reassured that they are normal variants. They are not premalignant and require no treatment.<sup>12</sup>

**FIGURE 115.7** Pearly penile papules

### § Penile ulcers

A common cause of penile ulcers is trauma, related to sexual activity, to the frenulum if it is congenitally tight. Such traumatic ulcers may be slow to heal and the frenulum may need surgical division. The ulcers

may resemble a venereal ulcer (e.g. syphilitic chancre or herpes simplex). Another important (although rare) cause is cancer of the penis. Various causes are listed in TABLE 115.1.

**Table 115.1** Causes of penile lesions

#### Non-ulcerative

##### Balanitis:

- *Candida albicans*
- diabetes mellitus
- poor hygiene

##### Skin disease:

- psoriasis
- lichen planus

#### Venereal warts

#### Ulcerative

##### Trauma (tender)

##### Cancer (non-tender)

##### Herpes simplex (tender)

##### Syphilis (non-tender)

##### Chancroid (tender)

### § Cancer of the penis

Cancer of the penis is rare, occurring in fewer than 1 in 100 000 of the male population,<sup>13</sup> though it can be much more common in the developing world. Some 95% of penile cancers are squamous cell carcinomas. Phimosis, smoking and poor hygiene are the main risk factors for penile cancer.<sup>14</sup> There is an association with being uncircumcised and HPV infection, particularly types 16, 18 and 31.<sup>13</sup>

Cancer usually starts as a nodular warty growth (or ulcer) on the glans penis or in the coronal sulcus.<sup>14</sup> Initially it may resemble a venereal wart. The presenting symptom may be a bloodstained or foul-smelling discharge as the lesion can be hidden by the foreskin. It is usually seen in elderly patients with poor hygiene. Associated lymphadenopathy, which is present in 50% of patients on presentation, may be infective or neoplastic.

### § Priapism<sup>15</sup>

Priapism is a persistent penile erection that continues hours beyond, or is unrelated to, sexual stimulation. Typically, the corpora cavernosa are engorged but the

corpus spongiosum and glans remain flaccid. It is a medical emergency, as it often leads to fibrosis of the cavernosal tissue and subsequent erectile dysfunction or impotence.

Subtypes of priapism include:

- Ischaemic (veno-occlusive or low flow)—this results from a failure of the detumescence mechanism (relaxation of the outflow of blood from the penis). The corpus cavernosa are rigid and tender to palpation, and the patient is in discomfort. It requires emergency treatment, and there can be subsequent penile oedema, ecchymoses and partial erections.
- Non-ischaemic (arterial or high flow)—this is from an unregulated cavernous arterial inflow. The penis is neither fully rigid nor painful. Trauma is often the cause. It does not require emergency treatment.
- Stuttering—this occurs from intermittent ischaemic priapism, and is manifested by repeated painful erections with intervening periods of detumescence. It may require emergency treatment if the events are prolonged, severe or frequent. Urologist consultation is advised.

The assessment focuses on distinguishing ischaemic from non-ischaemic. Apart from the clinical features mentioned above, cavernosal blood gases in ischaemic priapism will show a  $PO_2 < 30$  mmHg, a  $PCO_2 > 60$  mmHg and a pH  $< 7.25$  (normal venous blood shows  $PO_2$  40,  $PCO_2$  50, pH 7.35).

Duplex ultrasound can also be used, with ischaemic priapism showing little or no flow in the cavernosal arteries, and non-ischaemic showing normal to high blood flow. It can also demonstrate anatomical abnormalities such as a cavernous artery fistula in the perineum from trauma. A full blood count and film can also be part of the assessment, looking for abnormalities such as sickle cell disease, leukaemia, acute infections or platelet abnormalities. Drug screening can also be performed if suspected.

Emergency treatment for ischaemic priapism can include intracavernous injection of sympathomimetic agents such as phenylephrine as well as aspiration via a 19 or 21 gauge needle into the corpus cavernosum. If this fails, a surgical (cavernoglanular) shunt can be considered.

### § Peyronie disorder<sup>16</sup>

Peyronie disorder is a fibrotic process, sometimes associated with Dupuytren contracture, which affects

the shaft of the penis and results in discomfort and deformity on erection. It may result from trauma while the penis is erect. It usually affects men between 45 and 60. Typically, the patient presents with painful 'crooked' erections. There is abnormal curvature of the erect penis. The penile deformity may prevent satisfactory vaginal penetration. On examination, a non-tender hard plaque may be palpable in the shaft of the penis at the point where the penis curves. Mild cases require reassurance. The problem may increase, remain static or spontaneously lessen over 1–2 years. If there is ongoing discomfort or sexual dysfunction that distresses the patient, surgical treatment by penile plication (a sutured tuck on the opposite side to straighten the deformity) may be warranted. In more severe deformities, incision and grafting of the scar or implants can be considered. Steroid injections are not recommended.

### § 'Fractured' penis

A 'fractured' penis describes sudden rupture of the penile erectile tissue during intercourse, resulting in a snapping sensation with severe pain. The management is urgent urological consultation for possible surgical repair. The disruption can affect the corpus spongiosum (has a better prognosis) or the corpora cavernosa, in which case permanent erectile dysfunction is a possible complication.

### § Foreskin injury

Injuries to the penis are not uncommon and one is the entrapped foreskin in the trouser zipper, when attempts to free the zipper aggravate the problem. In the office, cut the zipper from the trousers (see FIG. 115.8) and under local anaesthetic (no adrenaline), crush the zipper with pliers to open the teeth of the zipper and free the foreskin. Another method is to use a scalpel to cut the zipper immediately below the metal tag.

### § Haematospermia

Haematospermia, which is blood in the semen, presents as a somewhat alarming symptom. It is sometimes encountered in young adults and middle-aged men. The initial step is to determine that the blood is actually in the semen and not arising from warts inside the urethral meatus or from the partner.

It usually occurs as an isolated event but can be secondary to urethral warts or prostatitis, or with prostatomegaly or prostatic tumour (especially in elderly patients). If a micro-urine shows no

**FIGURE 115.8** Entrapped foreskin in trouser zipper

Photo courtesy of Bryan Walpole

accompanying haematuria, and prostate-specific antigen and blood pressure are normal, reassurance and a 6-week review is appropriate as spontaneous cessation of haematospermia is the rule.

# 116 Disorders of the prostate

*Mind and body, like man and wife, do not always agree to die together.*

CHARLES COLTON (1780–1832)

The main function of the prostate gland is to aid in the nutrition of sperm and keep the sperm active. It does not produce any hormones so there is usually no alteration in sexual drive following prostatectomy.

## § Prostatitis

Prostatitis embraces a group of conditions with voiding discomfort and pain in the prostate referred to the perineum, low back, urethra and testes. It typically affects men aged 25–50 years. Prostatitis usually occurs in the absence of identifiable bacterial growth, when it is termed non-bacterial prostatitis. The prostate may develop acute or chronic bacterial infection. Acute bacterial prostatitis, while uncommon, can be life threatening if left untreated.<sup>1</sup>

Bacterial prostatitis is usually caused by urinary pathogens—*Escherichia coli* (commonest), *Enterococcus*, *Proteus*, *Klebsiella*, *Pseudomonas* or *Staphylococcus*. Rarely, chronic infections have been shown to be associated with *Chlamydia trachomatis*.<sup>2</sup>

Prostatodynia means the presence of symptoms typical of prostatitis but without objective evidence of inflammation or infection (see TABLE 116.1).

It is preferable to use the term ‘prostatitis syndromes’ to embrace the four terms used in TABLE 116.1.

## Clinical features of acute bacterial prostatitis

### Symptoms

- Fever, sweating, rigors

- Pain in perineum (mainly), back and suprapubic area
- Urinary frequency, urgency and dysuria
- Variable degrees of bladder outlet obstruction (BOO)
- ± Haematuria

### Signs

- Fever
- Rectal examination: prostate exquisitely tender, swollen, firm, warm, indurated

**DxT** dysuria + fever + perineal pain  
→ acute prostatitis

### Complications

- Abscess
- Recurrence
- Epididymo-orchitis
- Acute retention
- Bacteraemia/septicaemia

## Chronic bacterial prostatitis

Chronic bacterial prostatitis is diagnosed by a history of mild irritative voiding with perineal, scrotal and suprapubic pain. Ejaculatory pain can occur. The gland may be normal on clinical examination or tender and boggy. It should be suspected in men with recurrent UTI (see TABLE 116.2).

Table 116.1 Classification of prostatitis syndromes

	Prostatic pain	Prostatic rectal examination	Positive urine or prostate secretion culture	Positive prostatic secretion or urine white cells
<b>Acute bacterial prostatitis</b>	Yes	Very tender, swollen	Yes	Yes
<b>Chronic bacterial prostatitis</b>	Often	Normal or indurated	Occasionally	Low counts
<b>Non-bacterial prostatitis</b>	Often	Normal	No	Occasionally
<b>Prostate pain syndrome</b>	Often	Normal	No	No

**Table 116.2** Features of chronic bacterial prostatitis

Difficult to treat
Relapsing infection
Perineal pain
Some leucocytes in expressed prostatic secretions

## Investigations

- Urine specimens and expressed prostatic secretions (EPS) obtained after prostatic massage can show excess white cells.
- Culture of the urine or ejaculate may be negative or give low counts.
- Prostatic stones (demonstrated by plain X-ray or transrectal ultrasound) may prevent successful treatment.
- Prostate-specific antigen (PSA): elevation occurs with inflammation and may cause confusion with cancer.

## Treatment

### Acute bacterial prostatitis<sup>1</sup>

For milder infection, oral treatment for 14 days with trimethoprim, cephalexin or amoxycillin/potassium clavulanate is suitable, as per treatment of cystitis. For more severe infections:

amoxycillin (or ampicillin) 2 g IV 6 hourly  
*plus*  
 gentamicin 4–6 mg/kg/day as a single daily dose until there is substantial improvement, when therapy may be changed to an appropriate oral agent, based on the sensitivity of the pathogen(s) isolated, for the remainder of 10–21 days, depending on clinical response.<sup>2</sup>

Urinary retention or abscess formation almost always requires endoscopic deroofting for drainage.

### Chronic bacterial prostatitis

Treatment of chronic bacterial prostatitis is made difficult by uncertainty in differentiating it from non-bacterial prostatitis as cultures may grow low counts of what may be normal flora. Some 90–95% of cases of chronic prostatitis are not due to infection.<sup>2</sup> Avoid overtreatment with antibiotics and review regularly. Reassurance is important and it is worth suggesting frequent ejaculation and hot baths. Antibiotics should be used in patients who are culture positive with pus cells, based on culture susceptibility results. Regimes used include:<sup>2</sup>

norfloxacin 400 mg (o) 12 hourly for 4 weeks  
 or  
 trimethoprim 300 mg (o) daily for 4 weeks

## Non-bacterial prostatitis

This is the commonest and least-understood form. It is often recurrent and each episode can last several months. Recurrent antibiotic therapy is inappropriate.<sup>2</sup> The symptoms may reflect retrograde passage of urine into prostatic tissue with urate crystallisation. Management is targeted at symptom relief and can include NSAIDs, massage therapy and 5-alpha-reductase inhibitors (if BPH is present).<sup>3</sup> Alpha blockers, which have previously been recommended, are now considered ineffective based on a recent large randomised trial.<sup>4</sup> Emphasise good voiding habits. Avoid straining at the end of micturition. Encourage normal sexual activity and use stress management.

## Prostate pain syndrome

Prostate pain syndrome is considered part of the broader chronic pelvic pain syndrome.<sup>3</sup> It is clinically indistinguishable from non-bacterial prostatitis and the treatment approach is the same—some guidelines suggest they should be considered one entity,<sup>3</sup> although some clinicians will use the term ‘non-bacterial prostatitis’ when white blood cells are found in urine or prostate secretions. Perform a thorough genitourinary tract investigation. Psychological counselling or a pain clinic referral may be appropriate in refractory cases.

Prostate pain syndrome is a symptomatic diagnosis, and a useful assessment tool to monitor the severity, progression and response to treatment is the International Prostate Symptom Score (IPSS).<sup>5</sup>

## § Lower urinary tract symptoms (LUTS)

These symptoms can be grouped as voiding symptoms (obstructive) or storage symptoms (irritative).<sup>6</sup> Irritative symptoms may be caused by a bladder problem only. Obstructive symptoms are usually caused by the prostate (which can also cause irritative symptoms). The old term ‘prostatism’ is ill defined and best dropped.

## Voiding (obstructive) symptoms

- Hesitancy
- Weak stream
- Postmicturition dribble or irregular stream
- Incomplete emptying/urinary retention
- Straining

### Storage (irritative) symptoms

- Urgency
- Urge incontinence
- Frequency
- Nocturia
- Suprapubic pain

### § Bladder outlet obstruction (BOO)

Symptoms of BOO are present in most men after the age of 60 years. The commonest cause is benign prostatic hyperplasia (BPH). BPH is a histological diagnosis that, strictly, should not be used for symptoms. Only a minority of patients require surgery for relief of obstructive symptoms. Bladder outlet obstruction can also be caused by bladder neck obstruction and urethral sphincter spasm (see FIG. 116.1).

**DxT** poor urine flow + straining to void + frequency → BOO

### Clinical features of BOO

- Hesitancy
- Frequency of micturition
- Urgency
- Nocturia
- Slow interrupted flow
- Terminal dribbling
- Acute retention
- Retention with overflow incontinence (less common)
- Haematuria from ruptured submucosal prostatic veins can occur
- Rectal examination usually detects an enlarged prostate

*Note:* Small prostate glands can also cause BOO.

The medical history should ideally include an International Prostate Symptom Score (IPSS).<sup>7</sup> The physical examination should include an abdominal examination, a digital rectal examination (DRE) and a genital examination.

FIGURE 116.1 Diagrammatic comparison of bladder outlet obstruction

## Investigations

These include:

- midstream urine: microscopy, culture and sensitivity
- kidney function (urea, electrolytes and creatinine)
- PSA
- urinary ultrasound including a bladder residual volume
- voiding diary (frequency and volume measured for 2–3 days, and should be done in men with daytime frequency or who awoken two or more times a night to void)<sup>6</sup>

When initial assessment demonstrates the patient having non-bothersome LUTS with or without non-suspicious prostate enlargement, and the patient does not want treatment, it is reasonable not to investigate further.<sup>6</sup> The patient can be reassured and seen again if necessary. If there are bothersome LUTS, causes such as prostatic obstruction, overactive bladder or polyuria/nocturnal polyuria should be considered. Polyuria is defined as >3 L/24 hours, and nocturnal polyuria as being greater than a third of the 24-hour urine output.

If the initial assessment does reveal these or other concerns, such as an abnormal DRE/PSA, haematuria, recurrent UTI or palpable bladder, the patient should be referred to a urologist before treatment is advised.<sup>6</sup> Further investigations that may be organised by the urologist can include urine flow studies, cystoscopy and prostatic biopsy. A flow rate below 15 mL/s suggests obstruction and below 10 mL/s significant obstruction (see FIG. 116.2).

## Complications of prostatic obstruction

- Retention
- Urinary infection
- Bladder calculus formation
- Uraemia

## Advice for patients with mild symptoms<sup>8</sup>

- Avoid certain drugs, especially OTC cough and cold preparations.
- Avoid or reduce caffeine and alcohol.
- Avoid highly seasoned or irritative foods.
- Avoid fluids before bedtime.
- Keep active/increase activity.

## Treatment

Treatment options beyond basic management and watchful waiting (with yearly review) include medical management and surgical options.

**FIGURE 116.2** A visual scale of urinary flow. The numbers signify the flow rate in millilitres per second. When assessing a patient with voiding dysfunction, ask him to indicate which stream is closest to his own.

## Medical treatment

BOO patients with significant symptoms may be helped with alpha-adrenergic blocking drugs such as alfuzosin, doxazosin, tamsulosin, terazosin and prazosin to inhibit contraction of the smooth muscle in the prostate and bladder neck. Typical doses are tamsulosin 0.4 mg daily and prazosin 0.5 mg bd, or 1 mg nocte after commencing with 0.5 mg nocte. Prazosin can be increased to a maximum of 2 mg bd. Symptoms are not improved by increasing beyond this dose. Side effects can include dizziness, and complications can occur in cataract surgery in men who have used alpha blockers, possibly due to an effect on the smooth muscle that dilates the iris (called the intra-operative floppy iris syndrome),<sup>9</sup> so caution needs to be used here.

The 5-alpha-reductase inhibitors (5-ARIs, e.g. finasteride, dutasteride) reduce prostatic volume by reducing testosterone conversion, and can be used in men with large prostates in association with LUTS. They are not as effective in reducing symptoms as the alpha blockers and can have sexually related side effects such as decreased libido and ejaculatory

dysfunction. Urine flow improves by 3 months, plateauing at 6 months, but not to the same degree as with surgery. Two large recent studies support the combined use of alpha blockers and 5-ARIs in the medical management of BOO with large prostates.<sup>10,11</sup> Anticholinergic medication can also be used for symptoms caused by an overactive bladder.

### Surgical management

The gold standard surgical treatment for obstruction remains transurethral resection of the prostate (TURP)<sup>6</sup> (see FIG. 116.3). Open prostatectomy accounts for less than 1% of benign prostatic surgery today. Surgery should be considered for men with moderate to severe symptoms who are keen on intervention and have had the risks and benefits of the procedure fully explained (including failure of relieving symptoms).

Many new surgical techniques are appearing as potential alternatives to TURP.<sup>6</sup> These include minimally invasive procedures that can be done as an outpatient such as transurethral needle ablation (TUNA) or transurethral incision of prostate (TUIP). These may have less risk of complications, but are not as effective at relieving symptoms as TURP and may lack sufficient durability of effect. They are sometimes considered as an option for men with anaesthetic risk or with smaller prostates. Other new surgical techniques such as Holmium laser ablation and laparoscopic and robotic prostatectomy show promise but lack robust long-term data to date. They are also dependent on operator experience and local availability.

Risks involved with TURP include a 1% risk of urinary incontinence and also decline in sexual function (both of which have been shown to be similar to watchful waiting).<sup>12</sup>

Absolute indications for prostatectomy include deterioration in kidney function, the development of upper tract dilatation, retention (following drainage and assessment) and bladder stones. Eighty per cent of patients have surgery for bothersome symptoms.

### Postoperative guidelines for the patient

- There may be urgency even to the point of incontinence for a few days.
- Bleeding can occur intermittently for 3 weeks, so increase fluid intake.
- Avoid intercourse for 3 weeks.
- Orgasms continue but there is usually no emission with ejaculation. The semen is ejaculated back into the bladder.
- If obstructive problems recur early there may be a stricture.

*Note:*

- persisting postoperative frequency bothers about 15% of patients
- 10–15% reveal unsuspected cancer

### Drugs causing LUTS

Certain drugs can cause LUTS due to the effect of the drug on the bladder. It is very important for the family doctor to enquire about these drugs when evaluating such a patient. The problem is mainly an adverse effect of drugs with anticholinergic activity.

### Anticholinergics

- Atropine and hyoscine compounds, for example:
  - isopropamide
  - mazindol
  - phenothiazines
  - dicyclomine

FIGURE 116.3 The process of prostatectomy

- propantheline
- other belladonna alkaloids
- Antidepressants:
  - especially tricyclic compounds
- Antiparkinson agents, for example:
  - amantadine
  - benzhexol
  - benztropine
  - biperiden
  - orphenadrine
  - procyclidine

### Beta-adrenoceptor agonists

- Ephedrine
- Salbutamol
- Terbutaline
- OTC preparations (mainly for coughs and colds—e.g. sympathomimetics including ephedrine)

### § Prostate cancer

Prostate cancer is the commonest malignancy in men and the third commonest cause of death from malignant disease in Australia.<sup>13</sup> It is very much age dependent, with the risk increasing with age. Prostate cancer is rare before the age of 50 years, but by the age of 80 years, 80% of men have histologic carcinoma within the gland (but most are dormant).<sup>14</sup> The lifetime risk of being diagnosed by the age of 85 years is 1 in 5, but the risk of dying of prostate cancer by this age is 1 in 25.<sup>13</sup> Those men with a new diagnosis have a 92% chance of surviving for at least 5 years compared with the general population.<sup>13</sup> While this may sound reassuring, a younger man with a new diagnosis will have a higher risk of dying prematurely from prostate cancer as the cancer has a longer time available to progress.<sup>15</sup>

A family history can increase risk. The risk increases with a brother or father diagnosed with prostate cancer before the age of 60 years.<sup>16</sup> There is also increased risk for men with a first-degree relative with familial breast cancer (*BRCA1* or *BRCA2*).<sup>17</sup> Prostate cancer may be asymptomatic, even when it has extended beyond the prostate. It usually commences in the peripheral part of the gland. There are significant racial differences in the frequency that tend to change with migration, indicating that prostate cancer reflects environmental influences (and possibly dietary fat).<sup>18</sup>

### Clinical features

Unsuspected cancers are often detected by the tumour marker PSA (a glycoprotein) or histologically

after TURP. Clinical prostate cancer presents typically with rapidly progressive symptoms of lower urinary tract obstruction or of metastatic spread, especially to bone (pelvis and vertebrae).<sup>19</sup> Symptoms include BOO, acute retention, back or other bony pain, haematuria and uraemia, tiredness, weight loss and perineal pain.

Digital rectal examination (DRE) may reveal a nodule. Locally advanced cancer typically reveals a hard, nodular and irregular gland. The tumour may be large enough to obliterate the median sulcus. The borders may lack definition. On the other hand, with cancer, the prostate may feel normal.

Signs of abnormal prostate (DRE):

- hard lump
- asymmetry
- induration
- loss of median sulcus

### Investigations

#### Blood analysis

- PSA:
  - can be elevated without cancer (e.g. BPH, exercise, infection, instrumentation, recent ejaculation)
  - must be tested with DRE<sup>17</sup>
  - is prostate specific, not prostate cancer specific

#### PSA guidelines (ng/mL)

Individual laboratory reference values may vary from the figures stated:

- <4: normal (but in 15–25% of cancers)
- 4–10: intermediate
- >10: strongly suggestive of cancer
- >20: indicates metastatic spread

Other PSA parameters:<sup>20</sup>

- Age-specific PSA reference range:
  - 40–49 years: 0.25–2.5 ng/mL
  - 50–59 years: 0.25–3.5 ng/mL
  - 60–69 years: 0.3–5.5 ng/mL
  - 70–79 years: 0.3–7.5 ng/mL
- Free/total PSA ratio: BPH tends to have more variable PSA concentrations due to intermittent physical disturbance of the gland and subclinical prostatitis. This leads to 'showers' of inactive (non-protease) free PSA. Prostate cancer, however, constantly increases bound active PSA

so the F/T PSA ratio tends to be lower (below 8%) in prostate cancer. This ratio has been suggested as being useful in men with moderately raised PSA levels (4–10 ng/mL).

- Above age-related median PSA. This has been postulated as a technique for selecting out those men who should have their PSA monitored more closely.
- The rate of PSA changes. Otherwise known as PSA kinetics, these include the ‘PSA velocity’ (the rate of change in PSA levels) and ‘PSA doubling time’ (the time taken for the PSA to double). A high velocity or a short doubling time may suggest a urology review is indicated.

The role of all of these parameters remains controversial, as does whether we should be screening for prostate cancer in low-risk men at all.

Screening

The RACGP *Guidelines for Preventive Activities in General Practice*<sup>17</sup> state that screening for prostate cancer is not recommended unless:

- 1 the man specifically asks for it *and*
- 2 he is fully counselled on the pros and cons

Similar recommendations have been made by other authorities.<sup>21</sup> A consensus position reached in 2014 concluded:<sup>22</sup>

- asymptomatic men aged 50–69 can choose to have PSA testing after being counselled on the pros and cons of testing. Those tested should have a test every 2 years and a core biopsy if the PSA is >3.0
- there is insufficient evidence to recommend screening in men aged >70
- men should not be tested if they are not expected to live for another 7 years
- digital rectal examination (DRE) is *no longer recommended* in asymptomatic men presenting in general practice

Fully counselling a man can be challenging. A useful guide<sup>23</sup> on the outcomes of screening 1000 men aged 60 (with no significant family history and screened annually for 10 years) would result in the following:

- 2 men will avoid death from prostate cancer before the age of 85
- 2 men will avoid metastatic prostate cancer before the age of 85
- 85 men who do not have prostate cancer will have a biopsy

- 28 men will experience a side effect from the biopsy they consider a moderate/major problem
- 28 men will be diagnosed with prostate cancer, many of whom would have remained asymptomatic
- 25 men will undergo cancer treatment, many of whom would have remained asymptomatic
- 7–10 men will develop persistent impotence and/or urinary incontinence, and some will develop persistent bowel problems due to the treatments

Core biopsy

A urologist will consider biopsy guided by transrectal ultrasound if the DRE is positive or if the PSA is elevated, depending on the man’s individual risk profile, clinical findings and PSA levels. A biopsy is the only certain measure of diagnosis.

Grading and staging

A good way of explaining to patients about grading and staging is to say ‘the grade is how aggressive the cancer is, and the stage is how much there is and how far it has spread’.

From the biopsy, the pathologist determines the grading using the Gleason score (see **TABLE 116.2** and **FIG. 116.4**). The score is based on the addition of the grading of the 2 most common types of cells found in the samples (graded from 1, being well differentiated, to 5, most dysplastic). Therefore the lowest score possible is 2 and the highest 10. Prognosis is also determined by the ratio of the higher of the two histological scores (e.g. Gleason 7 with 80% stage 4/20% stage 3 will be worse than Gleason 7 with only 20% stage 4/80% stage 3).

Table 116.2 Gleason score and risk of cancer	
Gleason score	Threat from cancer
2–4	Low
5–6	Moderate
7	Intermediate
8–10	High

Staging<sup>24,25</sup>

Clinical staging is based on 5 sources of information:

- the extent of the primary tumour (T category)
- whether the cancer has spread to nearby lymph nodes (N category)

FIGURE 116.4 Gleason pattern (grading) scale of prostate cancer<sup>26</sup>

- the absence or presence of distant metastasis (M category)
- the PSA level at the time of diagnosis
- the Gleason score, based on the prostate biopsy (or surgery)

Local prostate gland disease (T1–T2) is based on the DRE and transrectal ultrasound (TRUS) with T3 to T4 indicating spread beyond the capsule. Stages T1 and T2 have a good prognosis, and some T3 tumours can be cured. Whole-body radionuclide bone scanning, CT, MRI scanning and surgical pathology results also assist staging. Axial skeleton metastases are involved in 85% of patients who die of prostate cancer.<sup>27</sup>

After the TNM status is determined, this information is combined with the PSA and Gleason scores in what is termed *stage grouping*, from I (the least advanced) to IV (the most advanced). This will help determine treatment options and prognosis. This information can also be put into nomograms <[www.nomograms.org](http://www.nomograms.org)> by either the doctor or patient to clarify the patient's status and options.

### Treatment<sup>28,29,30</sup>

Deciding on treatment options for prostate cancer needs to take into account not only the grade and stage, but also the age and general health/life expectancy of the patient, available treatments and, importantly, patient preferences. Psychosocial support (both at the time of diagnosis and subsequently) and

appropriate patient education will help make these patient preferences more clear.

Options for localised prostate cancer include radical prostatectomy, radiotherapy and no active treatment. The latter is now referred to as 'active surveillance', which means actively monitoring for changes such as a rising PSA or deteriorating biopsy results. Previously the term 'watchful waiting' was used, which was a more palliative approach used in the pre-PSA era (before 1990), which involved awaiting the appearance of symptoms or signs of local or systemic progression and then treating these as needed. Most of the evidence points to there being little difference (when the reduction in cancer risk is offset against the potential negative consequences of the interventions) in long-term outcomes between the three different approaches. This, however, needs to be put into the context of the individual patient's situation, his clinical presentation and his preferences, so active interventions may well be warranted.

Radical prostatectomy is most likely to benefit the patient with a relatively long life expectancy (>10 years), no significant surgical risk factors, a low volume stage and a low PSA and who, after being informed of the risks and benefits, prefers surgery. Approaches include radical perineal, laparoscopic and robot-assisted prostatectomy. Major complication issues include incontinence and impotence, and the risk of these will vary depending on the surgical approach and the patient's age and health.

Radiotherapy is also likely to benefit those with a long life expectancy and low-volume low PSA, who have a moderately (or worse) differentiated tumour and who, after being informed of the risks and benefits, prefer external beam or interstitial radiotherapy (brachytherapy). The main adverse reactions from external radiotherapy are faecal urgency and diarrhoea together with urine frequency. Impotence is common for up to 2 years after external beam radiotherapy.

Active surveillance is often used for those with a low life expectancy, or those who prefer to avoid the possible complications of surgery or radiotherapy. PSA monitoring is done for surveillance, or for follow-up after treatment with curative intent.

For locally advanced or metastatic disease, androgen deprivation is the cornerstone of treatment, the options being:

bilateral orchidectomy

or

daily anti-androgenic tablets, for example:

- cyproterone acetate (Androcur)
- flutamide (Eulexin)
- bicalutamide (Cosudex)
- abiraterone (Zytiga)

or

luteinising hormone releasing hormone (LHRH) agonists: depot injections of LHRH analogues, for example:

- goserelin (Zoladex)
- leuporelin acetate (Lucrin, Eligard)

Treatment combinations for small volume metastatic prostate cancer may prolong life, for example:

- orchidectomy plus flutamide
- LHRH agonists plus flutamide or bicalutamide—LHRH agonists cause an initial surge of testosterone so a preliminary anti-androgenic agent is advised to prevent a flare in the cancer.

As well as androgen deprivation, radiotherapy to bony metastases or local disease and other adjuvant therapy options can be considered.

### Complementary medicine

Among the disorders most widely promoted as benefiting from natural remedies are those of the prostate, though none has enough evidence to warrant its recommendation.<sup>6</sup> Herbal remedies that have been widely used include saw palmetto (*Serenoa repens*), stinging nettle (*Urtica dioica*), African prune

(*Pygeum africanum*, syn. *prunus africana*), willowherb (*Epilobium*) and cernilton.

Saw palmetto has been used widely, especially in Germany, with initial studies suggesting efficacy in LUTS consistent with BPH. However, a recent Cochrane review concludes it is not more effective than placebo.<sup>31</sup>

BPH has been treated with isoflavone phytoestrogens. A weak oestrogen agonist effect in males may antagonise the growth-promoting effects of androgens on the prostate. Epidemiological data indicate that in countries such as Japan where isoflavone diets are prevalent, prostatic enlargement occurs less with ageing. The most widely used source of phytoestrogens is soy protein. It is also present in lentils, chickpeas, some variations of beans and alfalfa sprouts.

A variety of nutrients may play a role in the development and progression of prostate cancer. There is evidence from some epidemiological studies that selenium, leucopenes (from tomato and tomato products), vitamin D, vitamin E, calcium and green tea in the diet protect against cancer of the prostate, though their true role remains largely unclear.<sup>32</sup>

# Part 8

## Sexual health

---

*You notice that the tabetic has the power of holding water for an indefinite period. He is also impotent—in fact, two excellent properties to possess for a quiet day on the river.*

DR DUNLOP, TEACHING AT CHARING CROSS HOSPITAL, 1913

Subfertility is defined as the absence of conception after a period of 12 months of normal unprotected sexual intercourse.<sup>1</sup> Interestingly, normal fertility is defined as 'achieving a pregnancy within 2 years of regular sexual intercourse' and applies to about 95% of couples.<sup>2</sup> The inability to conceive can be a very distressing and emotional problem for a couple, who need considerable care, empathy and relatively rapid investigation of their problem. In assessing a couple with the problem of subfertility (this term is a preferable way of describing the condition to the patients), it is appropriate to involve both partners in the consultation. In determining the cause of the subfertility, three basic fertility parameters should be investigated.<sup>3</sup>

- The right number of sperm have to be placed in the right place at the right time.
- The woman must be ovulating.
- The tubes must be patent and the pelvis sufficiently healthy to enable fertilisation and implantation.

As a general rule, the major factors limiting fertility are one-third female, one-third male and one-third combined male and female.<sup>4</sup>

In addition, there are couples who fulfil the three primary fertility factors (egg, sperm and tubes) but do not conceive. This is known as unexplained (idiopathic) subfertility.

### Key facts and checkpoints

- Infertility affects about 10–15% (1 in 7) of all cohabitating couples.<sup>4</sup>
- This incidence increases with age.
- After the age of 32 fertility decreases by 1.5% per year.
- About 15% of couples who do not use contraception fail to achieve a pregnancy within 12 months.<sup>5</sup>
- More than 5% remain unsuccessful after 2 years.<sup>5</sup>

- About 50% of couples will seek medical assistance.<sup>5</sup>
- The main factors to be assessed are ovulation, tubal patency and semen analysis.
- About 40% of couples have an identifiable male factor. Treatable causes are rare.
- The main identifiable causes of male infertility are failure of spermatogenesis, failure of sperm delivery and sperm autoimmunity.<sup>4</sup>
- The technique of intracytoplasmic sperm injection (ICSI) has revolutionised the treatment of male infertility.
- Female factors account for about 40%: tubal problems account for about half and ovulatory disorders for roughly the other half.<sup>4</sup> Polycystic ovarian syndrome (PCOS) is the most common cause of ovulatory dysfunction.<sup>6</sup> Treatable factors are the big three causes—tube disease, anovulation and endometriosis.
- The initial investigation for the man is semen analysis on two occasions. The initial investigation for the woman is a basal body temperature chart, associated with midluteal progesterone measurement.
- In about 20% of couples, no apparent cause is identified (idiopathic).<sup>4</sup>
- Sperm autoantibodies (IgG and IgA) can be detected in the blood and/or seminal plasma of 10% of infertile men (a special problem with vasectomy reversal).
- Current specialised treatment helps the majority of subfertile couples to achieve pregnancy.

### Physiological factors<sup>3,7</sup>

#### Male fertility

Fertility in the male requires:

- normal hypothalamic function producing gonadotrophin-releasing hormone (GnRH)
- normal pituitary function producing the gonadotrophin hormones—follicle stimulating hormone (FSH) and luteinising hormone (LH)

- normal seminiferous tubule and Leydig cell function
  - normal sperm transport and delivery
- Facts about sperm viability:
- the maximum number of viable sperm is found in the ejaculate after a 48-hour abstinence
  - after entering receptive cervical mucus, sperm are capable of fertilising an egg for at least 48 hours
  - sperm survive for less than 30 minutes in the vagina due to an acidic environment

## Female fertility

Fertility in the female requires:

- normal function of the ovulatory cycle, which requires:
  - normal hypothalamic–pituitary function producing the hormones GnRH, FSH and LH
  - normal ovarian function with follicular response to FSH and LH (see FIG. 117.1)
  - appropriate prolactin levels (which are normally low); excessive prolactin secretion (hyperprolactinaemia) causes anovulation
- normal tubal transport and access of the ovum to incoming sperm
- receptive cervical mucus
- normal uterus to permit implantation of the fertilised ovum

## Probabilities of pregnancy

About 50% of normal couples, having unprotected intercourse at least twice a week, will probably achieve pregnancy in 6 months, 85% in 1 year and 95% in 2 years.<sup>3</sup>

## Causes of infertility

Significant causes of infertility are summarised in TABLE 117.1 and illustrated in FIGURE 117.2.

## A diagnostic approach

It is important to see both partners, not just the woman.

## History

The following basic facts should be ascertained.

### The man

- Sexual function
- Previous testicular problems/injury (e.g. orchitis, trauma, undescended testes)
- Medical problems: diabetes, epilepsy, tuberculosis, kidney disorders
- Past history (PH) of STIs
- PH of mumps
- PH of urethral problems
- Genitourinary surgery (e.g. hernia)
- Recent severe febrile illness
- Occupational history (exposure to heat, pesticides, herbicides)
- Drug intake (possible adverse effects from):
  - alcohol
  - chemotherapy
  - anabolic steroids
  - aminoglycoside antibiotics
  - sulphasalazine
  - cimetidine/ranitidine
  - colchicine
  - spironolactone
  - antihypertensive agents

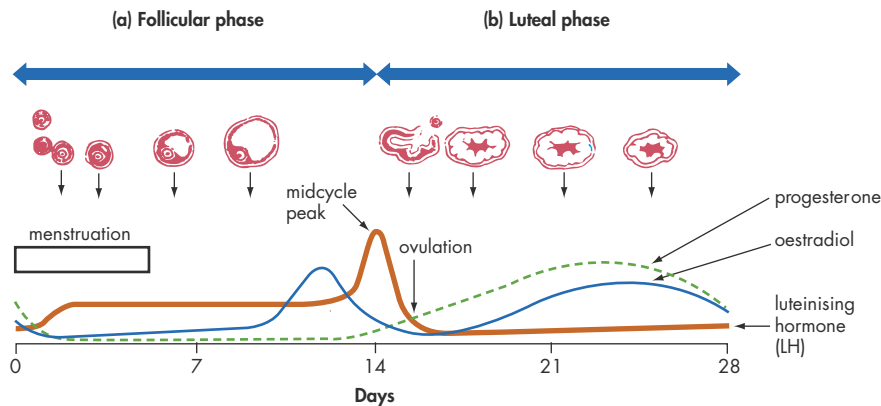

FIGURE 117.1 The normal ovulatory cycle: the midcycle peak of LH and FSH is at 14 days and ovulation occurs shortly afterwards

- narcotics
- phenytoin
- nitrofurantoin
- nicotine
- marijuana

### The woman

- Evidence of previous fertility
- Onset of menarche
- Menstrual history
- Symptoms of ovulation
- Symptoms of endometriosis
- PH of STIs and pelvic infection
- Previous IUCD use
- PH of intra-abdominal surgery (e.g. appendicitis, ovarian cyst)
- PH of genitourinary surgery, including abortions
- Obstetric history
- Body weight: eating disorders (anorexia, obesity)
- Drug intake:
  - alcohol
  - smoking, especially >20/day
  - oral contraception
  - anabolic steroids
  - major tranquillisers

### Combined history

- Frequency and timing of intercourse
- Adequate penetration with intercourse, and ejaculation
- Use of lubricants
- Attitudes to pregnancy and subfertility
- Expectations for the future

### Examination

A general assessment of body habitus, general health, including diabetes mellitus, and secondary sexual characteristics should be noted in both man and woman. Urinalysis should be performed on both partners.

### The man

- Secondary sexual characteristics; note any gynaecomastia
- Genitalia
  - size and consistency of the testes—can compare to an orchidometer: normal range 15–35 mL (average 18 mL); small in Klinefelter syndrome (approx. 7–8 mL)
  - palpate epididymis and vas (present and non-tender is normal)

**Table 117.1** Significant causes of subfertility

#### Female factors

##### Ovulation disorders:

- hypothalamic/pituitary disorders
- hyperprolactinaemia
- other endocrine disorders
- ovarian failure (e.g. oocyte ageing)
- stress
- PCOS
- weight-related ovulation disorders

##### Tubal disease:

- PID
- endometriosis
- previous ectopic pregnancy
- previous tubal ligation
- previous peritonitis

##### Uterine and cervical abnormalities:

- congenital
- acquired

#### Endometriosis

#### Male factors

##### Reduced sperm production:

- idiopathic
- congenital cryptorchidism (maldescent)
- inflammation (e.g. mumps orchitis)
- antispermatogetic agents:
  - chemotherapy
  - drugs
  - irradiation
  - heat
- Klinefelter syndrome (46 XXY)
- Sperm autoimmunity

##### Hypothalamic pituitary disease:

- hypogonadotropic disorder
- hypoprolactinaemia

##### Disorders of coitus:

- erectile dysfunction
- psychosexual ejaculatory failure
- retrograde ejaculation:
  - genitourinary surgery
  - autonomic disorders (e.g. diabetes)
  - congenital abnormalities

#### Ductal obstruction

#### Couple factors

#### Joint subfertility

#### Psychosexual dysfunction

FIGURE 117.2 The major factors involved in subfertility.

Source: Adapted from Kumar and Clarke<sup>1</sup>

- evidence of varicocele (controversial role)
- PR: check prostate
- note penis and location of urethra (always retract the foreskin for examination)

### The woman

- Secondary sexual characteristics
- Thyroid status
- Genitalia and breasts
- Vaginal and pelvic examination:
  - assess uterus and ovaries (normal—present, mobile and non-tender)
  - the adnexae (any masses)

### Investigations

These are usually performed after referral but the family doctor should organise initial investigations

to assess where to refer (e.g. andrologist, endocrinologist, gynaecologist).

### Initial investigations

#### Male—semen analysis

It is advisable to obtain two samples at least 80–90 days apart as the cycle of production of sperm is about 80 days. It requires a complete ejaculation, preferably by masturbation, after at least 3 days sexual abstinence. Use a clean, dry widemouthed bottle; condoms should not be used. Semen should be kept at body temperature and examined within 1 hour of collection.<sup>2,7</sup>

- Normal values:
  - volume >2 mL (average 2–6 mL)
  - concentration >15 million sperm/mL
  - motility >40% after 2 hours

- normal forms >4%
- velocity >30 microns/s

Female—ovulation status

- Educate about temperature chart and cervical mucus diary, noting time of intercourse (take temperature with thermometer under tongue before getting out of bed in the morning)—now considered to be of low value.
- Midluteal hormone assessment (21st day of cycle)—i.e. serum progesterone. This is the most common first-line test for ovulation (see TABLE 117.2).
- Early ultrasound (day 5–9 of cycle).
- Anti-Mullerian hormone—a predictor of ovarian function.

Table 117.2 WHO classification of ovulatory dysfunction<sup>6</sup>

Group 1	Hypothalamic–pituitary failure	Low FSH, LH (e.g. anorexia nervosa)
Group 2	Hypothalamic–pituitary dysfunction	Normal FSH (e.g. PCOS)
Group 3	Ovarian failure	High FSH (e.g. ovarian failure)

Subsequent investigations
